Entered at the Post Office at New York, N. Y., as mail matter of the second class.

Request for change of address should reach the New York office two weeks before the date of the issue with which it is to go into effect. It is difficult and often impossible to supply back numbers to replace those undelivered through failure to send advance notice. In sending us change of address, be sure to send us your old address as well as the new one.

Subscriptions, including the eight daily editions of the Railway Age published in June, in connection with the annual convention of the American Railway Association, Mechanical Division, payable in advance and postage free: United States, Canada and Mexico, $3.00 a year; foreign countries, not including daily editions of the Railway Age, $4.00. Foreign subscription may be paid through our London office, 34 Victoria Street, S. W. 1, in £ s. d. Single copy 35 cents.

The *Railway Mechanical Engineer* is a member of the Associated Business Papers (A. B. P.) and the Audit Bureau of Circulation (A. B. C.).

Railway Mechanical Engineer

Vol. 99 January, 1925 No. 1

More locomotive maintenance needed

Elsewhere in this issue will be found an abstract of the annual report of the chief inspector of the Bureau of Locomotive Inspection of the Interstate Commerce Commission which shows that during the fiscal year ending June 30, 1924, the commission's inspectors were compelled to order 5,764 locomotives out of service for the repair of defects which constituted violations of the law. In his report the chief inspector makes the following highly suggestive statement: "Conditions," he says, "are far from being satisfactory in so far as a proper compliance with the law is concerned. If due diligence is pursued by the carriers in seeing that locomotives are in proper condition and safe to operate before being offered for service, the commission's inspectors will not find it necessary to order any locomotives from service, which frequently causes serious inconvenience to the public as well as an added burden to the carriers."

It is evident, of course, that whether fully acceptable or not, neither the railroads nor the Bureau of Locomotive Inspection has any discretion as to observance of the rules and requirements of the Bureau, since they have the force of federal law. They are, however, generally conceded to be entirely sound and in fact represent nothing more than recognized good practice. Where conditions are permitted to develop which result in the necessity for removing locomotives from service to prevent violations of the law, it has been found that the railroads are not serving their own best interests. Entirely aside from the safety aspect of the case, with which the law is concerned, such conditions decrease the reliability of locomotives to such an extent that engine failures multiply and all of the attendant delays and expense are encountered in the conduct of transportation.

During the fiscal year ending June 30, 1924, there were considerably less locomotives out of service for repairs than during the preceding fiscal period. The number of accidents caused by failures coming within the scope of the law, however, is only about 10 per cent less than during the earlier period, and still much greater than during 1920, 1921 or 1922. This would indicate that although the number of locomotives actually reported unserviceable has been decreased, there was still much to be done in restoring a satisfactory amount of the mileage life to the locomotives in service, since many of the defects most commonly encountered are not likely to develop on power on which proper renewals and repairs have been made in the back shop. If conditions are to improve next year, then, the average number of months since shopping must be reduced. This will relieve the terminal organizations of excessive work on worn out power and make possible the current handling of such running repairs as are required.

One of the best indications available to the executive of the extent to which these ends have been accomplished will be found in the reports of its inspectors rendered periodically by the Bureau to each railroad. They should be followed closely and their indications used as a basis of action, not alone because this is required by law, but because in that way can the most economical and reliable locomotive service be obtained.

Mill room equipment and operation

One of the important factors in car shop operation is the mill room. Owing to the fact that this particular part of the car shop usually operates smoothly, providing lumber cut to size and machined as required, it frequently receives less attention than its importance warrants. The possibilities of material and labor saving or loss, dependent upon the way lumber is handled in mill rooms, are large. Some idea of the magnitude of railroad mill room operations in the aggregate may be gained when it is realized that the railroads purchase directly about 17.5 per cent of the annual timber cut of the country. Statistics of the Bureau of Railway Economics show that in 1923 the Class I railroads purchased approximately 2,388,800,000 board feet of lumber for which they paid nearly $100,000,000. The amount mentioned does not take into consideration lumber used for cross ties, poles, posts, etc.; therefore, a large proportion of the 2,388,800,000 board feet undoubtedly is handled in railroad mill rooms.

In mill room equipment one of the first essentials is an adequate supply of planers properly maintained so as to provide accurate, smooth and rapid work. The value of a four-side planer, particularly in shops which are pressed for output, can hardly be over-emphasized. This machine planes all four sides of a timber at the same time, eliminating three passes, and saving time and labor. It increases mill room and consequently car shop capacity. A full complement of saw equipment is required, including cut-off saws, self-feed rip saws, swing saws, band saws, etc. An adequate number of modern saw filing machines will assist materially in keeping these saws in the best condition for effective work. Other more or less standard tools which save labor and increase mill room efficiency and capacity are multiple spindle boring machines, jointers, mortisers, tenoners and gainers with boring attachments, multiple spindle shapers, dovetail machines, molding machines, automatic knife grinders, circular saw grinders, etc. One of the best labor saving tools in the pattern shop is the drum sander. This and other sanding machines greatly reduce the labor involved in finishing patterns and cabinet work to the required degree of smoothness.

Aside from machines of standard type many special machines have been developed by manufacturers and in some cases by railroad men which have proved effective

for such purposes as manufacturing wooden tie plugs and other similar items. When a mill room is properly equipped with modern machinery, the next essential is to arrange it so that the timber travels from one machine to the next through the shop, back travel being eliminated or reduced to a minimum. While many railroad mill rooms are now operating along the lines indicated with modern machinery and an up-to-date organization, the amount of money involved is such as to justify frequent checks to see if the most efficient operation is being secured, that needed machinery is available, that it is properly located, and that the mill room organization functions to the best advantage.

Why use inefficient boilers?

With the advent of extreme cold weather comes the realization on far too many northern railroads of the existence of a shortage of steam for heating and thawing purposes. This condition in itself is bad enough, but the remedy that is so often applied is worse. The installation of old locomotive boilers for stationary service is a practice that has very little to commend it. There is no condition, either from an operating or economical standpoint, that justifies a deliberate attempt to see how much coal can be burned in a given time and get so little from it. A locomotive boiler is an admirable steam generator when used on a locomotive with a strong induced draft, but when transferred to stationary service with natural stack draft or even mechanical forced draft, it leaves much to be desired as a means of efficient combustion. It will be argued that most installations of this kind are purely emergency ones and that the old locomotive boiler, even with its admitted inefficiency, satisfactorily meets the immediate demand because it can be quickly and cheaply put into service. The cost of operation, apparently, is not given very much consideration.

A suggestion in connection with this practice may not be entirely inappropriate at this time. A broad survey of the conditions surrounding the use of steam in yards and around engine terminals will very often disclose sources of enormous loss that are ordinarily overlooked. If proper attention is given to steam leaks at valves, hose connections, etc., as well as to the thorough lagging of all open steam lines, the present steam consumption may be materially reduced. A carefully prepared statement showing the distribution of steam uses, with particular attention to losses from leakage and radiation, will do more than any other one thing to emphasize the possibility of minimizing steam losses. If this subject is intelligently and thoroughly analyzed, the surprising discovery may be made that, by the expenditure of a comparatively small sum in proper maintenance and repairs, when the next season of cold weather approaches, the old locomotive boiler, instead of being drawn into a service where it can perform but poorly to say the least, may be consigned to the scrap pile where it belongs.

The machine tool outlook

Elsewhere in this issue appears an article on the machine tools purchased during 1924, which contains estimated expenditures on shop equipment for the coming year as well as a prediction that the budget figures given will be greatly exceeded at the end of the year. Predictions are easy to make but are far more effective if substantiated by facts. Let us see what facts there are to substantiate this forecast.

In order to purchase new equipment the railroads must first obtain the necessary capital. They have two means of doing this; first through net income and second, through the proceeds of the sale of an issue of bonds or stocks. Figures for the last four months of 1924 show that most of the railroads handled record breaking freight traffic which resulted in increased net operating income. This increase in net income was not due to a reduction in wages or taxation, or increase in freight rates, but largely through the increased efficiency of railroad operations. There is every reason to believe that this increase in traffic will continue in 1925. Since the presidential election, a steady increase of unfilled orders has been shown in the steel industry; there has been an increase of proposed construction work and a rise in the price of farm products which will increase the buying power of the farmer. These facts indicate that the railroads will be called upon to haul enormous freight tonnage during the coming year and this will ultimately result in increased net operating income.

The railroad officers have expressed optimistic views concerning freight traffic for the coming year. They are very cautious about making forecasts, but, in a series of articles by presidents of some of the leading railroads of the country published in the January 3 issue of the Railway Age they are unanimous in anticipating an increase in traffic for 1925.

It has always been much easier to raise capital with which to purchase railway equipment than for other purposes because equipment trust notes can be issued for the purchase of equipment, while practically all fixed improvements must be financed by the issuance of bonds or stocks or from net income. Therefore, the fact that the earning capacity of the railroads has been greatly improved due to increased traffic and to better operating efficiency will enable them more readily to finance permanent improvements in fixed property.

During the past year the railroads of North America have purchased 1,534 locomotives, 147,345 freight cars, 2,654 passenger cars and 130 rail motor cars according to compilations made by the Railway Age. For years the railroads have been making similar purchases of equipment and while a considerable portion of the new units is acquired to replace old units retired from service, there has been a steady increase in the number of locomotives and cars, and the replacements themselves have served to increase rapidly the average size of the units which must be maintained. This has not been accompanied by a proportionate increase in shop capacity or by the purchase of the modern machine tools required to meet the present demand for increased shop efficiency and, speaking generally, capacity to make needed repairs has long been taxed to the limit.

Railroad officers are rapidly coming to realize that much of the old machine tool equipment in the repair shops is obsolete and inefficient. An outstanding recognition of this fact is contained in the statement by L. F. Loree, president of the Delaware & Hudson, which appeared in the annual statistical number of the Railway Age, in which he said: "Perhaps the point in which railroad facilities are the weakest is in the machine tool equipment of the repair shops. The development of machine tools receives a great impetus from a war and from the growth of a new industry. During the past 15 years we have had the World War and the development of the automobile business. The effect has been to revolutionize machine tools and to render obsolete a large part of the machine tool industry."

The volume of machine tool purchases in 1924 indicates that the railroads have already taken a step forward in replacing their obsolete tools. In view of the promising business outlook for 1925 there is every reason to believe

that programs looking toward modernizing shop equipment will be developed on an even larger scale than during 1924.

Take up the lost motion

It is an established fact that one of the important factors in obtaining the maximum amount of output from a piece of machinery is to eliminate from it all lost motion. It is a common sight in the average busy locomotive repair shop to see workmen promenading up and down the aisles of the shops wasting valuable time that should be used for productive purposes. Upon investigation it will be discovered that these men are either going after tools or material, or are looking for the foreman to secure an order for material. Further investigation will reveal the fact that considerable time is lost in the morning and at lunch hour in starting promptly to work when the whistle blows. Some of the men will be found in groups engaged in a discussion of some sort; others may be reading, and still others taking a nap. These men will finish their discussion, complete the article they are reading, or slowly arouse from their sleep, gather their tools and amble back to their work. This is a daily occurrence and eats up valuable time.

Take, for an example, a locomotive repair shop employing 200 men. These men will average seven minutes a day getting started to work after the whistle blows (this is a very conservative figure). This will total up to approximately 47 man-hours a day, or 282 man-hours a week. Assuming an average of five minutes a day per man lost in securing tools, material or orders for material, which is a conservative average, in a week's time a total of 102 man-hours will be lost in this manner. These two items will amount to 384 man-hours a week, which, figured on a basis of 60 cents an hour, will amount to $230 a week, or $920 a month. If this is allowed to continue month in and month out, by the end of a year a little over $11,000 will be lost.

How can this situation be overcome? The time lost by the men in securing tools and material is a problem for the management to solve. The proper distribution of tools should be carefully studied and some means provided to reduce this source of lost motion to a minimum. One system of tool distribution which has been effectively used in various shops is to provide each machinist and his helper with a tool wagon in which to keep the tools he has occasion to use every day. Other tools, which are not so frequently used, are placed in the care of the foreman in charge who is held responsible for them. The specialization of mechanics on certain jobs keeps the number of tools required by each man within practicable limits for this scheme of distribution.

The distribution of material in railway shops has received considerable study in the past, but there is still room for improvement in many shops, especially in the convenient location of material stock bins in the shop for small parts. If the men are educated to the proper utilization of these bins, they will save themselves many unnecessary steps, and if they are working on a piecework basis, will increase their daily earnings. Another item which needs additional study is the method of giving out orders for material. In many shops the foreman in charge has to write out these orders. It is often the case that a workman seeking material, loses considerable time in locating the foreman before he can get an order for the material. A great deal of this lost motion could be overcome if the issuing of material orders were concentrated at one point in the shop where the men could get an order for what they want. This point should be situated on the way to the storehouse, or the point at which the material is kept; then no time would be lost.

After the management has, by the proper distribution of tools and materials, reduced to a minimum the non-productive hours lost through these sources, it is then in a position to solicit the co-operation of the men to do their part. When the men are convinced that the management is sincerely striving to eliminate wasteful methods and practices which, if accomplished, will benefit them as well as the company, then and only then will they co-operate in taking up the lost motion for which they are primarily responsible.

New Books

Eye Hazards in Industrial Occupations. *By Louis Resnick and Lewis H. Carris, 247 pages, 6 in. by 9 in. Price* $1.50 *with linen and* $2.50 *with fabrikoid binding. Published by the National Committee for the Prevention of Blindness, Inc., New York.*

The National Committee for the Prevention of Blindness has been doing much towards bringing to the attention of industry and the country at large, the means of eliminating the causes of eye injuries in industrial occupations. In publishing this volume, it has undertaken to serve as a clearing house for the great fund of information regarding this particular hazard which has been developed by the numerous industrial associations, governmental agencies and individual corporations interested in accident prevention and health promotion.

The volume has 10 chapters with 59 illustrations and three appendices. The various chapters include such subjects as the nature and cause of eye injuries, the elimination of eye hazards by engineering revision, first aid treatment for eye injuries, the correction of defective vision and diseases affecting the eyes. Railway officers and safety inspectors will be particularly interested in the chapters on industrial lighting and safety education. These chapters are well illustrated and the effects of poor lighting, the proper amount of illumination required in shop buildings, the education of officers and employees and the enforcement of safety rules and regulations, are discussed in an instructive and entertaining manner. Appendix I gives a list of industrial poisons that present hazards to the eyes. Appendix II consists of the goggle code of the American Steel and Wire Company. Appendix III is a supplementary reading list on the subject of eye hazards.

This handbook, which was written to replace publication 12, issued in 1917, furnishes a wealth of valuable information for safety engineers, inspectors, committeemen, physicians and nurses.

A Study of the Locomotive Boiler. *By Lawford H. Fry.* 157 *pages, illustrated. 6 in. by 9 in. Price* $4.00. *Published by the Simmons-Boardman Publishing Company,* 30 *Church street, New York.*

This volume is planned as a study of the operation of the locomotive boiler and to deal with tests and methods of testing. No particular attention is given to details of construction and familiarity with the general arrangement is assumed. Beginning with the experimental tests on locomotives of the Liverpool and Manchester Railway in 1834, the progress of testing methods is outlined down to the present time. The theory of combustion and the relation of various forms of fuel to the generation of steam in locomotive boilers are analyzed. In studying the operation of a locomotive boiler it is highly desirable to draw up a "heat balance"; that is to say, to ascertain how the heat available in the coal fired is distributed, to find what proportion is usefully employed in evaporation and how the remainder is divided among the various avenues of loss. Chapter III outlines the data necessary and the method developed for computing a heat balance. The chapter fol-

lowing offers for comparison a number of balances thus obtained. Chapter V deals with the detailed study of the processes by which the heat produced by combustion is taken up by the boiler heating surfaces. Two distinct and independent processes are involved; that of radiation from the fire to the firebox surface and that of transfer by contact of the heated gases with the cooler boiler heating surfaces. Equations are developed for carrying through the computations for both cases and typical examples given for applying these formulas. The following chapters deal with the transfer of heat from the gases to the flues with a consequent progressive fall of temperature of the gases as they pass through the flues and escape at the smokebox temperature. The general effect of the various conditions on the rate of heat transfer in flues is given with formulas from which the exact effect of these conditions can be computed. Tables to facilitate such computations are included.

A study of heat absorption as affected by the rate of operation and by the boiler dimensions and the methods of determining boiler efficiency constitute the final chapters in the book. Many useful tables, giving the results of tests, the proportions of boilers, combustion calculations, comparisons of calculated and test results and other data make up the final section in the book. For the designer, the railroad officer or student in locomotive design the information given in this book should prove of the utmost value as it is practically the only complete analysis of the physiology of the locomotive boiler; that is, the problems of the boiler that enter into the production of steam through the medium of proper combustion and the absorption of the developed heat by the boiler surfaces.

What Our Readers Think

Finding amount of wear in main rod brasses

LYNCHBURGH, Va.

TO THE EDITOR:

It is a regular occurrence for enginemen to report that both ends of the main rods are pounding badly. The usual manner in which the inspector determines the amount of wear in the brasses is to try them with a pin bar. This is a poor practice on account of the heavy weight of the modern main rod. Another way is to remove the brasses and caliper the pins and brasses. This method is positive but consumes a great deal of time.

I determine their wear by the tram method. I carry with me a small 5-in. by 2-in. tram. When the brasses of a locomotive are reported as having excessive wear, I have it spotted on the top quarter. I then put a center punch mark on the crosshead near the front end key and place one end of the tram in it. The hostler then applies the brakes, opens the throttle, and reverses the locomotive several times. In doing this a mark will be scribed on the main rod which, when measured, will show how much the brass will have to be closed.

The wear of the back end brasses may be determined in the same manner, except that the punch mark is put either on the eccentric crank arm or near the center of the main crank pin.

The amount that the driving box wedges are out of taper, can be determined in the same way. Place the locomotive over a pit and set the wedges up tight. Put a center punch mark near the top and bottom of the driving box. While the hostler is "pumping" the engine, scribe on the engine frame the amount the wedge is out of taper. This will give the amount to be planed off the wedge and also which end is to be planed. W. R. McIvor.

A word in favor of charcoal iron

PARKESBURG, Pa.

TO THE EDITOR:

In the September number of the *Railway Mechanical Engineer* there was published an abstract of a report of the committee on Pitting and Grooving in Boilers of the Master Boiler Makers' Association in which it was stated that: "It is generally believed that charcoal iron is more homogeneous than steel and that iron tubes are, therefore, more resistant to corrosion than are drawn steel tubes. Whether or not this is true, the writer is not prepared to say. It would seem as if steel could be made as homogeneous as iron and it is evident that if it were so made, it would be just as good."

There is another important reason for the superiority of charcoal iron boiler tubes, namely, the presence of slag, which is thoroughly distributed throughout the metal. The product of the charcoal knobbling fire is a sponge consisting of globules of practically pure iron, the pores of the sponge being filled with molten slag. The subsequent heating and mechanical operations necessary to convert the crude iron into a finished product, draw the slag out into filaments or thin strips which, while not continuous for the length of the tube, overlap to such an extent that every cross section of a charcoal iron boiler tube, will show a remarkably complete distribution of slag. An analysis of a finished tube or sheet of charcoal iron will reveal a surprising chemical uniformity.

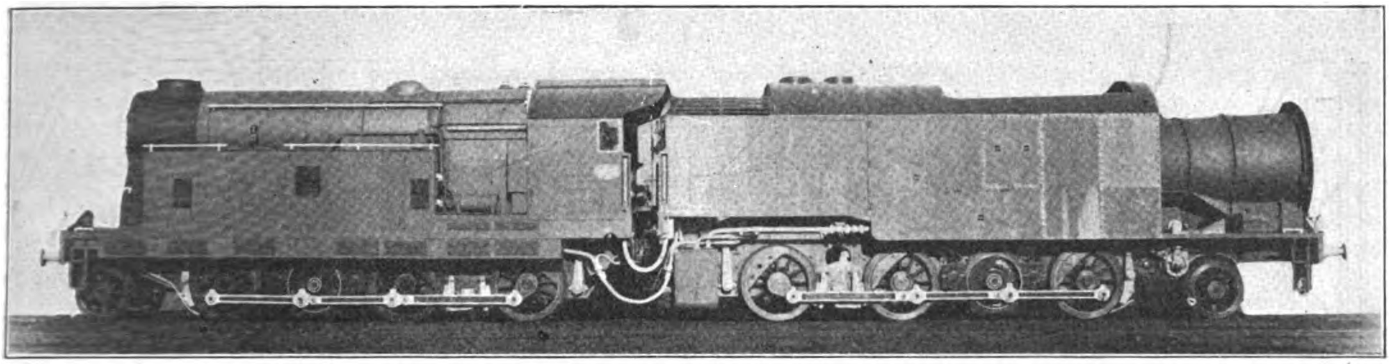
Steel on the contrary is purposely freed from slag before it is poured into the moulds where, on account of varying densities and gas pressure, the mass is in constant ebullution until it freezes. Due to this internal motion and the fact that the impurities are lighter than iron, they are found to be segregated, generally towards the top center, but also to a certain extent, throughout the entire ingot.

The presence of the slag or cinder filaments in wrought iron is responsible for the well known fibrous appearance of its fracture when nicked and broken. The resistance to fatigue shown by wrought iron, which is greater than that possessed by steel of an equal or even considerably higher tensile strength, is also very likely due to this subdivision of the cross section. In other words, the iron possesses to some degree, the greater resistance to repeated bending. This may be illustrated by a wire cable as compared with a solid bar of the same cross sectional area.

It is true that corrosion due to pitting is less likely to take place in a homogeneous metal than in one in which the impurities are segregated, by reason of the fact that chemical uniformity results in balanced electrical potentials. It is also recognized that no metal can be absolutely homogeneous and that under certain conditions pitting will occur. However, the point I wish to stress is that slag, being non-metallic, is definitely more resistant to the action of acids and to decomposition by electrolysis and consequently to corrosion in general, than pure iron. If corrosion does start, it is obviously of advantage to have within the metal barriers or obstacles of high resistance to corrosion to impede and check its progress so as to postpone failure or prevent it entirely.

This structural resistance to corrosion, possessed by charcoal iron, is of equal if not greater importance than the homogeneity of the metal in comparison with steel, in respect to the greater service that may reasonably be expected of charcoal iron. S. H. WOODROFFE.

Metallurgical engineer, Parkesburg Iron Co.



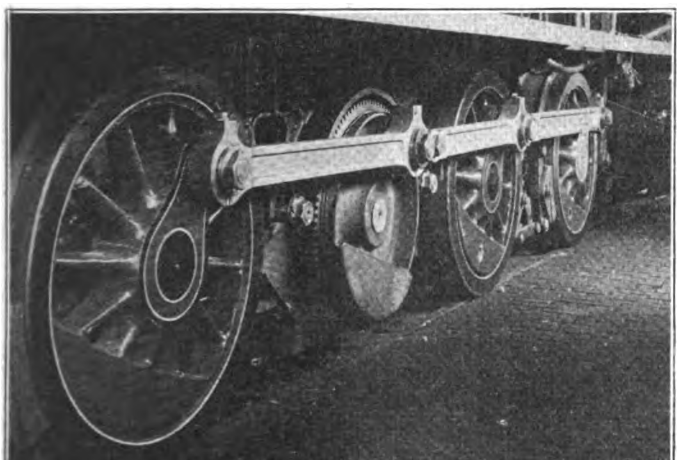
Side view of the Ramsay turbo-electric locomotive

Ramsay turbo-electric locomotive*

Practicable condenser of evaporative type developed—Speed of running controlled electrically

By George F. Jones and T. Laurence Hale

IT may be said that just as the cylinder, boiler and firebox have become fundamental parts of the ordinary locomotive, so do they determine the degree of its thermal performance and the limit of its possible power development. With the present-day demands for increased hauling capacity together with greater need for economy in fuel consumption, emphasizing, in these respects, the limitations of the orthodox designs of locomotives, it is not surprising to find engineers contemplating the attractive possibilities offered by locomotive development along lines other than the conventional.

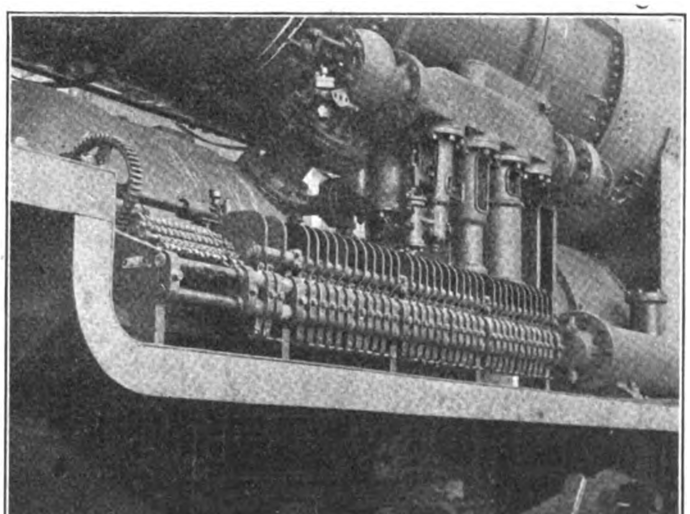


Power is transmitted to the driving wheels by a spur pinion and wheel which are enclosed, and run in an oil bath

It is apparent that there is great room for improvement when it is considered that a locomotive of the ordinary type has a thermal efficiency of only approximately six per cent and that doubling its thermal efficiency would reduce the fuel consumption by half or, alternatively, allow a much more powerful engine to be built with the present practical limits of firebox area.

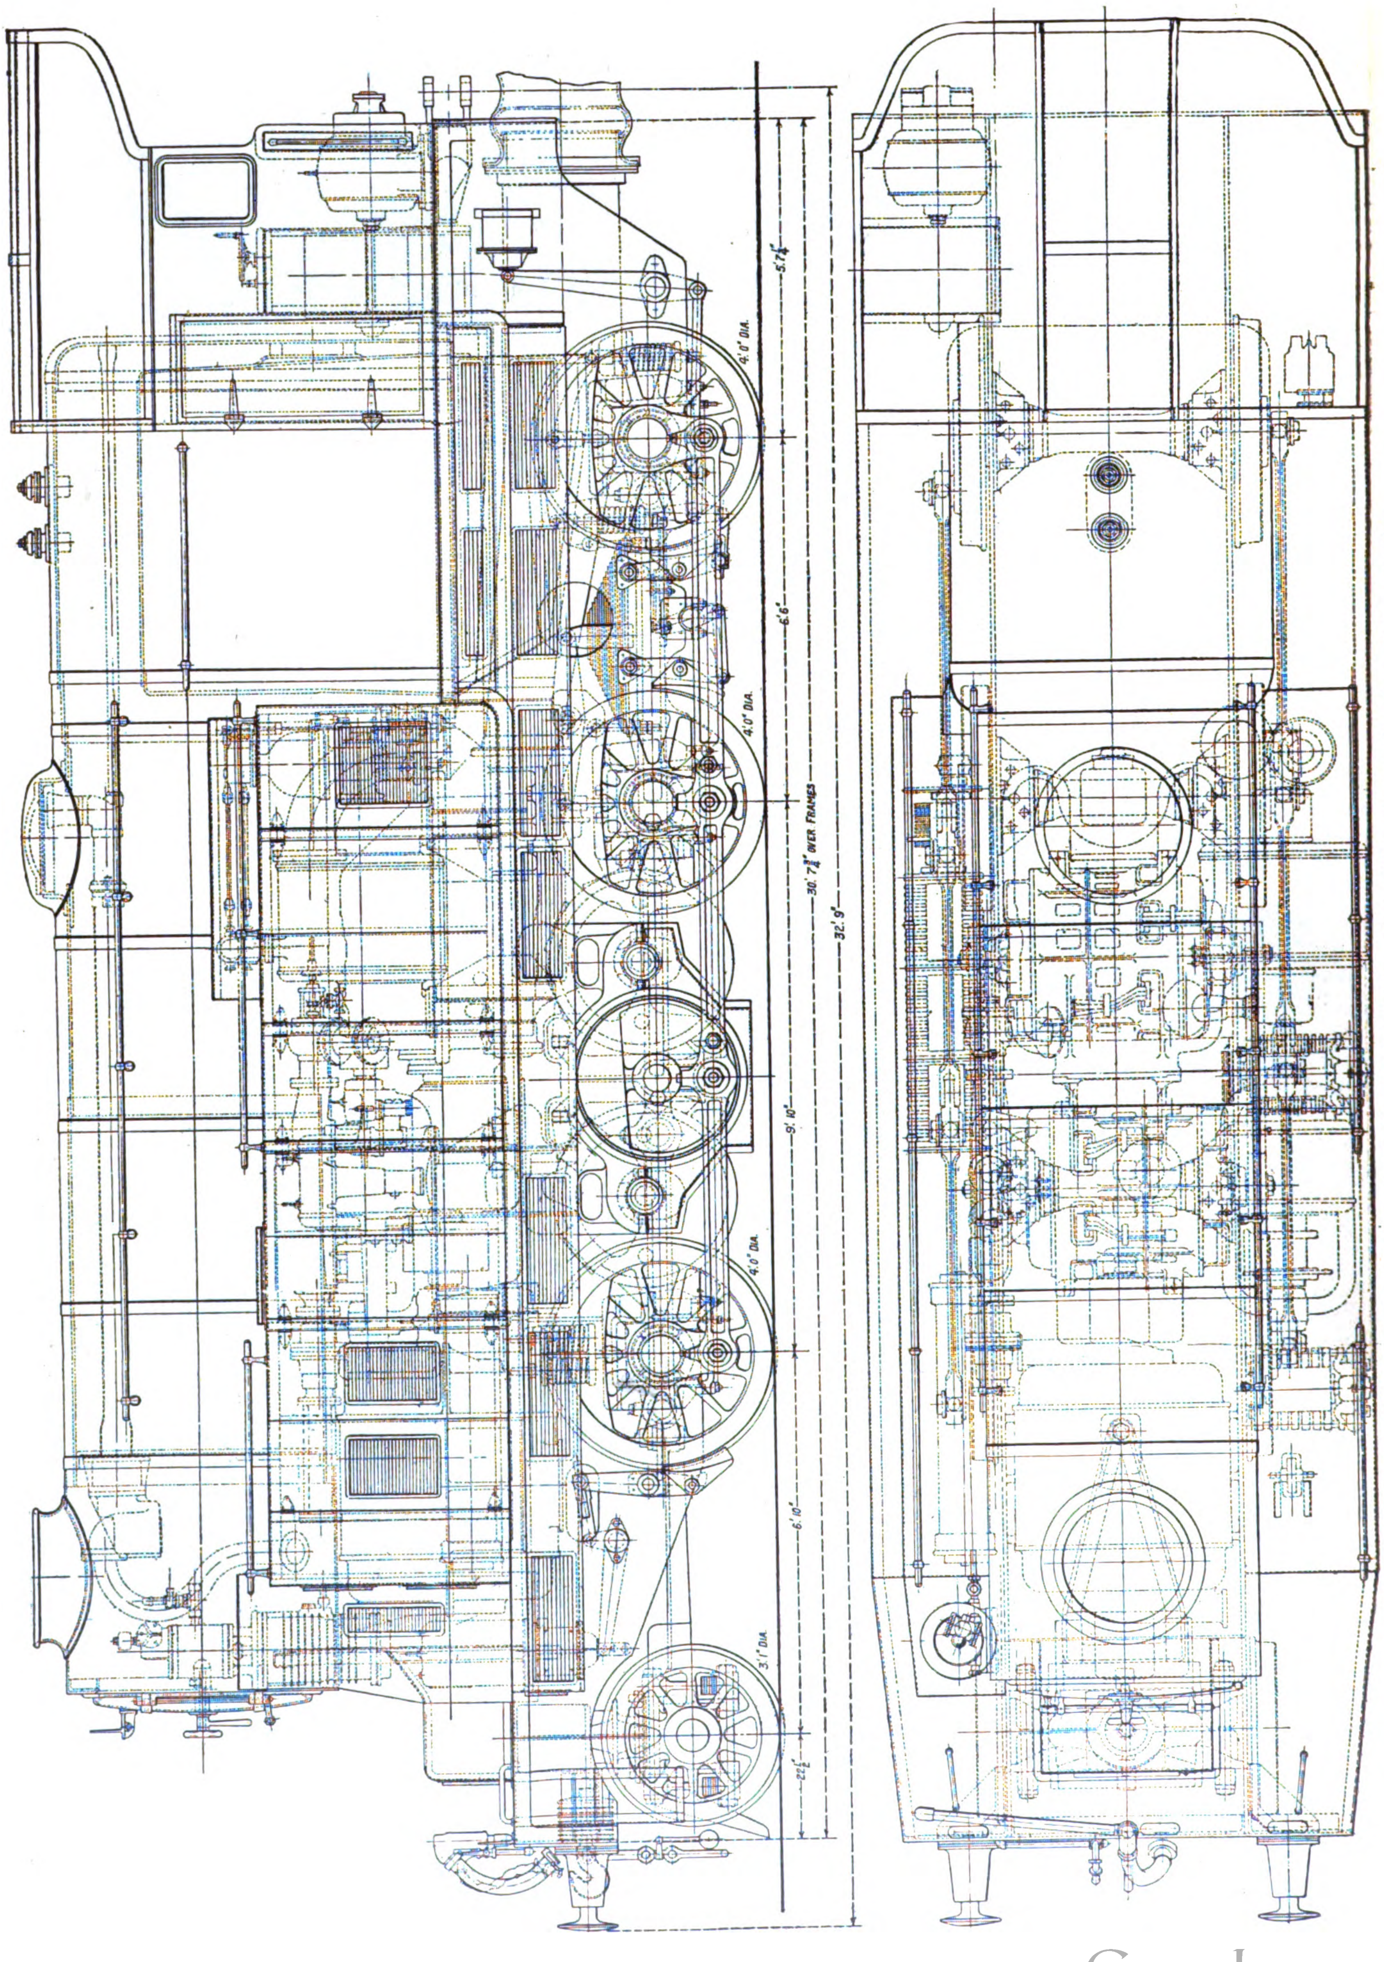
The replacing of cylinders by the steam turbine is an innovation in locomotive construction, but not more so than the application of condensation which is rendered possible by its introduction. From a thermodynamic point of view, it is evident that turbo locomotives, whatever their systems of power transmission, whether electrical or gear, largely depend for their economies in fuel consumption upon the efficiency and reliability of their condensing plant.

It is to be understood that the Ramsay locomotive is regarded as experimental, designed and constructed for the purpose of obtaining technical data and demonstrating the capabilities of the type. It conforms to British standard practice as regards the restrictions imposed by the load line gage, etc., although, naturally, in view of the radical departure in design, it has been confined mainly to test and demonstration running, rather than everyday service. It may be mentioned that compact and uniform designs were disregarded in the interests of experiment, the motor driven auxiliaries, in every case, having



Covers removed on right side to show the grid resistances and turbine governor

*Abstract of a paper presented before the annual meeting of the Railroad Division of the American Society of Mechanical Engineers.

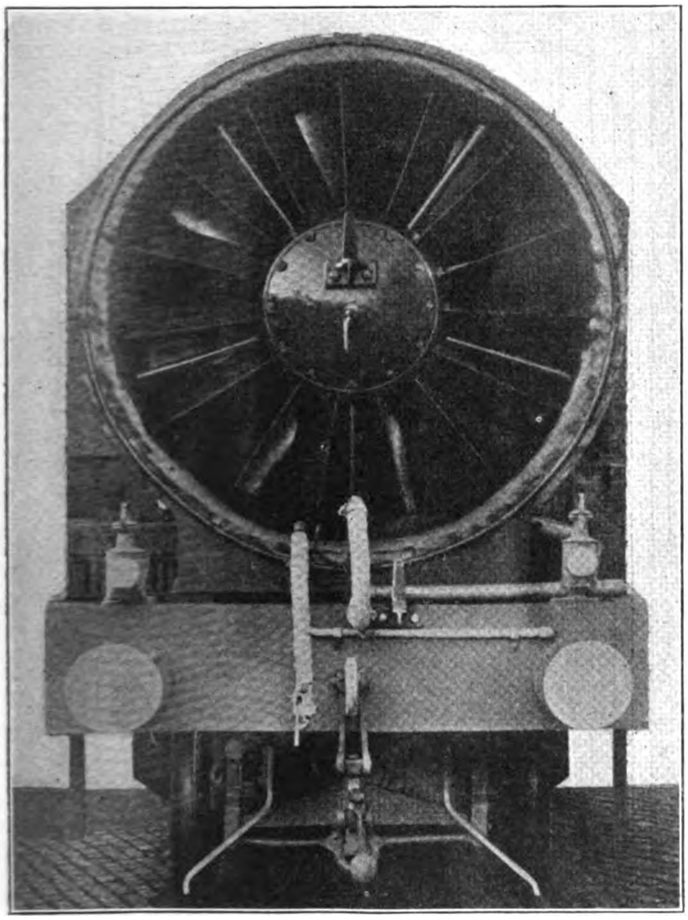


Elevation and plan of the forward section of the Ramsay turbo-electric locomotive

been purposely kept separate and ungrouped from the main power plant in order readily to obtain their particular power consumptions. In addition, many power registering devices, gages and instruments have been fitted, greatly in excess of those necessary to the ordinary equipment, all of which tend to give the locomotive, especially the cab, an intricate and complicated appearance.

General description

The locomotive consists of two portions, the front and rear, connected by a special form of universal joint. The front portion incorporates the boiler, forced draft set and driver's cab, the main turbo-alternator set and the auxiliary direct-current turbo generator being situated under the boiler. The rear portion of the locomotive is practically devoted to the condensing plant with axial fan, condensate extracting pump, etc. Room, however, has been found for the main water tank and coal bunker. Communication between the turbines and condenser is by way of the 24-in. diameter exhaust pipe which is provided with a flexible rubber connection reinforced by internal rings of aluminum.



Rear view of the locomotive showing the condenser fan

Each portion of the locomotive carries two driving motors, each pair of motors being bolted to a center cross-bearer which carries a transmitting shaft and spur wheels. Pinions are keyed to the motor shafts and these mesh with the spur wheels, the power being finally transmitted through coupling rods from the spur wheels to the driving wheels in the ordinary manner. One of the illustrations shows the spur wheel and pinion shafts, the pinions having been removed. Both are enclosed in a gear case and run in an oil bath. The gear ratio is 2.8 to 1.

The main turbine is of the impulse type and contains nine stages. The mean blade diameter is 36 in. It is designed for a steam pressure of 200 lb. per sq. in., and the steam is superheated to a total temperature of 685 deg. F., exhausting to a vacuum of 27 in. The turbine is flexibly coupled to a three-phase alternator and has a speed range of 1,800 r.p.m. at starting to 3,600 r.p.m. at 60 m.p.h. The three-phase alternator is designed to develop 890 kw. at a maximum pressure of 600 volts.

The auxiliary turbine is a single stage machine flexibly coupled to a direct-current generator, which provides the energy for the excitation of the main alternator poles as well as for the auxiliary direct current motors driving the condenser fan, condenser rotor, condenser extracting pump and the forced draft set for the boiler. It also supplies the necessary current for lighting the train. The auxiliary turbine operates under the same steam conditions as apply to the main turbo set.

The boiler is of the ordinary locomotive type and the combustion chamber is supplied with air by a high speed forced draft set situated on the locomotive cab. A simple locking device is provided on the furnace door to prevent a blow-back, the door being prevented from opening by a safety catch when the forced draft fan is in operation.

The transmission of power from the main turbine to the driving motors is three-phase, current being supplied from the alternator to the four alternating current slip ring motors, each motor having a continuous output capacity of 275 b.hp. and one hour's rating of 360 b.hp.

The following are the tractive forces at the rims of the driving wheels for the acceleration period from rest to 60 miles per hour:

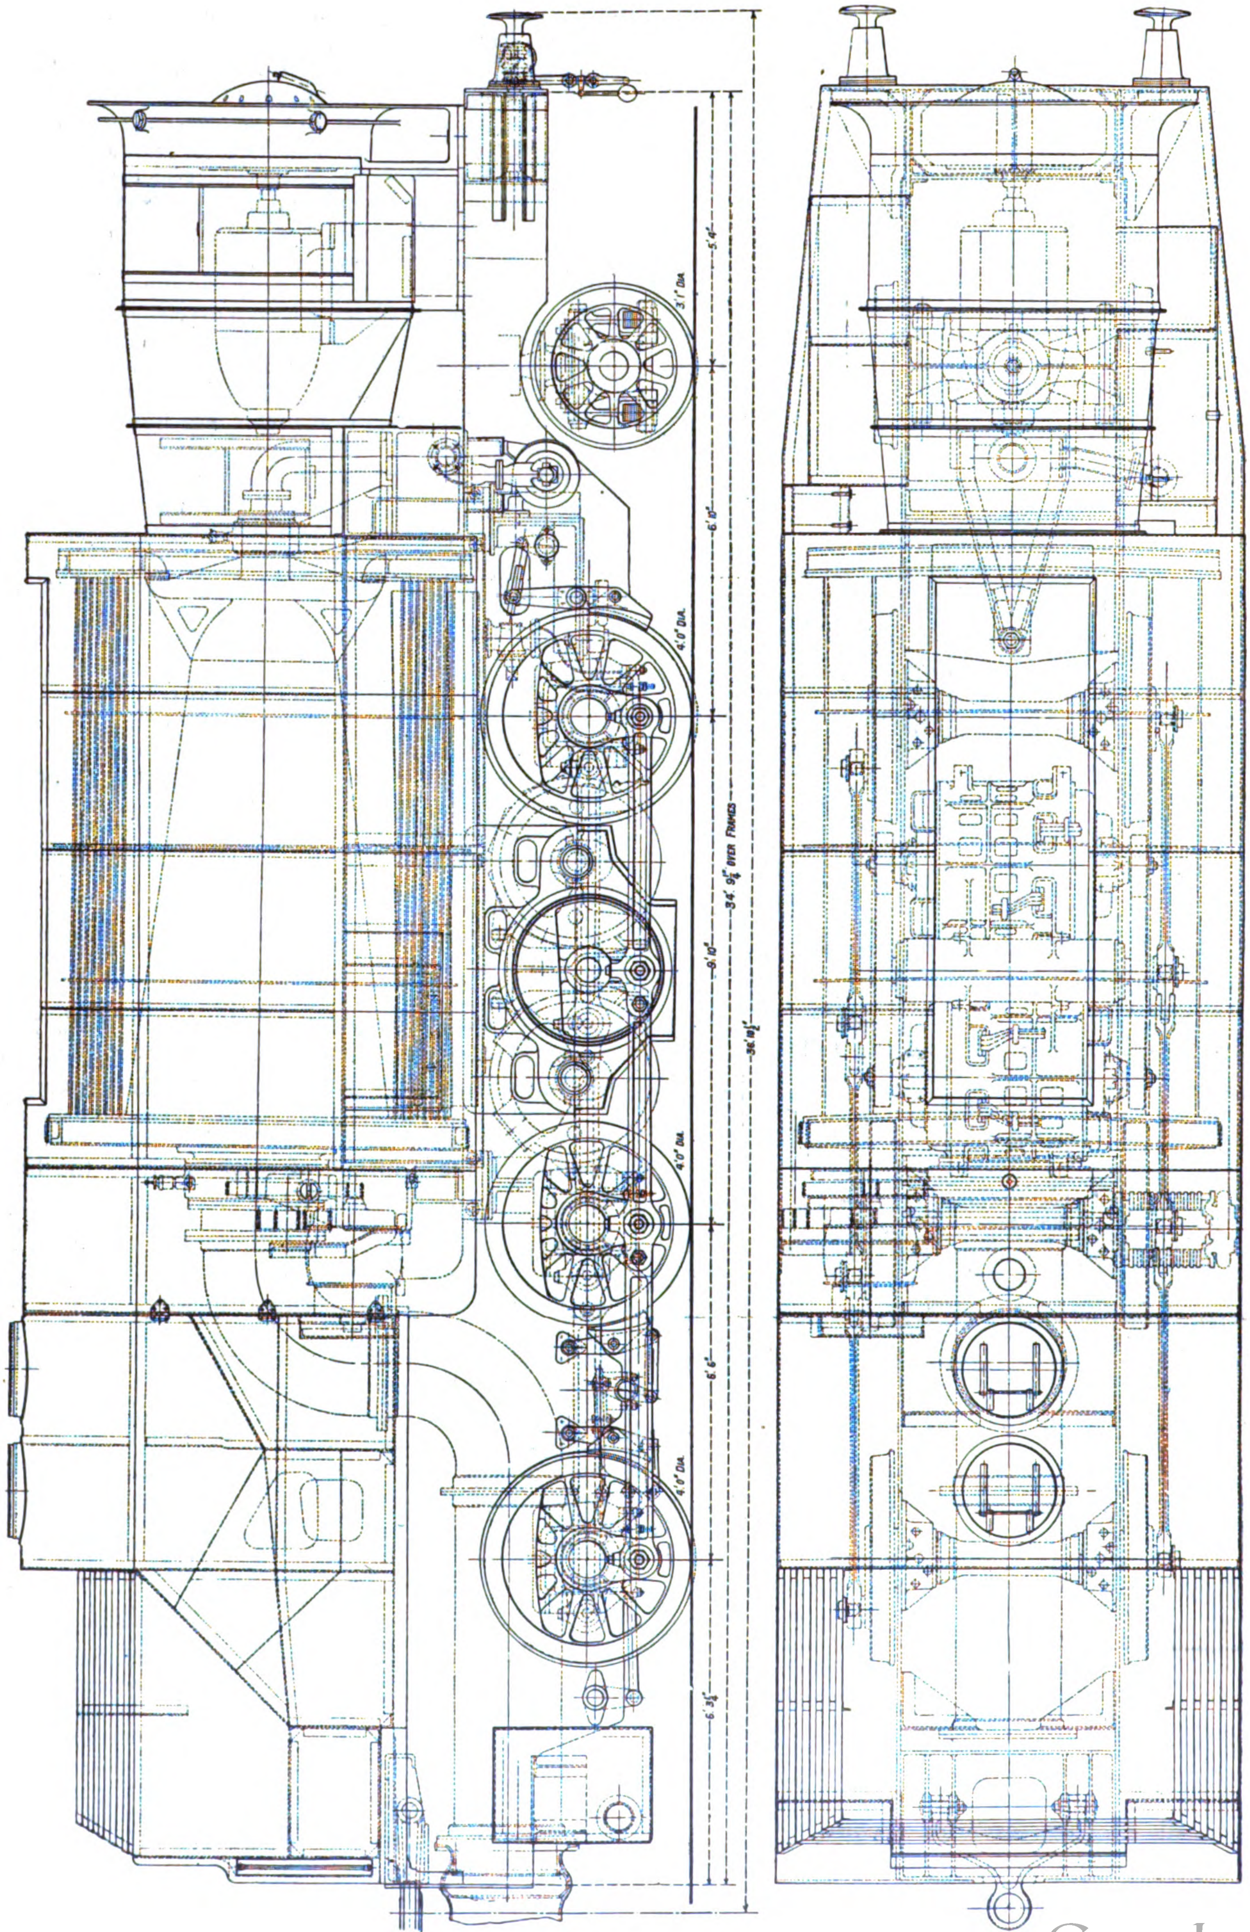
Miles per hour	Tractive force
Starting	22,000 lb.
15	22,000 lb.
30	11,050 lb.
60	8,600 lb.
Normal running, 60 miles per hour	6,000 lb.

Design and description of the condensing plant

As the success of a locomotive of this description depends in such a large measure upon the design and action of its condenser, it is perhaps not irrelevant to give a very brief review of the groundwork which influenced the adoption of the principle of evaporation as the basis of design for the present condenser.

In the light of previous experience of the difficulties of recooling condensing systems, it was decided to attack the exhaust steam by direct means. It was fully realized that the alternative method to evaporation, that of direct cooling by air alone, involved employment of large condensing surfaces and excessive fan power, and that such a type of condenser would depend for its success largely on atmospheric conditions, and, while probably producing a satisfactory vacuum in low temperature countries, the system would be at a great disadvantage and far from satisfactory in hotter climates. Attention was, therefore, turned towards evolving a suitable condenser on the direct cooling system based on the evaporative principle as being the system to successfully meet the atmospheric conditions of all countries.

In design, the ordinary evaporative condenser has progressed but little and still remains practically as originally conceived; such test results as existed were unreliable and it was, therefore, necessary to carry out a series of preliminary experiments on small scale condensing apparatus with fans to produce a current of air and so intensify the evaporative effect. The importance of maintaining a thin and unbroken water film upon the condensing surfaces was easily demonstrated and, of the numerous methods and contrivances tested with a view to producing satisfactory water filming of the surfaces under a blast of air,



Elevation and plan of the tender and condenser section

the simple method of completely immersing the surfaces in water before exposing them to the air current was found to give the most reliable and proper film effect. Repeated tests on a small condensing plant proved the type to be exceedingly economical in water consumption, in practice only approximately one pound of water being evaporated to condense one pound of steam. The fan power required was reasonably low while the rate of heat transmission was found to be moderately high and sufficient to bring the condensing surface well within the practical limits.

Further experiments were carried out on a plant containing some 400 sq. ft. of surface. For the sake of simplicity, the condensing surfaces were composed of ordinary brass condenser tubes and, as a natural development to facilitate the process of filming, they were arranged in the form of a circular cage, or hollow drum. The drum, supported between bearings, was rotated in a tank containing water, the tubes passing through the water as they rotated.

The condenser was supplied with air by an axial fan and was tested in conjunction with a steam regenerator and the necessary wet air pump, water filming of the surfaces and resultant evaporation taking place successfully. The promising results from this experimental work led to the design and construction of the present locomotive condenser.

Reference to the drawing shows the general arrangement of the rear portion of the locomotive. Ordinary condenser practice was observed in the construction of the drum, which consists of an annular nest of standard ¾-in. brass condenser tubes ferruled into two headers. The exhaust steam entering one header is condensed, and the resultant condensate is collected and drawn off from the other header and returned to the hot well by the rotary extraction pump as hot and clean feed for the boiler. The trunnions of the respective headers are fitted with air tight glands of the steam sealed self-adjusting type. This design of gland has given every satisfaction in resisting air leakage into the condenser.

As will be seen, a small motor, driving through a spur gear, turns the drum which is housed in a sheet metal casing, the bottom of which forms a tank containing the water for purposes of filming which is fed from the main tank. A pneumatic float maintains the water at a constant level.

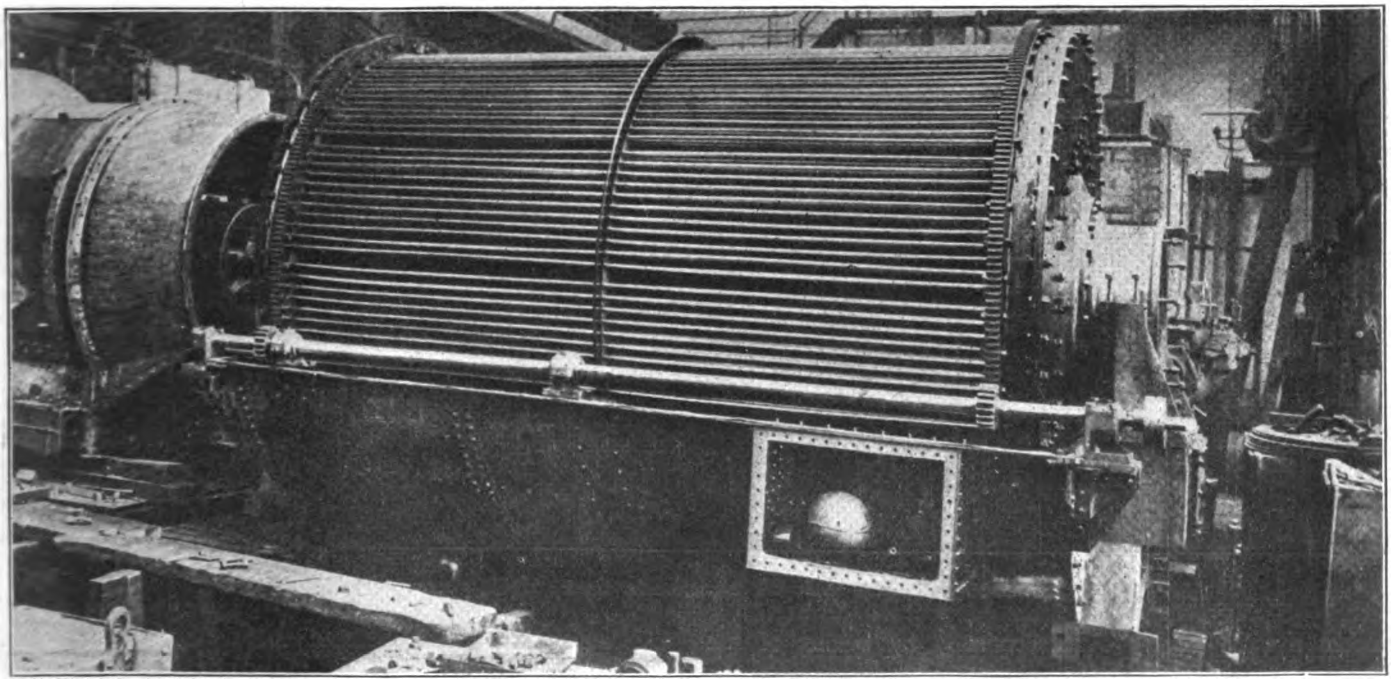
The condensate extracting pump is of the ordinary rotary condenser design, while the air pump is of the steam ejector type and has two stages; it is supplied with steam from the boiler through a reducing valve.

Before being erected on the locomotive, the complete condensing plant was fully tested in conjunction with a 1,500-hp. triple expansion engine and satisfactory results were obtained.

Control of power and speed regulation

As will be seen, the starting torque of the motors is about three times that of the normal and is obtained as follows: Before starting the locomotive, the auxiliary turbine is run up to speed, 3,000 r.p.m., thus providing excitation for the main alternator and energy for the motor-driven auxiliaries. The main turbine set is then run up to half speed; viz., 1,800 r.p.m. At this period the motors are connected in cascade by the master controller in the driver's cab. It is then that the locomotive may be started.

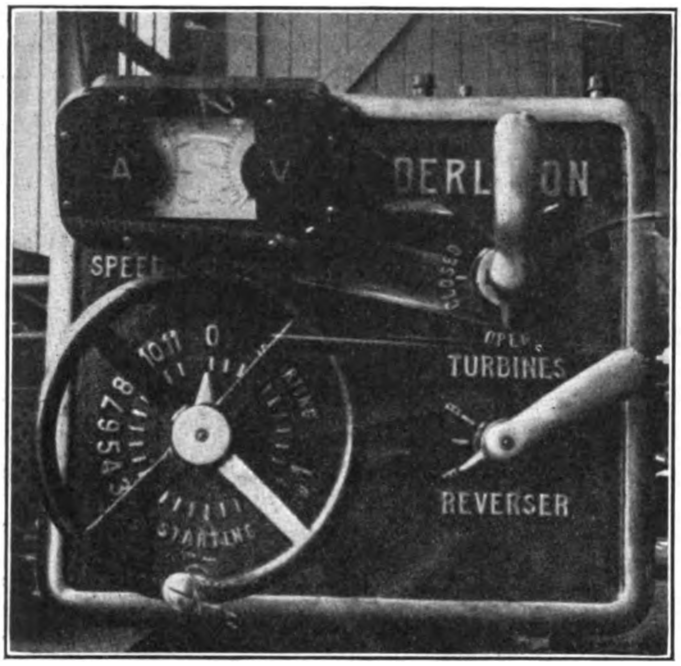
It is well known that when a turbine speeds up from rest to full speed, its torque decreases in the ratio of 2 to 1, and when passing through the period of half speed its torque is one and one-half times the normal. This is the torque of the main locomotive turbine when running at starting speed; namely, 1,800 r.p.m. Again, two alternating current motors when connected in cascade and running at half the alternator speed have twice the turning moment that they have when connected in parallel with the same power consumption. Therefore, with the driving motors in cascade and the main turbine running at half speed, the torque from rest to quarter speed will be two times 1.5, or three times the normal torque. The motors now being connected in parallel, the turbine still running at half speed, the speed of the locomotive increases from one quarter to one-half speed and the torque is then 1.5 times the normal. The turbine speed is then increased



General view of the condenser with its casing removed

to the maximum and the torque drops from 1.5 times the normal to normal.

In controlling the speed of the Ramsay locomotive from



The entire control of the locomotive is centered at this master controller

rest to 60 m.p.h., the following sequence of operations is observed: After the main and auxiliary turbines have been brought to speed by means of the hand wheels in the cab which control the steam inlets, all control of the locomotive is carried out electrically by means of the master controller in the cab. To start the locomotive, the controller wheel is moved to the first notch, thereby closing the excitation circuit of the alternator and connecting the driving motors in cascade with resistance wholly in circuit. Further movement of the control wheel cuts out resistance until a first running position of 15 m.p.h. is obtained. If a greater speed is desired, the controller wheel is moved further which changes the motor connections from cascade to parallel. The excitation circuit being again closed, the motors once more operate under current, resistance being cut out until a second free running speed of 30 m.p.h. is reached.

Further increases of speed are obtained by further moving the controller wheel around, step by step, whereby the setting of the main turbine governor is correspondingly altered, that is, the speed of the turbo-alternator is increased and thereby the periodicity. In this manner the speed of the locomotive can be increased from 30 to 60 m.p.h. A reduction in the speed of the locomotive is obtained by turning the controller wheel quickly back to the zero position, thus observing the reverse succession of operations to those of starting up to full speed. The excitation circuit being opened, the motors are without current and ready for starting up again in cascade.

Reversing the locomotive is, of course, effected by reversing the driving motors in the ordinary way. The general arrangement of the front portion of the locomotive is illustrated, showing the resistances, which are of the grid type, arranged under the running plates on either side. Both vacuum and Westinghouse brakes are fitted.

Principal dimensions and proportions

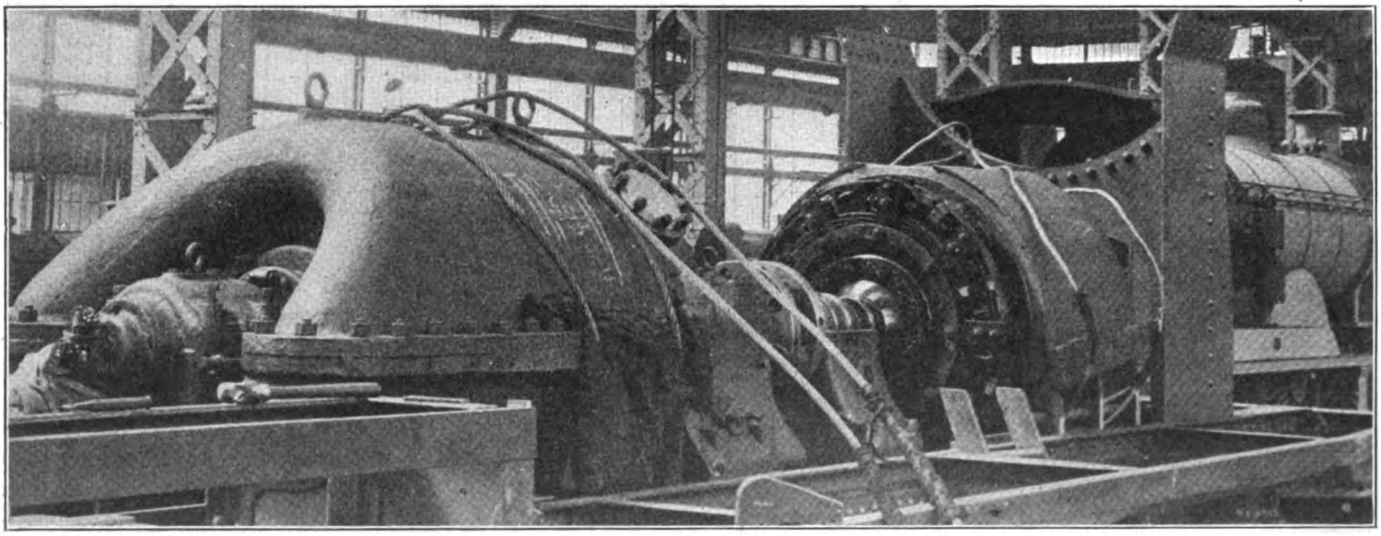
Length overall	69 ft. 7 in.
Length wheel base, total	59 ft. 4 in.
Length, rigid wheelbase	16 ft. 4 in.
Driving wheel diameter	4 ft. 0 in.
Height from rails to center line of boiler	10 ft. 3 in.
Maximum width	9 ft. 0 in.
Total heating surface of boiler	1,543 sq. ft.
Grate area	28 sq. ft.
Tractive force at starting	22,000 lb.

Shop and main line testing

The trials to which the Ramsay locomotive have been subjected have extended in one form or another over a prolonged period and often under adverse atmospheric conditions.

Shop tests, to ascertain the reliability of the special electrical control, were carried out before the locomotive proceeded to the Horwich works of the London, Midland & Scottish for actual running trials. By disconnecting the terminals of the alternator and connecting it to water resistance, it was possible to make many tests which did not justify a main line trail and afforded convenient means of obtaining readings on the condenser which would otherwise have been difficult to procure with the locomotive in motion. Numerous tests were made under these conditions and a large amount of technical data collected.

In addition, several main line trials have been accomplished and on these occasions the locomotive hauled heavy trains without difficulty, a vacuum ranging from



Turbo-generator unit on locomotive frame during assembly

80 to 95 per cent being regularly attained and held. Smoothness of running was pronounced, due to the constant and even turning moment exerted by the driving motors.

At no time during the run did the temperature of the condenser exceed 135 deg. F. which corresponds to a vacuum of 25 in. of mercury. The work of running and firing was carried out by ordinary railway employees and, as all the work in speeding up the locomotive is performed electrically, the duties of the engineman, so far as controlling the locomotive is concerned, are confined to the turning of the controller wheel, the operations of which have already been described, while the duties of the fireman are not as onerous as those connected with the ordinary locomotive.

In considering the efficiency of the condensing plant, some regard must be paid to the amount of power consumed in its operation, and, as in this case, the major portion of the cooling is due to evaporation, the power absorbed by the fan is proportionately low. The average power consumption for the three-condenser auxiliary motors ranges between 25 b.hp. at low loads to 40 b.hp. at high loads. The heat from the air ejector steam exhaust was recovered in the hot well.

No difficulties were experienced on account of deposits of scale and, although the filming water was far from pure, the slight scale which formed on the tubes assisted rather than impeded the water filming. Inspection of the inside of the tubes and headers showed them to be clean and free from deposit or corrosion after some months running.

The foregoing is but a brief description of a locomotive which has proved beyond doubt that the application of the turbine and condenser to locomotive use is rational and reliable. The transmission of energy from turbine to locomotive wheels may be either carried out by mechanical gears interposed between the turbine and wheels, or electrical means may be employed. For moderate powers, there is much to be said in favor of the former, but for large powers the balance of the advantages lies with the latter means.

The exhaustive tests taken over a long period have demonstrated conclusively that there is now little difficulty in providing condensing apparatus which will maintain the requisite economical vacuum when dealing with the heaviest traffic.

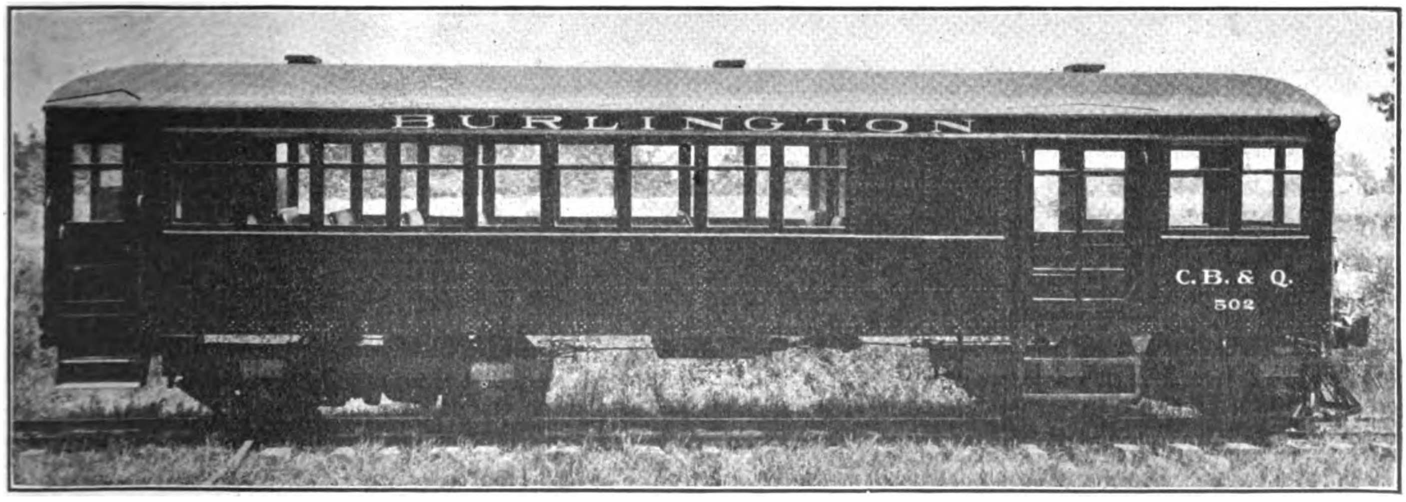
Gasoline car with independent power units

New self-propelled car for the Burlington embodies several unusual features of design

THE Edwards Railway Motor Car Company, Sanford, N. C., has recently completed a gasoline motor car for the Chicago, Burlington and Quincy which represents an interesting departure from the usual design of this class of equipment. The motors, one on each truck, are not only entirely removed from the car body with a consequent saving of space, but are arranged for independent operation, to permit handling the car under varying operating conditions with greater economy.

This car is equipped with two double trucks into each one of which has been built a complete power plant which can be operated independently or together as operating conditions may require. This construction serves to eliminate all direct motor vibration from the car body; eliminates universal joints, long drive shafts, angle drives and numerous gears. An additional advantage is the fact that no space is taken up in the car body for the motors. If one power plant should fail completely, the other unit remains to operate the car. This construction also has a maintenance advantage in that an extra or reserve power truck can be kept on hand and if a mechanical failure occurs, the trucks can be changed in about 45 minutes.

Both front and rear trucks follow closely the conventional four-wheel passenger coach type of construction, with such modifications as are necessary to install the power plant. Wheels are 30 inches in diameter, rolled



Edwards gasoline rail motor car with a motor on each truck

steel A. R. A. contour; outside journal boxes are used and are fitted with Hyatt roller bearings; the axles are four inches in diameter and are made of chrome nickel steel, heat treated. Coil springs are used over each journal box. One large transverse semi-elliptic spring is located under the bolster.

The power plant

Each power unit consists of one Buda four-cylinder motor, 5-in. bore by 6½-in. stroke, developing 60 hp. at 1,200 r.p.m. A heavy-duty multiple disc clutch transmits the power to a four-speed transmission of the constant mesh type which, together with a special final drive and reverse mechanism, provides the same number of speed changes in both forward and backward directions.

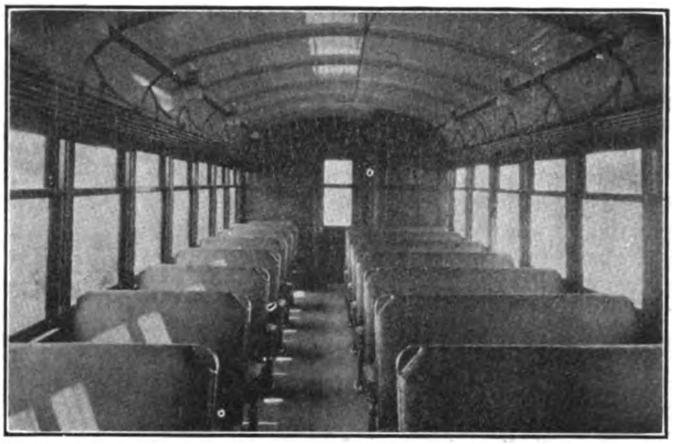
The complete power plant is mounted on a sub-frame which is suspended within the regular truck frame by four cantilever springs attached to swing motion hangers. The connection from the final drive to the axle is with two chains running in oil tight housings. This method of mounting, which is patented by the builder, permits the frame containing the power plant to move vertically or horizontally and as there is no rigid connection between the driven axle and the power plant frame, the driving machinery is protected from rail shocks and vibration, which is essential to the life of the machinery in a self propelled car, and especially so when the power plant is on the trucks.

One 65 gallon gasoline tank is located under the car body, arranged for convenient filling from the outside. This tank supplies fuel to both motors.

Over each motor there is placed a trap door in the floor which permits access to the motor for making all necessary adjustments, removal of cylinder heads, grinding valves, etc. The motors are also easily accessible from the outside of the car from each side. The truck can be removed from under the car in a very short space of time, and with the truck out the entire power plant is accessible for all kinds of repairs.

Each power plant has a separate set of controls so arranged that both motors can be operated separately or together as desired. A mechanical control, simple in construction is used because of the fact that in changing transmission gears, it is necessary for the operator to use the sense of touch and feel the gears in mesh, which can be done only with a mechanical control. For example, should the car be running with only one motor at a speed say of 25 or 30 m.p.h. and the driver sees the necessity of using the second motor to ascend a heavy grade, he can start up the second motor and put it directly in high gear without any clash of gears as he can easily bring the gears in mesh by the sense of touch.

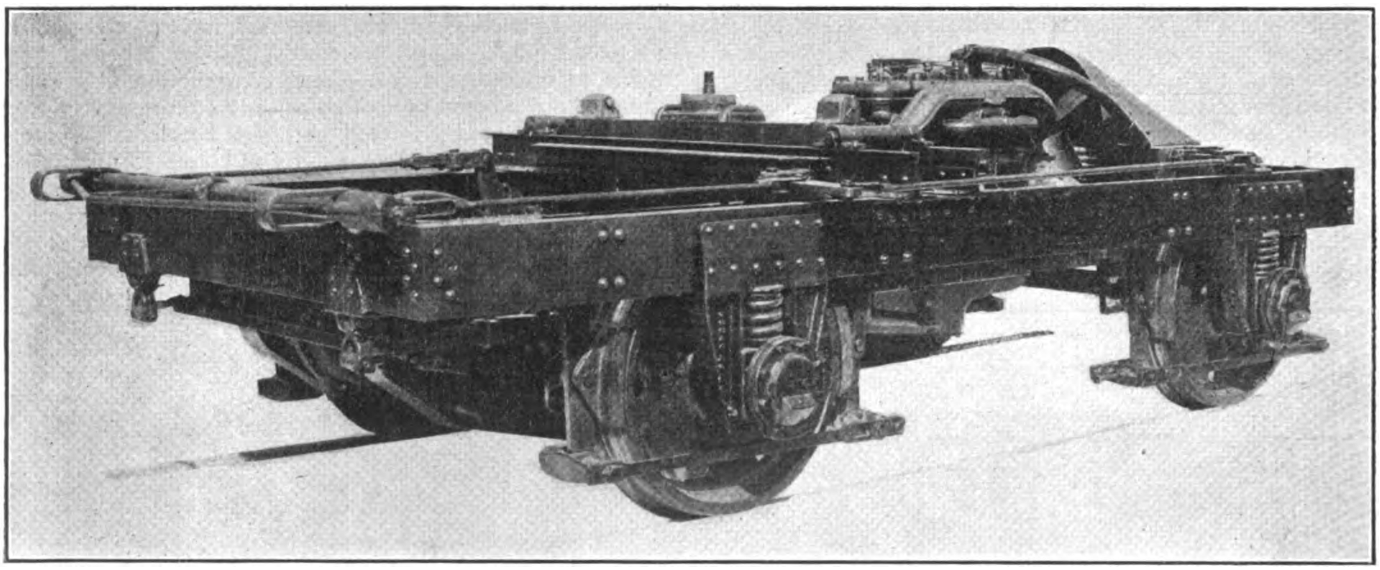
In some designs of self propelled railway cars, considerable power is taken from the motors operating the car for operating various accessories such as the air compressor, electric lights, radiator fan, etc. On this car, no power is taken from the driving motor for these purposes. The total horsepower output of the motors is used to propel the car.



Interior view of the passenger compartment

The two engine principle offers possibilities for economy in that it permits the use of one engine on level track and with light loads, and both engines on grades and for heavy loads. The power and fuel consumption thus keeps pace with actual needs. In handling heavy loads this method reduces to one half the amount of load and strain on the clutch and transmission gears as compared to cars with only one power plant, thus reducing the wear and maintenance of these parts. The car is so designed that when only one power plant is used, none of the parts or machinery of the second power plant are in motion (except the drive sprockets and chains). Therefore, there is no wear on the power plant that is not in use.

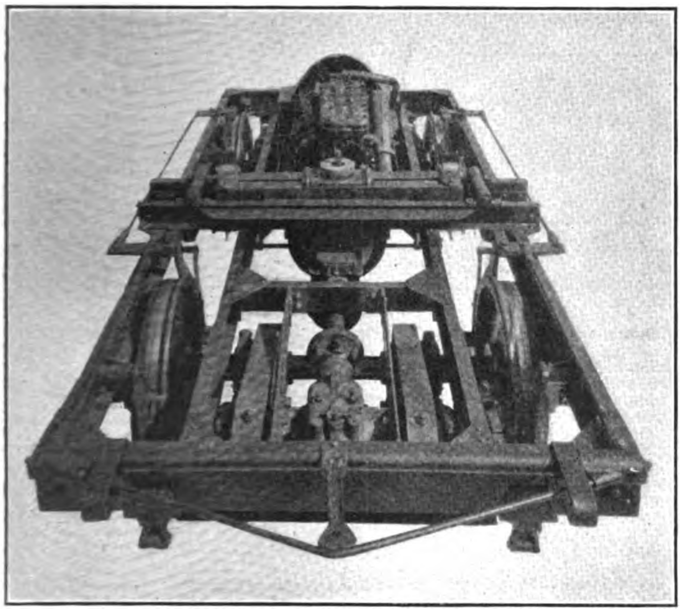
A Kohler automatic light and power plant is installed



Rear and side view of the truck, showing the brake arrangement and journal boxes

in the driver's cab. This plant furnishes 110-volt direct current for operating the lights of the car, driving the air compressor and operating the motors of the heating system. The lighting plant has 2,000 watts capacity and is driven by a small 3-hp. 4-cylinder motor, the complete unit occupying a floor space of only 15 in. by 33 in. In addition to the above electric plant, each driving motor is equipped with a generator, self-starter and a storage battery. This system will also supply current to several auxiliary lamps located in the car for emergency use. The electrical equipment includes a powerful 240-watt headlight.

A complete standard Westinghouse air brake system of the straight air type with emergency feature is installed on the car. The air compressor is of the regular street car type, operated by the auxiliary power plant. In addition to this air brake system, there is an efficient hand brake system operated by a ratchet located conveniently for the driver.



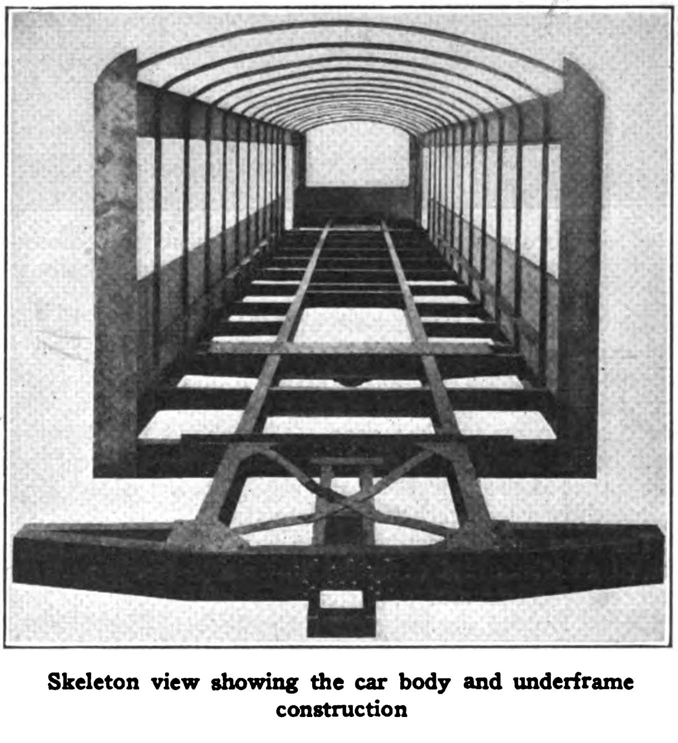
Top view of the truck, showing the motor suspension and driving arrangement

In view of the fact that the motors drive separate axles and are in no way connected except through the rails, it is not necessary that they be perfectly synchronized. Through the control system, the motors are synchronized near enough for all practical purposes. In operation no loss of power can be detected due to any failure of perfect motor synchronization. It is possible to cut either motor in or out while the car is in motion. When 75-hp. motors are used, a maximum speed of 45 m.p.h. can be obtained on level track and with 100-hp. motors 55 to 60 m.p.h. The car will operate at the same speed in both forward or backward directions.

The car body is constructed of steel with wood interior finish. The center sills are 8-in. 20.5-lb. I-beams. The side sills are ⅜-in. by 3½-in. by 6-in. steel angles; the cross members are pressed steel shapes. The side posts are steel tees ¼ in. by 1¾ in. by 1¾ in. These tees also form the car-lines and are in one continuous piece, running from side sill to side sill. The corner posts are formed from 12-gage steel and run from side sill to letter panel. The side sheeting and letter panel is 16-gage patent leveled copper bearing steel. The letter panel extends about six inches back on top of the roof and is flanged down to form a stiffener for the roof. The roof is of the turtle back type, extending the full length of the car. Roof boards are ⅜-in. by 2½-in. tongue and grooved poplar, dressed to a smooth surface, painted and covered with canvas bedded in white lead. The rear platform is of the enclosed vestibule type with trap doors over the steps. The floor inside is laid with yellow pine of double thickness with a deadening felt between the layers. The inside finish, consisting of doors, sash, partitions and panels below the rail, is birch, stained natural mahogany. The car has one toilet with dry hopper and a Dayton sanitary water cooler. Parcel racks are provided in the passenger compartment which run the full length on both sides over the seats. The seats are of the non-reversible type with pressed steel pedestals, wall and aisle plates, upholstered in leather. The seats on one side of the aisle are 52 in. wide for three passengers and 34 in. wide on the other side for two passengers. This leaves a 23-in. aisle through the car. The total seating capacity is 41 passengers. The principle dimensions of the car are as follows:

Total length of car	43 ft. 0 in.
Length over car body	42 ft. 11¼ in.
Length of baggage compartment	17 ft. 0 in.
Width of baggage compartment	9 ft. 1 in.
Length of passenger compartment	22 ft. 7 in.
Width of passenger compartment	9 ft. 1 in.
Width over sheathing	9 ft. 6 in.
Height from floor to ceiling	8 ft. 0 in.
Height from rail to top of car	12 ft. 4 in.
Height from rail to floor	4 ft. 3 in.
Bolster centers	25 ft. 6 in.
Total weight	39,000 lb.

Attractive electric light fixtures are provided throughout the car. Other equipment consists of signal bell, air sanders, alarm bell operated by air, electric classification lamps, fire extinguishers and hot air heating system. Special light weight standard M.C.B. couplers are provided at both ends of the car, fixed at the standard draw bar height.



Skeleton view showing the car body and underframe construction

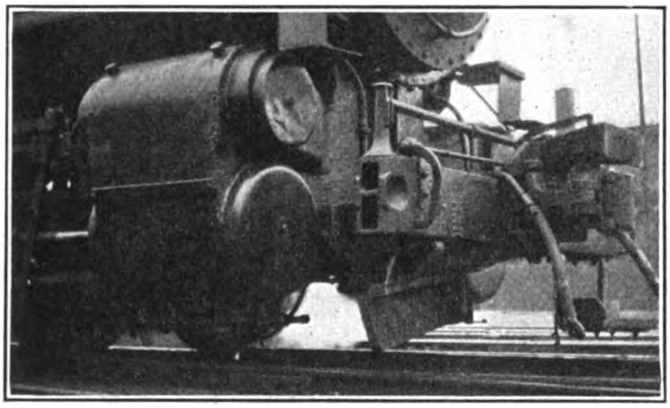
---

THE DETROIT, TOLEDO & IRONTON, aiming to provide safety in the greatest possible degree, has established a rule requiring that when cars are being pushed, particularly in yards and on industrial tracks, a brakeman must be stationed on the leading car, and he must have a mouth whistle. The same rule applies when yard engine, either pulling cars, or without cars, is moving backward; the brakeman must be on the footboard of the tender.

Bureau of Locomotive Inspection report

Conditions show the need for more careful inspection and thorough repair

THE thirteenth annual report of the chief inspector of the Bureau of Locomotive Inspection to the Interstate Commerce Commission for the fiscal year ending June 30, 1924, shows a reduction in the number of accidents and also in the number of persons killed and injured. A total of 1,005 accidents occurred in 1924 which were due to defective, inoperative or missing parts. The greatest number of accidents was due to defective grate shakers of which there were 96, 83 accidents were due to defective reversing gears, 66 to defective squirt hoses, 51 to injector steam pipes, 43 to boiler explosions, 41 to defective flues and 38 to defective brakes and brake rigging. An abstract of the report follows:



This footboard was caught on a frog and bent back, causing the trainman to be thrown to the track and seriously injured

The percentage of locomotives found defective decreased from 65 per cent during the year 1923 to 53.4 per cent during the last year. This shows an improvement in the condition of motive power during the year, yet below that of the year 1922, when 48 per cent of the locomotives inspected were found defective.

The condition of motive power is reflected in the number of accidents and casualties to persons resulting from failures of parts and appurtenances of locomotives and tenders. During the last year there were 1,005 accidents, resulting in the death of 66 persons and serious injury to 1,157 others. While this is a reduction as compared with the previous year, it is a material increase over the year 1922, when there occurred 622 accidents resulting in the death of 33 persons and the serious injury of 709 others.

During the year there were 43 boiler explosions, which resulted in the death of 45 persons and the serious injury of 59 others. The statement made above with respect to the total number of accidents during the year also applies to accidents due to explosions. The total explosions during the year decreased 24.6 per cent as compared with that of the preceding year, but an increase of 30 per cent over the year 1922.

Attention is called to the increased seriousness of explosions as reflected by the loss of life. The effect of a boiler explosion is in direct proportion to the size and suddenness of the initial rupture which causes the explosion and the temperature and volume of the water in the boiler at the time of the accident. The volume of water increases with the size of the boiler and the temperature of the water increases as the steam pressure increases, consequently the failure of a large boiler carrying high pressure is much more serious in effect. This is illustrated by the fact that 57 explosions during the year 1923 caused the death of 41 persons, while 43 explosions during the last year caused the death of 45 persons. The

NUMBER OF LOCOMOTIVES REPORTED, INSPECTED, FOUND DEFECTIVE, AND ORDERED FROM SERVICE

Parts defective, inoperative or missing, or in violation of rules	1924	1923	1922	1921

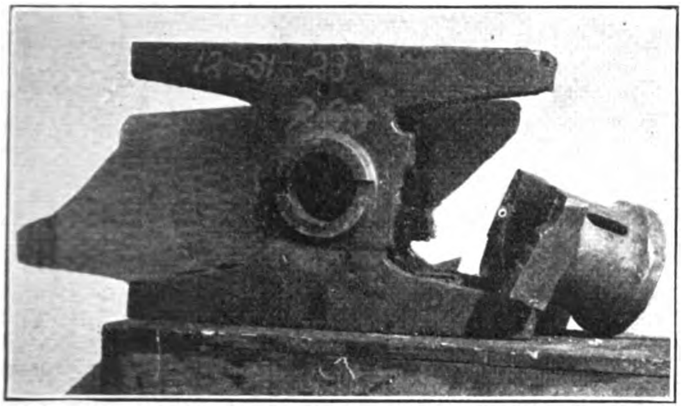
Locomotives ordered out of service	5,764	7,075	3,089	3,914

reason that more people are not killed and injured by locomotive boiler failures is due to the fact that there are usually only two persons on the locomotive at the time of the accident. If such explosions were to occur at stations or other congested places, the results could not be estimated. These facts forcibly demonstrate the necessity for a high standard of construction, maintenance, and operation of locomotives. Because of defects developing from day to day and trip to trip, the utmost diligence must be pursued if serious accidents are to be avoided.

While most of these explosions were caused by the



Both webs of this crosshead contained old fractures extending over 75 per cent of the cross-sectional area

crown sheet having been overheated due to low water in the boiler, contributory defects or causes were found in 52.4 per cent of the cases, which again illustrates the necessity for better construction, inspection, and repair of all parts and appurtenances.

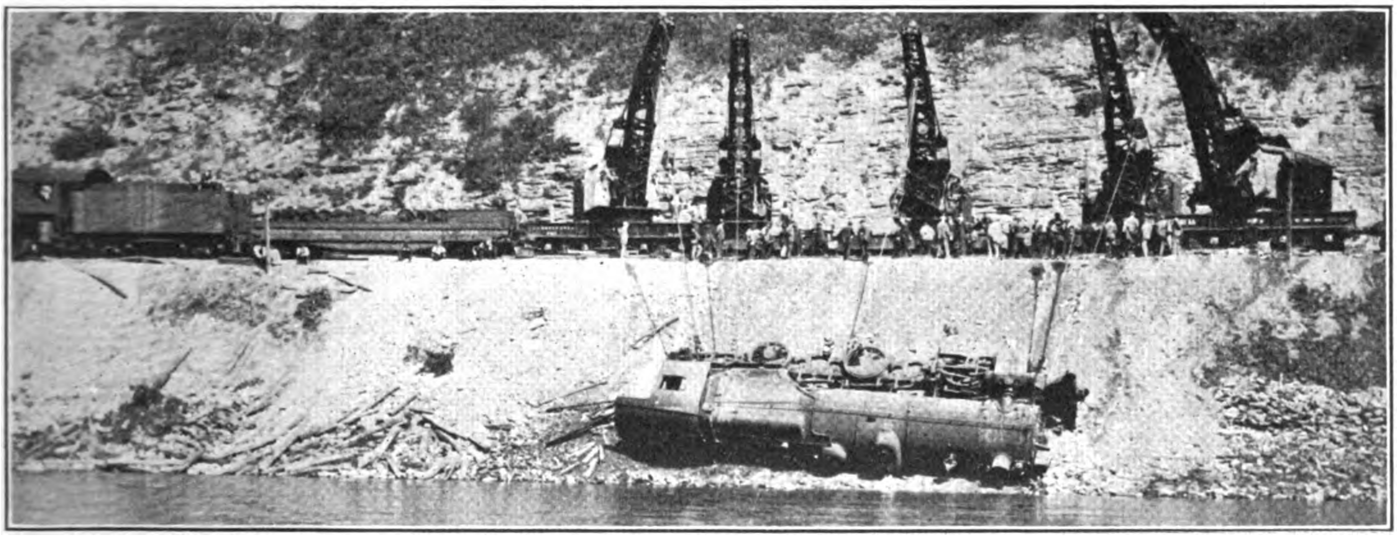
In the ninth, tenth, eleventh, and twelfth annual reports reference is made to investigations and tests made by this bureau on a number of railroads to determine the action of water in the boiler and its effect upon the water-indicating appliances. These investigations established without question that gage cocks when screwed directly into the boiler do not correctly indicate the general water level while steam is being rapidly generated and simultaneously escaping from the boiler. It is recommended that a suitable water column be applied to the boiler with three gage cocks and one water glass attached, with an additional water glass applied on the left side or boiler back head so that those operating the locomotive may have accurate knowledge of the general water level in the boiler under all conditions of service.

The water column as recommended is the most accurate device yet invented for this purpose. Accurate knowledge of the height of the water in the boiler is most essential to safe and economical locomotive operation. Water columns, as recommended, have been applied to practically all new locomotives constructed since the publication of our report and to a large number of locomotives previously in service. It is essential to safe and economical locomotive operation that water glasses and gage cocks be so constructed, located, and maintained that they not not only register the correct height of the water in the boiler, but that they be conveniently located and easily seen and read by the engineman and fireman from their usual and proper places in the cab. The duties of locomotive enginemen are among the most hazardous and exacting. Anything that detracts their attention for any length of time from the track and signals ahead creates peril to locomotive and train operation.

Autogenous welding has not yet reached a stage of development where it can be safely used on any part of the boiler where the strain to which the structure is subjected is not carried by some other construction which conforms to the requirements of the law and rules. This is also true in the case of fire-box crown-sheet seams where overheating and failure are liable to occur, on sheets which have been weakened from any cause to the extent of becoming unsafe and on seams on the boiler back head, except where the welded seams are covered with a patch applied with patch bolts, studs, or rivets which will prevent the escape of scalding water and steam into the cab, should the welding fail.

The most prolific source of casualties due to failure of autogenously welded seams has been in fire-box crown sheets and it has been conclusively demonstrated that the loss of life and limb due to fire-box failures depends very largely upon whether or not the sheets or seams tear.

Approximately 78 per cent of autogenously welded seams involved in fire-box failures have torn, while 15.4 per cent of riveted seams involved have failed. The fatalities where sheets tore have been about eight times as great as where they did not tear. From July 1, 1915, to June 30, 1924, autogenously welded seams were involved in 26.9 per cent of the crown-sheet failures, while 50.7 per cent of the total persons killed in such accidents was where the autogenously welded seams were involved. From the standpoint of safety, this clearly shows the



Locomotive derailed by the failure of a lug on a driving spring hanger gib, which allowed the hanger to work off the gib

necessity for construction of fire-box sheet seams in the strongest practical manner, especially in the so-called "low water zone", or on such seams as may be within 15 in. of the highest part of the crown sheet measured vertically.

The autogenous welding process is in a state of development and in order to avoid hindering the progress or development of any process of such great value when properly and discreetly used, the Bureau of Locomotive Inspection has hesitated to ask the commission to establish or approve rules or regulations restricting its use which might retard its development. However, unless the carriers confine its use to parts and appliances where there is less possibility of failure, accidents and injuries recommendations for more restrictive measures will have to be made in the near future.

Soon after July 1, 1922, it was brought to the attention of the commission that inspections, tests, and repairs were not being made by many of the carriers as required. It therefore became necessary for our inspectors to obtain information to show that locomotives were being used while in violation of the law so that court proceedings could be instituted. It was also necessary that our inspectors issue special notices for repairs in accordance with sections six and nine of the law, witholding 7,075 locomotives from service during that year until proper inspections and repairs were made. During the last year our inspectors were compelled to issue special notices for repairs which ordered 5,764 locomotives out of service.

Considerable improvement has been made by a large number of carriers, yet conditions are far from being satisfactory in so far as a proper compliance with the law is concerned. If due diligence is pursued by the carriers in seeing that locomotives are in proper condition and safe to operate before being offered for service, the commission's inspectors would not find it necessary to order any locomotive from service, which frequently causes serious inconvenience to the public as well as the imposition of an additional burden upon the carriers affected.

Result of a boiler explosion due to low water

Derailments of locomotives on curves

A practical application—The factor of wheel bearing is worked out for a 2-10-2 type

By Roy C. Beaver and Marion B. Richardson†*

Part II

IN order to illustrate the practical application of the analysis given last month, let us consider the case of a Santa Fe type locomotive having the weights and dimensions given in Fig. 9. First find the actual weights on the rails under each wheel. Referring to Fig. 6 let $d = 60$ in., which is the gage of the track plus the width of one rail head plus the widening of the gage on the curve. Also let the height of the center of gravity of the locomotive be $h = 96$ in. and the elevation of the outer rail be $e = 4$ in. Then, from the formula $e^1 = \frac{eh}{d}$ we find the value of e^1 to be 6.4 in. Then we may reduce the formulas $R = \frac{W\left(\frac{d}{2} - e^1\right)}{d}$ and $R^1 = \frac{W\left(\frac{d}{2} + e^1\right)}{d}$ to $R = .393W$ and $R^1 = .607\ W$ for the outside and inside wheels respectively. Using these formulas and the weights given in Fig. 9, we obtain the following results:

Location	Wheel	Lb.
Leading truck	Outer	11,200
	Inner	17,300
First driver	Outer	22,165
	Inner	34,235
Second driver	Outer	21,969
	Inner	33,931
Third driver	Outer	23,816
	Inner	36,784
Fourth driver	Outer	23,501
	Inner	36,299
Fifth driver	Outer	23,698
	Inner	36,602
Trailing truck	Outer	22,990
	Inner	35,510

Considering the coefficient of friction between the wheel and the rail to be .20, and multiplying the above weights on the drivers by this factor, we obtain for the forces necessary to slide the wheels the following amounts:

Driver	Outer wheel, lb.	Inner wheel, lb.
Front	4,433	6,847
Second	4,394	6,786
Third	4,763	....
Fourth	4,700	7,260
Fifth	4,740	7,320

Now suppose we have two trailing truck centering springs in tandem, each spring having an outer coil 8 in. in diameter of 1-in. round steel and nine coils and an inner coil 5½ in. in diameter of ⅝-in. round steel and 15 coils. Also, let each spring have an initial compression of four in. and a further compression, due to curvature.

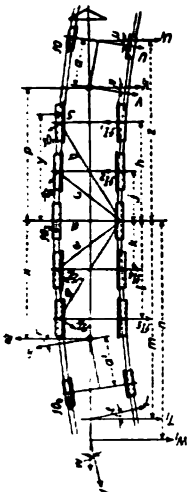

Fig. 5—The forces and reactions of a locomotive when curving

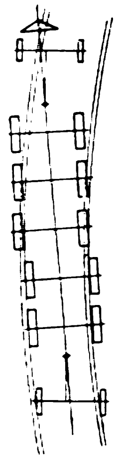

Fig. 3—Position a locomotive tends to assume when the guiding forces are removed

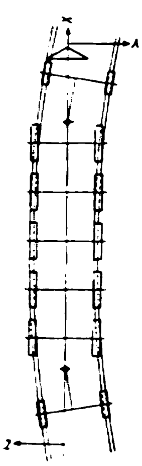

Fig. 2—A locomotive without flanges on a track

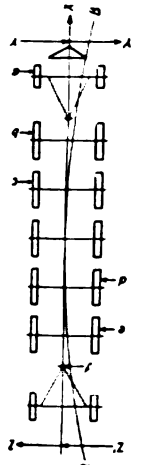

Fig. 1—A locomotive without flanges on a plane surface without rails

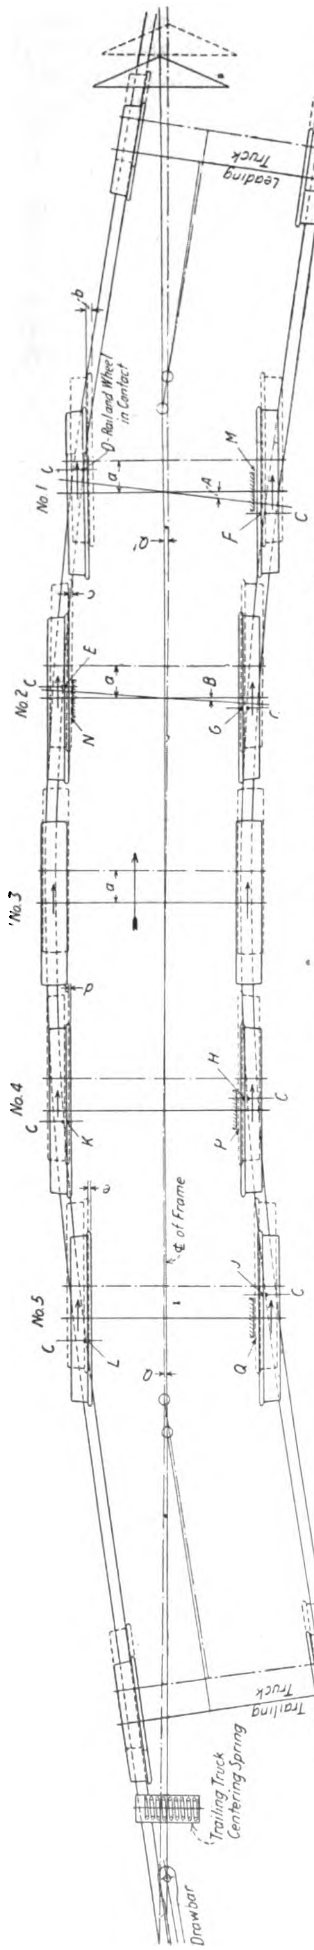

Fig. 4—A locomotive on a curve, showing a first and succeeding position

of two in., making a total of six in. Thus for the outer coil, $d = 1$ in., $r = 3.5$ in., $n = 9$ in. and $F = 6$ in.; and for the inner coil $d = \frac{5}{8}$ in., $r = 2.44$ in., $n = 15$ in. and $F = 6$ in. Substituting these values in the formula

$$T = \frac{FGd^4}{64nr^3}$$

we obtain for the outer coil, $T = 3{,}037$ lbs. and for the inner coil $T = 821$ lbs. The sum of these two, or 3,858 lbs. is the load on the spring when compressed. If the angle $t = 1$ deg. 30 min., then $T_1 = T \cos t = .9996\ T = 3{,}856$ lb. This shows that the force T_1 may be considered equal to T for all practical purposes.

Suppose the drawbar pull to be the nominal figure of 30,000 lbs. acting through a two-degree angle. Its side thrust, then, is $W_1 = W \tan 2\ deg. = .0349\ W = 1{,}047$ lbs.

Having calculated the resisting forces, let us next consider their moments. We obtain by solving right tri-

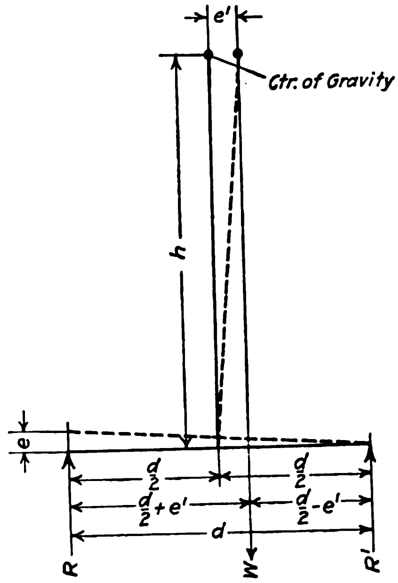

Fig. 6—Diagram showing the effect of the elevation of the outer rail

angles, the values for the diagonal distances given in Fig. 9. Using these values, and those for the other forces given in Fig. 9, we obtain the moments:

Driving wheel		In.-lb.
First outer	146.82 × 4,433 =	650,853
Second outer	89.94 × 4,394 =	395,196
Third outer	60.00 × 4,763 =	285,780
Fourth outer	89.94 × 4,700 =	422,718
Fifth outer	146.82 × 4,740 =	695,927
First inner	134.00 × 6,847 =	917,498
Second inner	67.00 × 6,786 =	454,662
Fourth inner	67.00 × 7,260 =	486,420
Fifth inner	134.00 × 7,320 =	980,880
Trailing truck spring	305.00 × 3,856 =	1,176,080
Draw bar pull	331.00 × 1,047 =	346,557
Total resisting moment		6,812,571

The next step will be to evaluate the overcoming reactions. If the leading truck weighs 3,500 lb., then the weight on the truck is 28,500 — 3,500 = 25,000 lb. Referring now to Fig. 7, if the distance from center to center of the rockers is 14 in., and the lateral movement of the bolster due to curvature is 4 in., then $r = 3$ in. and $s = 11$ in. From the formulas $Z_1 = \frac{Zs}{r+s}$ and $Z_2 = \frac{Zr}{r+s}$, we find these reactions to be 19,643 lb. and 5,357 lb. on the outer and inner rockers respectively. The angle z depends upon the design of the bolster, and is usually about 18 deg. The horizontal components of these vertical reactions are then $Y_1 = Z_1 \tan 18$ deg. $= 19{,}643 \times .3249$

= 6,382 lb. and $Y_2 = Z_2 \tan 18 \deg. = 5{,}357 \times .3249 =$ 1,740 lb. The total leading truck reaction is then $U =$ 6,382 + 1,740 = 8,122 lb., the lateral component of which is $U_1 = U \cos u$, which for a 1 deg. 30 min. angle gives $U_1 = 8{,}122 \times .9996 = 8{,}118$ lb., so that the effect of this angle may also be neglected in practice.

The reaction of the leading truck radius bar center pin may be computed from the formula $V = \frac{fOd}{a}$, in which f is the coefficient of friction, .20, O is the weight on the outer leading truck wheel, 11,200 lb., $d = 60$ in., as before and $a = 80$ in., from Fig. 9. Then $V = 1{,}680$ lb. and for a 1 deg. 30 min. angle v, its lateral component is $V_1 = V \cos v = .9996\ V = 1{,}679$ lb., from which it may also be seen that the effect of this angle may be neglected in actual work.

The trailing truck radius bar center pin reaction may likewise be found from the formula $R = \frac{dfO_6}{a^1}$, in which $d = 60$ in. as before, $f = .20$, the weight on the outer wheel being $O_6 = 22{,}990$ lb. and $a^1 = 89$ in. from Fig. 9. This gives $R = 3{,}100$ lb. with its lateral component $R_1 = R \cos r$, which for a 1 deg. 30 min. angle gives $R_1 = 3{,}100 \times .9996 = 3{,}099$ lb. showing that in this case too, R may be taken for R_1.

Using the moment arms given for these reactions in Fig. 9, we find the moments of these three reactions to be:

		In. lb.
Leading truck pivot................	166 × 1,679 =	278,714
Leading truck	246 × 8,118 =	2,098,028
Trailing truck pivot................	171 × 3,099 =	529,929
Total of all moments........................		2,906,671

The difference between this total moment and the total of the resisting moments must be taken care of by the flange of the leading driver, acting through the moment arm y, or 6,812,571 — 2,906,671 = 3,905,900 in. lb. for the leading flange. If the point of contact between the flange and the rail of this driver is 3 in. ahead of the

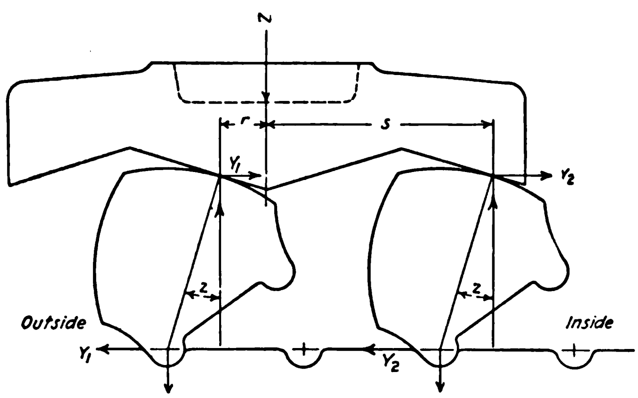

Fig. 7—Reactions in the leading truck

center of the wheel, then its moment arm is, referring to Fig. 9, 137 in. Dividing the otherwise unbalanced moment of 3,905,900 in. lb. by this arm gives 28,510 lb. as the thrust that must be produced by this flange.

Considering now the angle of incline, i, in Fig. 8 to be 80 deg., we find that the vertical component of this thrust of 28,510 lb. is $S_1 = S \cot i = 28{,}510 \times .1763 = 5{,}026$ lb. We also find that the pressure normal to the rail is $s = \frac{S}{\sin i} = \frac{28{,}510}{.9848} = 28{,}950$ lb. The vertical reaction of the friction due to this normal pressure is $s_1 = f^1 s \sin i$ = $.35 \times 28{,}950 \times .9848 = 9{,}978$ lb. The sum of these two vertical reactions, or 5,026 + 9,978 = 15,004 lb., must be overbalanced by the weight on the wheel if a derailment is not to result. Referring to the above computation of weights on the various wheels, we find that the outside leading driver exerts a load of 22,165 lb. on the rail, which is sufficient to hold the wheel down.

The factor of wheel bearing in this case is $\frac{22{,}165}{15{,}004}$ = 1.47, and as long as it is greater than 1.00, we do not need to fear trouble from the wheel climbing the rail. But .47 does not give very much of a margin and it is easy to see that it would not take very much variation in any

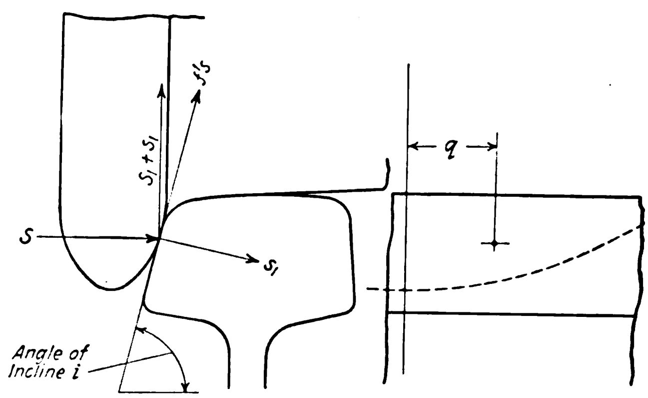

Fig. 8—Relation of the horizontal to the vertical forces at the wheel

one or more of the numerous conditions entering into this factor to bring it down to 1.00, or even lower, and thus cause a derailment. For example, a low joint may momentarily cause a reduction of weight on the leading driver—momentarily, yet just long enough to allow the wheel to climb the rail. A slight increase in elevation may do the same thing. A rail, out of line even for a short distance, may cause an added side thrust sufficient to do the trick. The locomotive may be just out of the shop, still somewhat stiff, and with the lateral taken up to the minimum, so that the binding action causes extra pressure and friction on the leading flange, the tires may still have their tool marks, which greatly increases the coefficient of friction. All of these factors tend to lower the wheel's advantage over the rail. These as well as many other conditions may be mentioned, which are contributory to the lowering of the factor of wheel bearing to the danger point of 1.00.

Benefits derived from this study

The value of a study such as this is not so much in setting forth the principles involved, or in being able ot calculate actual forces and stresses, or even in being able successfully to investigate cases of derailments and find the the causes thereof, as in being able to point out the conditions in the locomotive, track or operation which may be improved to prevent such derailments. The study is more of a means than an end in itself. So it would be well, in order to attain the desired end, to discuss some of the factors involved in the light of their effect on locomotive, track and operating conditions.

Locomotive conditions

Probably the locomotive condition which has the greatest effect in increasing the factor of wheel bearing is the lubrication of the leading flange. This lubrication makes a marked decrease in the coefficient f^1 with a proportional decrease in the vertical reaction s_1. All modern heavy

locomotives should have flange lubricators and in case of a derailment, the lubricators should be the first thing examined to see if they are working properly. Of next or nearly equal importance is the smoothness of the tire surface. We read of automobile tires that are geared to the road, and we get the same effect from locomotive tires that have finishing tool marks left on the tread due to chattering wheel lathes. A lathe should be powerful enough to take a finishing cut over the whole tread with a contour finishing tool without chattering. Of course tool marks soon wear off, yet the records show that many derailments take place with locomotives just out of the shop, on which the tires are not yet worn smooth. The pressure between the leading flange and the rail and its consequent vertical frictional and wedge reactions are not so great if the locomotive does not bind in the curve. There are several devices which may be employed to advantage in order to lessen or eliminate binding. The lateral or hub clearances may be increased on all the drivers or only on the front and rear hubs. This however, cannot be carried too far, on account of the I. C. C. limits for lateral, which require the wheels to be dropped, in case the lateral is too great. Yet the wear is greatest when the lateral is the least and even a little increase helps.

Setting the tires of the front and back wheels closer, back to back, than the others helps to lessen the binding. The use of blind tires on the main wheels, which has been assumed in this study, also helps. In addition to these remedies for binding there are also other devices, such as floating axles, which could be considered to advantage. But when such devices are used, they require a slightly different treatment of the problem of finding the factor of wheel bearing, due to the changed method of guiding, increased overhang of the leading truck, etc. It may also be observed that the coning of the treads of driving wheels has an effect on the situation. The coning soon wears off, but while it lasts, it does not act the way it should. By referring to Fig. 4 it will be seen that since the axles are held parallel to the frame and not radial to the curve, the fourth and fifth drivers have their large diameters rolling on the inner rail and their small diameters rolling on the outer rail. This is just the opposite from what we would like to have, with the result that the longitudinal slipping of the wheels is increased. The two leading drivers behave in the desired way, but since they are coupled to the others by the side rods, the effect of their good behavior is lost.

From the foregoing discussion, the benefit of the weight on the leading drivers and leading truck is apparent. These weights should be made as large as possible consistent with journal bearing pressures and rail loads. The driving wheel weight enters directly into the factor of wheel bearing and the leading truck weight enters directly into a guiding reaction which has a large moment arm and is therefore valuable. It may be observed from Fig. 7 and the discussion relating to it, that in curving an additional weight is thrown on the outer leading truck wheel, thus helping to increase its factor of wheel bearing and thus keep it on the rail. Sharp flanges are often blamed for derailments and sometimes justly, but in a case of this kind it would seem that they would be more advantageous than harmful. They increase the angle of the inclined plane between the flange and rail and thus lower the vertical force necessary to resist the side thrust. Long wheel bases, other things being equal, cause more binding in a given curve than short ones. Whether they would cause an increase in the factor of wheel bearing is something that would have to be determined for each case; for the moment arms of the resisting forces increase, at the same time the moment arms of the guiding reactions also increase, and an investigation would have to be made to determine if the one increased more than the other.

Mention has already been made of the resistance of the trailing trucks to curving, but these trucks become guiding trucks when backing, so that we can do no more than try to get a good compromise for the amount of their side thrust. The same is true of the leading trucks, except that the forward motion should be favored at the expense of the backward. While the effect of a booster on the trailing truck has not been taken into account in this study, such a device has a real bearing on the problem. For the traction of the booster has a lateral component which assists the curving of the locomotive by an outward thrust in forward motion.

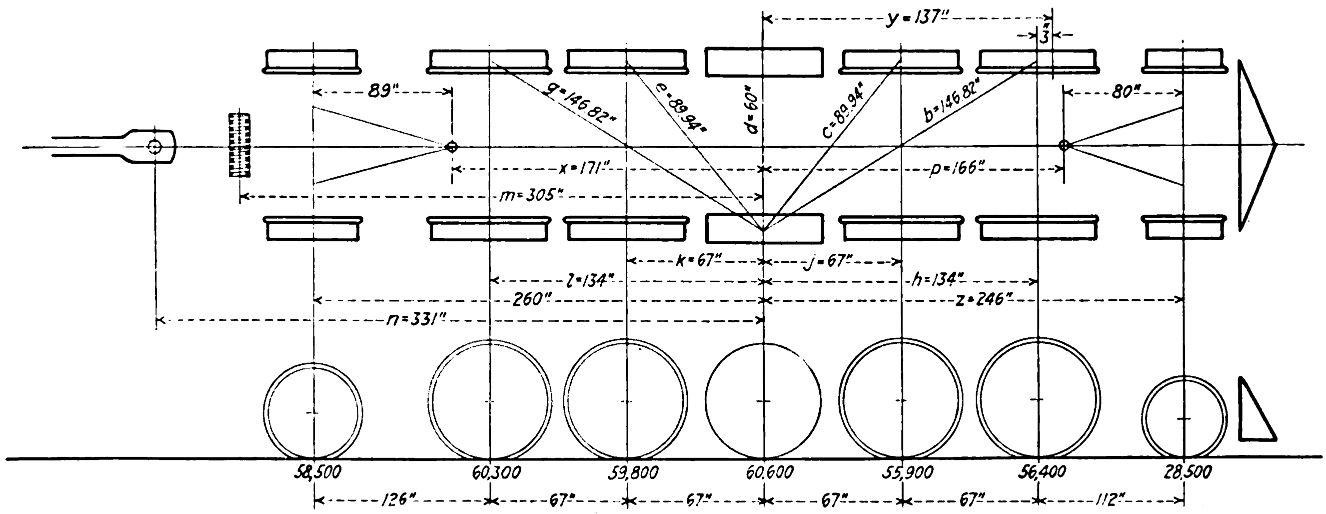

Fig. 9—The wheel loads and dimensions of a typical Santa Fe type locomotive

Track conditions

The track condition having the most important bearing on the problem is probably the elevation of the outer rail. Each locomotive requires a certain particular elevation for each speed and curvature so that, at best, any given elevation is a compromise. And since heavy locomotives require little elevation at low speeds this becomes the operating problem of running these locomotives faster or the fast trains slower, or by making a compromise to the end that the elevation may be reduced consistent with safe

operation of fast trains. The elevation operates at very slow speeds, as already shown, to relieve the outer rail of weight and to place it on the inner rail. Or, in the case given, the outer leading wheel carries 22,165 lb. and the inner leading wheel, 34,235 lb. for a four-inch elevation. Now if the elevation was increased so that the outer load of 22,165 lb. were reduced to 17,147 lb., which was found to be the vertical reaction, there would be nothing to prevent the wheel from climbing over the rail. Thus we see that rail elevation is a direct factor in the problem.

Next to elevation comes the matter of curve-worn rails. The worn surface simply provides the inclined plane up which the flange, if not restrained by weight, rolls to freedom. The more curve-worn the rail, the easier the ascent and the more difficult the work of holding the wheel down.

It would seem from this study that the track gage has little bearing on the problem, provided it is great enough to prevent binding, and in order to do this for Santa Fe type locomotives, it must be a little wider than standard on curves of eight degrees or more. Mention has already been made of track surface and alinement, and of the fact that variations in these, as well as in elevation, may cause momentary disturbances in the balance of forces sufficient to cause a derailment. The general use of spiral curves is helping to relieve locomotives of the sudden side thrust when entering a curve with the consequent sudden lowering of the factor of wheel bearing, thus making for the safer operation of heavy locomotives.

Operating conditions

While it has already been stated that any locomotive should be able to be operated at any reasonable speed over any curvature for which it is suitable, and that the locomotive and track conditions should be altered if necessary to make operation safe, yet it is profitable to see what effect operating conditions actually do have on the curving of locomotives. For example, it may be difficult to persuade a locomotive engineman to "widen on her" on a curve where he may have been on the ground the trip before, yet we must conclude from the study of the problem that an increase in speed helps reduce derailments, for not only does the coefficient of friction decrease with the speed, but also the effect of centrifugal force begins to be felt in helping to hold the outer wheel down. This deduction is borne out in practice. Locomotives that derailed at a particular place and a certain speed were found to traverse the place safely when the speed was increased. The use of steam and brakes also has some effect, for it has been found that locomotives will sometimes drift around a curve when, at slow speeds, the use of either steam or brakes would cause the wheels to tend to line up against the lateral, apparently increasing the binding and friction. Reference has already been made to the beneficial use of the booster on curves, the use of steam just mentioned not being intended to apply in the case of the booster. Reference has also been made to the reduction of the elevation which may be permitted by decreasing the speed of high-speed trains on curves that are giving trouble with heavy low-speed locomotives.

Summary

In order to grasp the situation as a whole, let us summarize the conditions which make curving easier and derailments fewer. In making changes, each of these conditions should be considered in the light of other related conditions, and the changes made should always be consistent with safety of operation and economical maintenance. These conditions are:

In the locomotive—
- Flange lubrication.
- Smooth tire and flange surfaces.
- Increase in hub clearance.
- Decrease in gage spacing of tires.
- Use of blind tires on main drivers.
- Use of floating axles.
- Decrease in coning of wheel treads.
- Increase of weight on the leading drivers and engine truck.
- Decrease of the trailing truck's side thrust.
- Increase of leading truck side thrust.

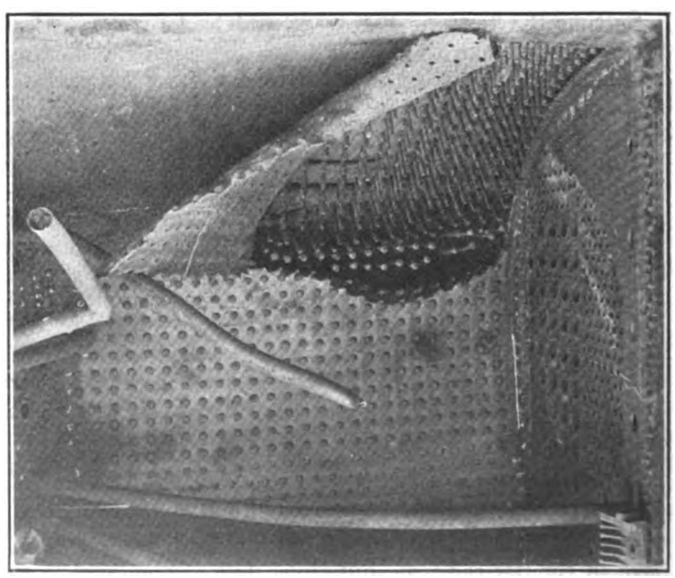
In the track—
- Decrease of the elevation of the outer rail consistent with the safety of high-speed trains.
- Removal of curve-worn rails.
- Maintenance of good service.
- Maintenance of good alinement.
- Widening of the gage on curves to prevent binding.

In operation—
- Judicious use of speed on curves.
- Drifting around curves.
- Use of booster on curves.
- Reduction in speed of high-speed trains to permit some elevation to be taken out of the track.

This method of analysis may also be used for the investigation of the factor of wheel bearing of the leading truck by assigning a calculated value to the side thrust of the leading driver and solving for the vertical reaction of the leading outside truck wheel. It may likewise be used for the investigation of derailments of either drivers or trailing truck wheels when the locomotive is running backward.

New Santa Fe locomotives for the C. N.

An article by C. E. Brooks, Chief of Motive Power, Canadian National, describing the new Santa Fe type locomotives recently purchased by that road, was published in the December, 1924, issue of the *Railway Mechanical Engineer*. It was stated in the title of this article that these locomotives were the largest of their type in the world. This statement is incorrect. While these locomotives are of exceptional weight and tractive force, there have been a number of others of the same type built which are of heavier weights and larger capacity, examples of which are those built for the Baltimore & Ohio and the Great Northern. The author of the article was not responsible for the incorrect statement.

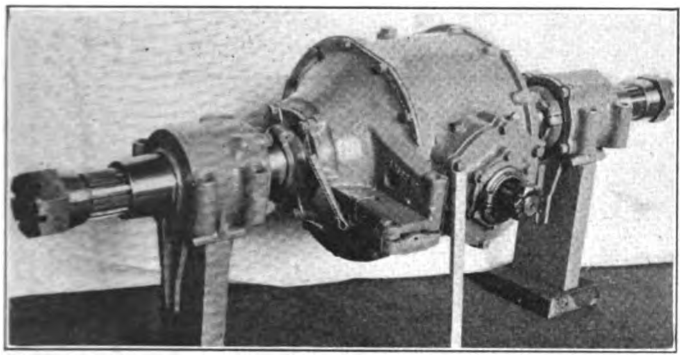


Failure of a portion of the flue sheet, crown sheet seam and side sheet seam which had been autogenously welded

Motor car of large capacity

Brill coach has seats for 59 and will haul a trailer seating 60 additional persons

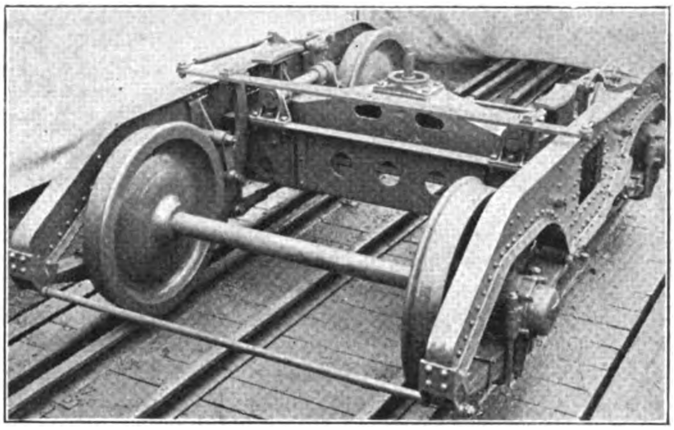
THE J. G. Brill Company, Philadelphia, Pa., has designed and built a large gasoline motor-driven passenger coach which has a maximum seating capacity of 59 and will haul a trailer with an additional seating capacity of 60. The car, designated by the builder as its Model 75, is driven by a six-cylinder motor which develops 190 hp. at 1,300 r.p.m., the power from which is delivered through a transmission of unique design to both axles of the forward truck. The motor is mounted at the forward end of the car body.



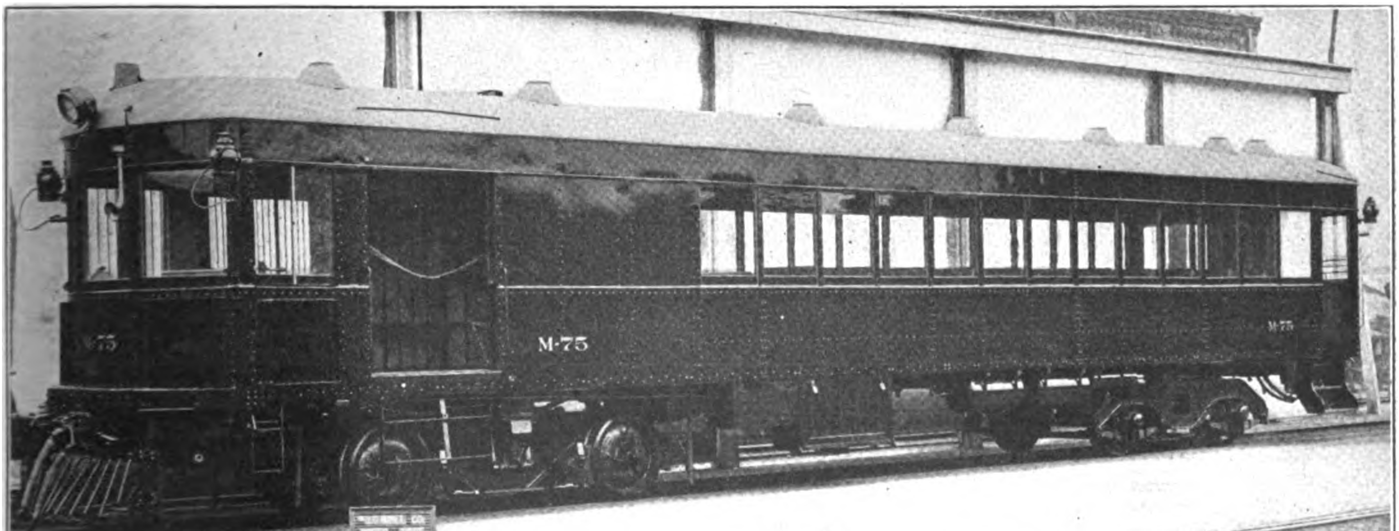
One of the axle gear cases, with the torsion spring seat showing at the left side

The transmission is of the drop shaft type. It was specially designed to take care of the powerful motor with which the car is equipped and is particularly noteworthy because of the fact that it is built into the bolster of the forward truck. One of the illustrations shows this bolster removed from the truck. The driving shaft from the engine is coupled through suitable universal and slip joints to the upper part of the two projecting shafts. This shaft is carried through the bolster and a shaft drive is taken off from the rear end for the operation of the air compressor. The lower of the two projecting shafts is connected at each end with a driving shaft leading to the gear case of the adjoining axle. This construction has materially reduced the normal angularity of the driving shaft from the engine and has practically eliminated the angularity from the shafts leading from the transmission to the axles.

This transmission provides five speed ratios, two of which involve the countershaft which is located at one side of the transmission output shaft. These two speeds are used only in starting and accelerating the car. For the remaining three speeds, the countershaft is idle and, as they operate at the same efficiency, each may be used as a running speed according to the requirements of grade and load conditions. The gears for the fourth and fifth speeds, the faces of which always maintain a fixed relation with each other, are of the spiral type. The gears for the lower three speeds, owing to the sliding relationship which must be maintained, are of the straight tooth type. All gears, however, are always in mesh, the changes being made by means of jaw clutches. Ball bearings are used throughout for all of the shafts and are also provided



The trailer truck

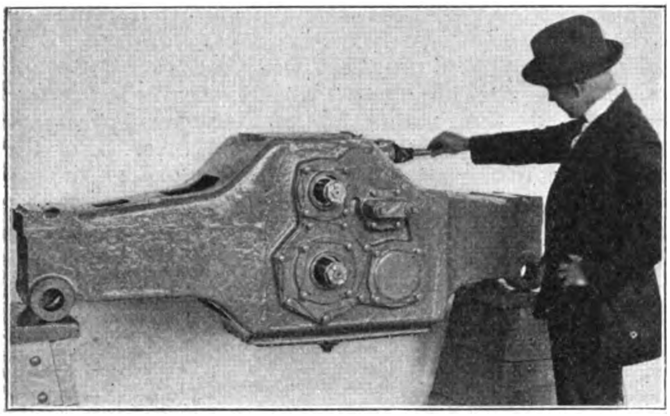


The Brill Model 75 motor car—length, 55 ft.; weight, 53,000 lb.; seating capacity, 59

between the driving shaft and the gears which run idle upon it.

The transmission always runs in one direction. The reverse is provided in the axle gear case, the bevel driving pinion meshing with two bevel gears, one or the other of which is connected to the shaft by a double clutch. The car may thus be operated with equal efficiency in either direction. The connections from the gear shift and reverse levers have been so designed that they compensate for the angularity of the trucks on curves.

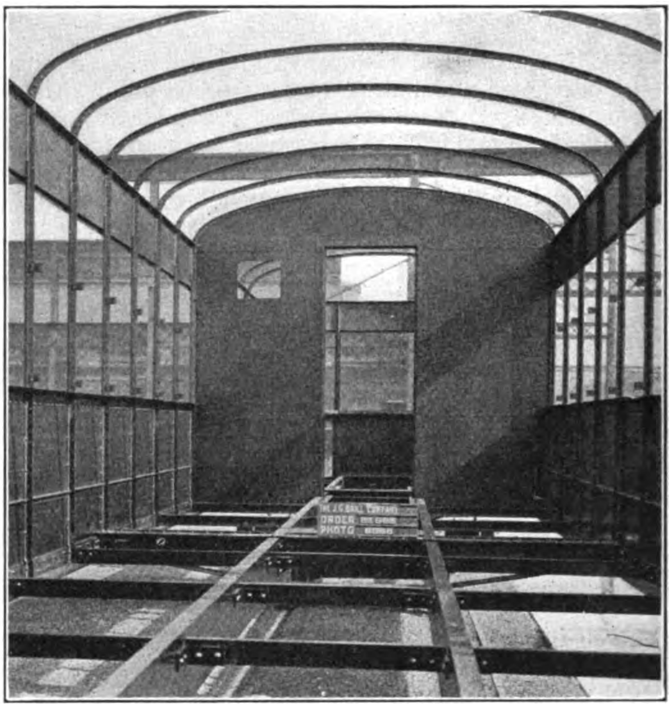
Both power and trailer trucks are generally similar in



The driving truck bolster—The figure is touching the gear shift arm

design. In the power truck, however, the side frames and journal boxes have been placed inside the wheels, while in the trailer truck they have been placed outside the wheels.

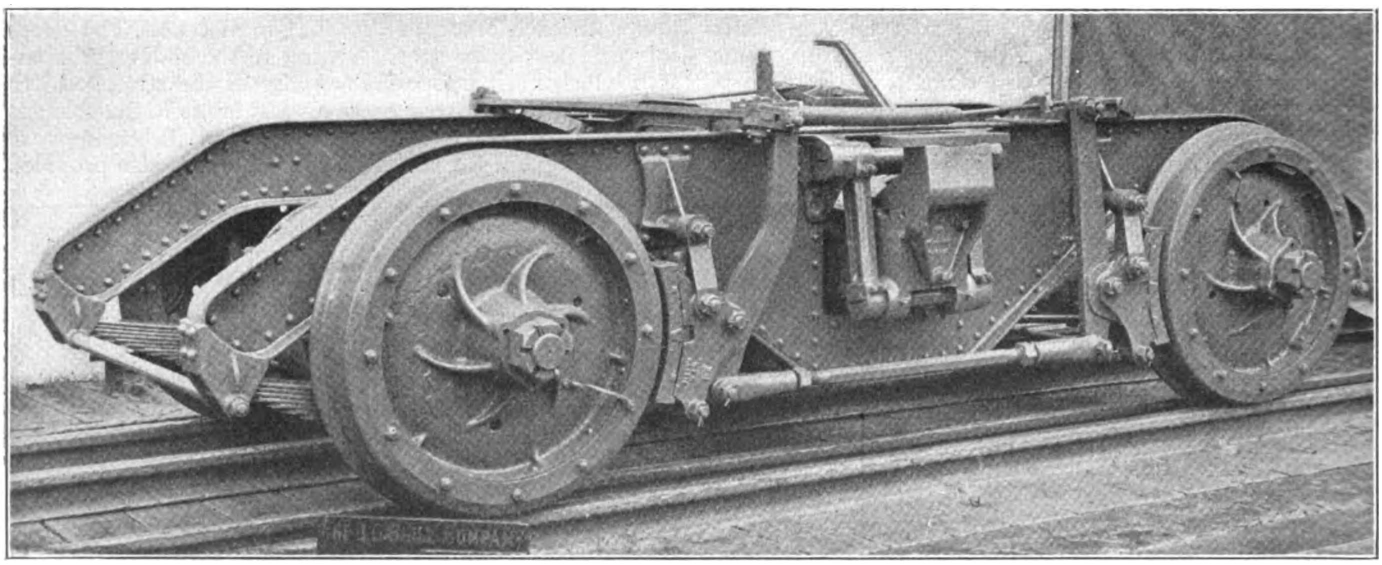
The side frames of both trucks are built up of double plates with the T-section flanges and fillers and stiffeners riveted between them. The axle suspension follows automotive practice in that the journal boxes are secured directly to the centers of the semi-elliptic springs. The bolsters of both trucks are supported on swing links. The on the end of the axle is drawn up. The torque is delivered to the wheels through a spline connection on the axle between the inner ends of the collets. This arrangement permits the wheels to be readily removed with a special puller when the removal of the axle from its gears becomes necessary. The axles are of heat treated alloy



The body and underframing of the Model 75 car

steel and are fitted with Timken taper roller bearings packed in grease. The wheels are of rolled steel, 33 in. in diameter, with M. C. B. flange and tread contour.

The motor is of the six-cylinder, four-cycle type, with 6-in. by 7-in. stroke. The size of the valves has been



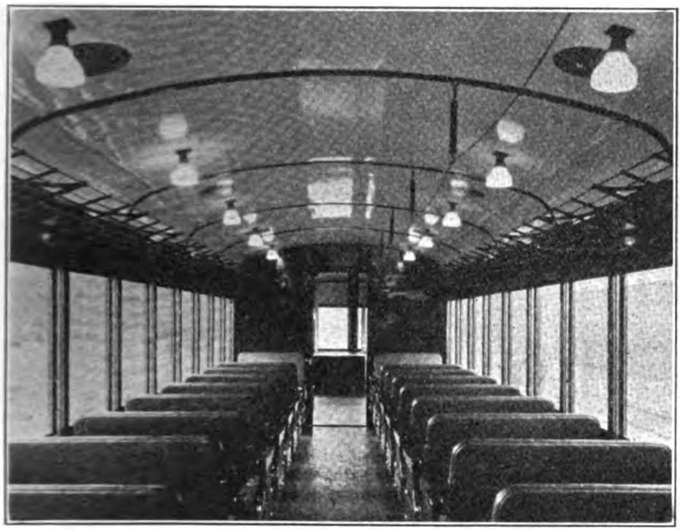
The driving truck with inside journals

links of the power truck are secured directly to the outside of the side frame, while those of the trailer truck are supported from the transom members.

The driving wheels are not pressed on the axles, but are secured by means of two taper collets which are securely clamped between the wheel fit and the axle when the nut kept down by using two intake and two exhaust valves for each cylinder. The engine develops a torque between 780 and 800 lb. ft. from a speed range of 500 r.p.m. to approximately 1,200 r.p.m., dropping off at higher speeds to approximately 740 lb. ft. at 1,500 r.p.m. The horsepower ranges from 75 at 500 r.p.m. to 150 at 1,000 r.p.m.;

190 at 1,300 r.p.m., and about 206 at 1,500 r.p.m. The fuel consumption per brake horsepower from 800 to 1,300 ranges between .5 and .6 lb. The engine drives through a multi-disk clutch of large diameter, fitted with a clutch brake which facilitates bringing the heavy driven parts into proper speed relationship for the operation of the gear shift. This clutch, the propeller shafts, the transmission and the axle gear housing, while developed along the lines of automotive practice, are of special designs larger than stock types, to take care of the heavy power transmission involved with minimum of maintenance or operating difficulty.

The engine is fitted with a starting motor operating



Interior of the coach, looking toward the baggage room

through a Bendix drive, a 12-volt generator of 1,000 watts capacity, two carburetors, two ignition systems, one a Delco distributer and the other an Eisemann high tension magneto, and a centrifugal pump driven water cooling system, the radiators of which are fitted in the front end walls of the car. All mechanical equipment involved in the driving of the car is included as a part either of the motor unit or the driving truck. Either or both of these units may be removed from the car and replaced within the duration of an ordinary lay-over period.

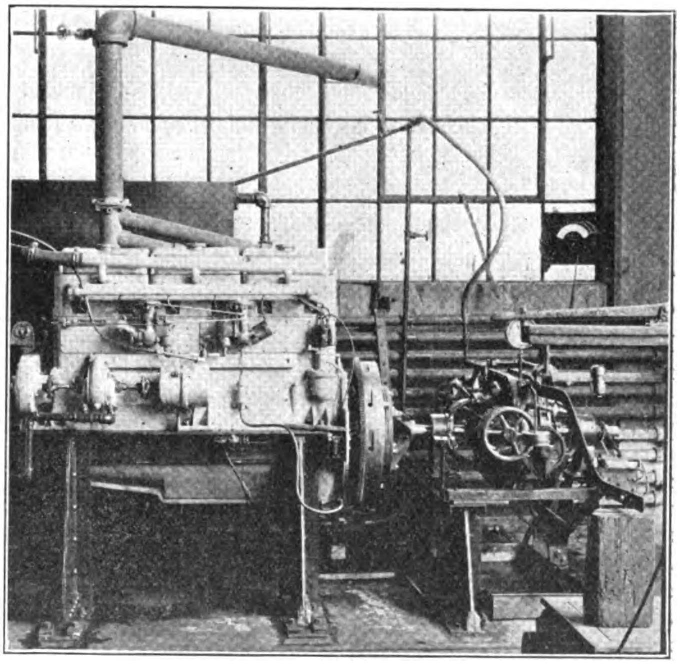
The car body is built to dimensions which closely conform to those of standard steam passenger equipment. The underframing consists of two 10-in. channel center sills which extend the entire length of the car body, angle side sills, built-up body bolsters, a diaphragm cross-tie at the center of the car and numerous floor supports. The body structure includes a frame of light T-section posts to which are riveted the outside steel side sheets and letter board. Carlines of sections similar to the posts support the roof, which is of wood covered with canvas embedded in white lead. The partitions between the baggage room and passenger compartment and between the passenger compartment and the vestibule at the rear are of steel plate riveted to a light weight framework of structural steel.

A feature of the inside finish of the car is the method of guiding and retaining the single bass window sash. This is accomplished by the use of Grill patented brass post casings which grip the sash with a sufficient spring action to prevent rattling. The sash are removed or replaced by springing back these casings and no removable window stops are required. These casings, designated by the trade name of Renitent, were primarily developed for use on street cars. The doors, casings and moldings are of dark stained mahogany, the ceilings are finished with Agasote and the side lining below the windows is of mahogany faced Haskelite ply wood.

The car body has a total length over ends of 55 ft. The baggage compartment, including the hood for the engine, is 16 ft. 3 in. The passenger compartment is approximately 34 ft. long and the rear vestibule is approximately 4 ft. long inside at the center. Access to the baggage room is obtained through 4-ft. door openings on either side of the car and the vestibule doors have a clear opening of 2 ft. 5⅝ in. The vestibule is entered by means of four steps on either side, the openings over which are closed by Edwards trap doors. The seats in the passenger compartment are furnished by the builder of the car. They are of the stationary type for two passengers each and have aisle arm rests. With this arrangement there is a clear aisle space of 30 in., which is large enough to permit the use of seats wide enough for three passengers on one side and two passengers on the other by using a type from which the isle arm rests are omitted.

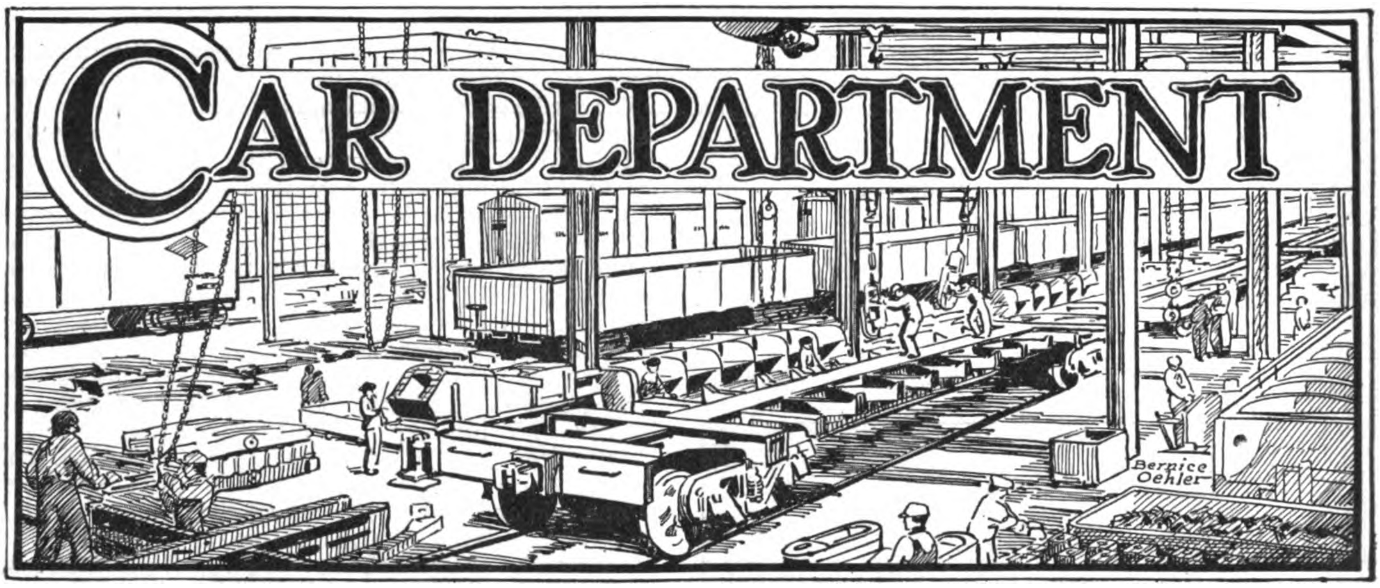
The interior photograph shows that the car is fitted with continuous parcel racks on each side of the passenger compartment and with 12 lights mounted on the ceiling, 6 along either side of the car. A saloon at the rear end is fitted with a dry hopper and a Giessel drinking water cooler. The car is heated by a Peter Smith hot water heater installed at the rear end of the baggage room.

On a trial trip recently made with this car, the car without trailer demonstrated its ability to accelerate up to 25 miles an hour at the rate of one mile per second.



The motor of the Brill Model 75 car on the testing block

Operating at the recommended engine speed of 1,300 r.p.m., the car develops a speed of approximately 59 miles an hour in high gear, 49 miles an hour in second gear, and approximately 24 miles an hour in third gear. As these three speeds are all direct drive, they are equally available for running and permit the handling of the trailer at the lowest of the three speeds on grades a little steeper than 1¾ per cent. Without the trailer it is calculated that the engine will be capable of maintaining the maximum speed in high gear on grades up to approximately 1 per cent and that it will maintain the lowest of the three direct drive speeds on grades of considerably over 3 per cent. The maximum speed may be maintained with a trailer on light grades up to about 0.35 per cent.



Improving car department service*

An interesting discussion of the methods which tend to make the "Milwaukee" car department an unusually effective organization

By L. K. Sillcox

General Superintendent of Motive Power, Chicago, Milwaukee & St. Paul, Chicago

Part I

SERVICE, such as implied in the title of this address, is dependent on an adequate organization, properly selected, adequately directed and constantly followed up. The elements involved are both human and material. In the first place, it is understood that each administration has its problems presented in a way peculiar to itself, so that any suggestions for change ought to be carefully weighed and, if found at all desirable, modified or improved upon to fit the actual condition in mind, then woven into the policies already obtaining, to the extent found most favorable to an enlargement and betterment of existing methods. Changes are hardly ever profitable, if hastily carried out; confusion and distrust are avoided if time is taken to consult with and receive suggestions from those directly affected.

A great deal of pressure is brought to bear from certain sections for even larger management units than we now have and yet the dangers of such a move are not often thought of and even less evidently expressed. There are those who urge more extensive railway grouping, those who feel that all of the freight cars in the country should be constructed, operated and maintained by one single organization and quite a number of other propositions similar in purpose, which are brought to attention from time to time. It is important in every circumstance where judgment must be passed to seek fundamental facts and principles. The aim should be, in any event, to preserve the personal equation and if large management groups can be so skillfully conducted as to meet this need, much of possible danger is avoided. Again, attention is directed to the thought that in any endeavor where individual initiative is lacking or conditions make the exercise of it unimportant, we are sure to travel in a negative direction. Competition is a necessity either in business or for a healthy sense of personal merit.

The one great thing that keeps the railroad service of our country to the present standard it has attained, even though some properties are not able to operate on a paying basis, is the element of attainment; still the public reaps the benefit. There is a fact to be reckoned with in our daily life as railroad men which cannot be expressed in dollars and cents. It is given freely, wholeheartedly and constantly—an ever living pride in the operation of the railroad each of us may be privileged to serve. I hesitate to bring so much data from the administration I am connected with, but if it is accepted as a few leaves from our book of experience and never in the sense of self-satisfaction, I shall feel some good has obtained. In addition let me say that such presentation as is made should be credited to the faithful support accorded by my associates.

Car design

It is necessary to adapt the question of car design to service (regardless of territory) with the object of having equipment which will give a maximum of return with a minimum of delay because of not being in the proper condition. The question of car design is ever progressing in that there is a rather constant advance in the methods of

*Abstract of a paper read at the regular monthly meeting of the Car Foremen's Association of Chicago, held December 8 at the Great Northern Hotel, Chicago.

operation as well as *universal* and *interchangeable* use, which must be kept pace with in the design of equipment. For the past 15 years there has been a considerable increase in the size and tractive force of locomotives in order to meet the demand for larger individual trains and thus reduce the unit cost of train and engine crew expense per ton mile. This has brought about a demand for freight equipment which will meet the changing conditions so that there has been a very marked enlargement in thought regarding the matter of strengthening parts, especially in the body bracing, underframing, draft members, etc. In common with other carriers our experience shows that these conditions generally develop into a demand for a plan of work or a program of improvements to freight cars such as will cause the major portion of ownership to be universally acceptable as to strength requirements and protect the owning road in current maintenance expense. For this purpose an analysis of the equipment owned with a view to determining that which has not been giving the proper service or which could not be brought up to operating demands is imperative and can usually be divided into:

(1) Those cars built of recent years which are of such design as to practically meet present conditions with maximum service.

(2) Those cars which have been built prior to the operating change referred to, but which could not be dismantled consistently because of age, general design and capacity and, therefore, which can be made subject to a special improvement program on the basis of a study of physical characteristics.

(3) Those cars which because of age, capacity, design and condition are not considered fit to be improved and, therefore, can be run until worn out and then dismantled.

The second item was found to embrace from 25 to 35 per cent of the total equipment in our case, and was affected by the policy of the carrier, for some 20 years previous, as to the rate of turnover in acquiring new and retiring old equipment.

Improvement program

It can be said, in general, where there has been a steady and accurate retirement program with an acquisition factor designed to offset the same, that it forms one of the easiest methods of overcoming obsolescence in design, but where retirements have been deferred with a consequent lack of new equipment acquired, the problem of overcoming obsolescence or the inherent design of equipment which does not permit of maximum service, is one involving large proportions and a great deal of expense when a change in policy is forced by reason of expanding service demands. Such a condition usually requires years to overcome. It is necessary to analyze each series of cars and determine what improvements or changes are required to make them fit for maximum service, then to work out a bill of material and labor schedule for each and determine the total cost. As a matter of convenience this plan is easily followed if each class of car is given a schedule number, the schedule representing the bill of material and amount of work to be done.

A program of this kind involves the selection of car shops best adapted to each kind of work with a corresponding organization of forces, stock of material, shop facilities, etc. The location of shops in the vicinity of loading stations is a factor of importance with respect to economy in transportation. Considerable supervision of such work is required to see that material is at hand to keep forces fully employed and that the work is done as prescribed and the output is at the proper rate. It is possible to set up a definite output based on a specific number of men allotted for the work at each point and then keep a definite record of the work done so that the

status of same may be known at all times. An illustration of the manner in which it is possible to follow the general work, based on other reports of greater detail and confined to location, is given in Figs. 1 and 2.

In any such plan there is, of course, a great deal of heavy work done in the nature of repairs in kind and in many cases it can be determined by estimates before the work is done, whether or not it will constitute rebuilding as prescribed by an accounting method or will be considered as heavy repairs with certain charges to capital account for improvements. This is merely another expression of the fact that obsolescence is overcome to the degree that equipment when reinforced to meet present day strength requirements is accounted for in the books as new and the expected life cycle will be relatively extended. Freight car repairs, if carried on so as to give maximum car service at a minimum cost, usually result in dividing the work into two groups; that is, the repairs which must be made at certain frequent intervals to overcome wear of certain parts, and repairs which are naturally accumulated until the heavy repair cycle is at hand. All carriers renew, by force of circumstances, such items as wheels, axles, brake shoes, brasses, air-hose, couplers, etc., in their proper cycle between heavy repairs to the entire car. This is a natural sequence, if maximum service is to be obtained with a minimum repair cost and at the same time having the situation in control as to developments which require further improvements.

Office of Master Car Builder

Fig. 2—Monthly report of schedule repair work by stations

The turnover of equipment both in the matter of retirement, acquisition, rebuilding and heavy repair work is a very important feature in developing car repair programs and especially in determining the policy to be pursued after an analysis along this line has been made. For instance, the average age of equipment owned, while a vital factor in the proper knowledge of the repair situation, has not, for the most part, accurately reflected conditions as to requirements of policy with respect to physical factors on such roads as are subject to Interstate Commerce Commission accounting rules, as was the case prior to 1914. In that year the I. C. C. issued a classification of accounts, providing that the rebuilding of equipment in cases where the cost of the work constituted the major portion of the value be considered as renewed, and as this required calling equipment new under such circumstances, the life cycle was for this reason begun anew. This changed the situation considerably in the case of some administrations from their former practice, because prior to that time the life cycle of the car continued from the original date built regardless of the nature of the ensuing repairs or improvements and it was entirely optional with the owner whether or not it would be considered that cars were dismantled and used in building up new equipment or whether the original unit would be continued, as such, regardless of the work done. The requirements of the I. C. C. classification covering rebuilding made it possible for those who elected to do so to adopt a policy of refinancing and reconditioning equipment out of operating expenses in the first instance with a consequent adjustment of accounts and transfer of proper charges to capital account, all of which has generally been affected by the operating ratio as a determining factor in the extent to which the rebuilding of equipment could be carried out. In recent years, however, it has been found that other administrations have been able to borrow money on the new valuation of rebuilt equipment because, presumably, they could not bear the operating charge in the first place, even though this would eventually be credited to operating expenses and charged to capital.

Rebuilding programs must be carefully developed

The extent to which rebuilding and heavy repair work is carried on is very important. Heavy repair work can be reduced to a formula so far as requirements are concerned when an analysis is made of equipment to determine its physical characteristics on a broad scale and then set up the heavy repair cycles. These cycles run from 8 to 12 years, depending upon the characteristics of the

equipment. If a carrier owning 100,000 cars has had a turnover of rebuilding and heavy repairs at the rate of 10,000 cars per year, then it is apparent that the general overhauling cycle runs about 10 years. A more detailed analysis will doubtless develop certain cars requiring renewal cycles of eight years, others considerably more than that. The idea here is that a close regulation of the nature of repairs and, therefore, the general maintenance cost will finally resolve itself down to what is now being done in the case of locomotives, where there is a constant analysis required to determine the proper balance between running and classified repairs based on many considerations, one of which might be pointed out here as being the miles run out and miles restored in classified repairs. In the case of freight cars, years might be substituted for miles, considering years run out and years restored in overhauling. Much can be done along the lines of determining frequency of heavy repairs in further detail by records showing how this is progressing by types or series of cars. Returning again to the example of a road having 100.000 units, the following division is possible:

Cars		Age	
10,000	at	2 years	20,000
15,000	at	5 years	75,000
10,000	at	8 years	80,000
20,000	at	10 years	200,000
10,000	at	18 years	180,000
5,000	at	20 years	100,000
10,000	at	25 years	250,000
10,000	at	26 years	260,000
10,000	at	27 years	270,000
100,000			1,435,000

Average age, 14.35 years.

The policy of heavy repairs and rebuilding the past 10 years shows the average yearly number of cars so overhauled at 5,000 per year, or once every 20 years. The new program will require, after an analysis of equipment, an average of nine years between heavy work, so that the program will have to be increased to 11,111 cars per year, of which 5,000 will be rebuilt and thus renew the life cycle, and reduce the average age gradually to approximately 10 years, if the usual 20-year life is to be maintained.

But if an acquisition program is followed consistent with ownership, then there will be 5,000 cars retired and 5,000 new cars purchased, which will reduce the requirements for rebuilding to less than 11,111 cars, because of reducing the average age thereby. In the latter plan there will be an approach to the average age of 10 years but further analysis will be required to determine the extent of heavy work to be done to prevent the overhauling of obsolete cars to maintain the proper ownership complement.

Capital charges for rebuilt cars

It may be of interest to note further that the extent to which this kind of work can be transferred to capital charges is not always simply governed by the physical valuation in relation to capital investment, but as before stated, by the operating ratio, which is another way of stating that the amount of property required to perform the service is not, in every instance, the only factor, but the density of traffic as a whole or the volume handled which justifies building up capital out of operating expenses on the one hand, and direct capital charges by means of acquisition of new equipment on the other hand. Factors of this nature must be known and analyzed if a further and proper regulation of equipment is to be had consistent with local conditions, and any study will reveal the fact that at the present time there appears to be some difference in policy between carriers in this respect. Therefore, it is not possible to express specifically a general plan for common use. This is one of the reasons why the situation is not yet propitious for the central control of all the equipment in the country as a whole. Whether desirable or not, it will be many years before this problem can be fully solved and brought to a state of uniformity throughout the country. What makes this question of such great importance is that the maintenance of freight cars involves not only repairs, but includes charges for depreciation on the investment in existing cars and retirement charges (or deferred depreciation) involved in cars taken out of service. This is one of the cases in railway accounting where maintenance carries the burden of the investment, the only item eliminated being interest on investment, which is a fixed charge not included in maintenance.

While a schedule of improvements is an essential feature of any railroad policy in order to meet changing conditions in operation, there are other factors in the ordinary maintenance of equipment, such as painting programs, special attention to refrigerator equipment, repairs and inspection to permit selection of cars for specific loading, so that loads may move to destination without interruption, etc. In order to follow up a maintenance policy closely and have it regulated in accordance with what the revenues will permit, it is necessary to be able to decrease or increase special program work accordingly and also regulate other plans in maintenance policy such as inspection, light repairs, etc. [As an illustration of a rather close supervision of the various kinds of work at hand, Mr. Sillcox here presented quarterly freight and passenger car repair bulletins outlining the plan to be followed for three months and regulating the work to be done according to what conditions will permit.—EDITOR.]

Classification of inspection

Freight car inspection can be organized and classified so as to reduce the method of reporting thereof to a system rather complete in itself because carriers are not only concerned with their own repair policies, but must inspect both system and foreign cars for safe movement in trains whether the load originates on home or foreign lines.

In general, inspection may be divided between that required in the interchange of cars among railroads and that required to make the movement of trains safe over the handling line. Interchange inspection is standardized more or less under A.R.A. regulations, but it is within the province of the individual carrier to develop methods of freight train inspection with a view toward uninterrupted service. Some lines divide their freight train inspection into a number of groups, possible three classes, designated as numbers one, two and three, and have grouped their inspection forces accordingly, based on considerations of business demands and expenses.

The so-called inspection number one can be considered as that given to trains at larger originating terminals and to cover not only the condition of the equipment, but the manner in which the loads are to be placed and to enforce existing rules with the object in mind of having continuity of movement obtain. Inspectors at these points can be impressed with the importance of having loads in condition to move to destination without additional expense to shipper or carrier. Such inspection can cover the acceptance for service of all necessary items such as wheels, axles, journal packing, draft gear and brake rigging, body, trucks, etc. Special attention is often insisted upon to the body when cars are inspected initially to be placed for loading or for moving empty into territory originating freight subject to damage. This often involves the changing of wheels, etc., particularly in the case of stock cars before movement to loading territory. Close attention can also be given to safety appliances. An organization to carry out a plan as mentioned, can be

stated as consisting of two ground men, one roof man and two follow-up men, covering a string of cars from one end to the other, but when time is the ruling factor, two such gangs can be placed on one string, each working towards the middle from opposite ends. Such an organization may be provided for at terminals where there are approximately 2,000 loads and 900 empties or more moved each 24 hours. The organization for inspection depends upon the number of cars handled and the nature of traffic.

Inspection number two can be provided for at intermediate terminals at distances ranging from 150 to 300 miles from terminals where class one inspection is given. It may be applied at division points and smaller originating or interchange stations. The work covering the checking over for safe movement such items as wheels, axles, brake rigging, journal packing, draft rigging, safety appliances, air brakes, etc.

Class three inspection may be given to trains inbound or outbound at points after having received number two inspection at a distance of approximately 300 miles. The spacing of inspection stations, of course, depends upon the layout of the railroad. Inspectors can be stationed at points where they are in a position to observe trains moving into yard, looking for defects on wheels, brake connections, journal boxes, draft rigging and safety appliances. There should be a clear understanding in the matter of inspection as to what it means to "bad order" cars, and have them switched to repair tracks in cases where it would be possible to make repairs in the train yard. Switching is expensive and should be conserved, even though it is not charged to freight car repairs. Much can be done to save this expense and expedite the movement if handled in train yards.

While all that has been said relates to action which may be taken by car department employees, the element of possible loss to the service from lack of attention in avoiding cases of rough handling, cornering of cars, failure to release air brakes in making stops prior to taking siding for an opposing train, resulting in pulling out drawbars, and delaying both movements, etc., such losses may be avoided by proper co-operation and adequate appreciation in working out a plan in any given instance, for it is evident to most car men that losses of this character occur too frequently and that they are not sufficiently enumerated. A poor crew can generally manage to set out a few cars each day or burn off a journal occasionally, while it takes a wide awake and experienced train crew to treat boxes in such a way as to bring all of their cars safely into the terminal or save fuel in seeing that side doors on box cars, when picked up, are properly closed, not leaving the job entirely up to the other fellow or even overstraining themselves in these acts of constructive helpfulness. Laxity in practice has resulted from technicalities being applied, such as car men being called, in many cases unnecessarily, to couple hose, incurring expense entirely out of proportion to the work thus performed and which, for the most part, seemingly could not have been originally anticipated or even implied in the formulation of schedule rules. I recall a condition resulting from orders being issued requiring car men to scrub out cabooses which resulted in the men involved seeking information as to possibility of eventually being assigned to "redcap" duty in train yards. While the thought expressed may seem remote it clearly indicates the trend of mind on the part of car men who may be diligently applying their efforts in the interests of the service.

Qualifications and examination of inspectors

The requirements are that an applicant for a position of inspector must be thoroughly conversant with methods of car repair and construction, be between the ages of 21 and 45, must pass examination for sight and hearing, must be able to read and write, must answer 75 per cent of the 24 questions usually covered in the examination and, if he fails the first time, will be given only two more opportunities. The third failure disqualifies him. The examination papers are kept on file by the local car foreman. The questions usually comprise such items as inspector's duties, grouping of car parts so as to classify inspection accordingly, the functions of various car parts so as to establish the reasons for intensive inspection, questions as to loading rules and their requirements, safety appliances, air brakes, A. R. A. interchange rules, etc.

Air brake inspection

There are so many parts of equipment which require inspection and proper care to attain efficient service that it is not possible to concentrate too much on one particular item of inspection without neglecting the others, yet the inspection of air brake apparatus is one of the most important, not only as a matter of safety, but to reduce

Chicago, Milwaukee & St. Paul Ry. Co.
Air Brake Bulletin
March 15, 1924

Under this heading is published air brake news of interest, rulings and other matters. You are invited to raise any question on these bulletins, addressing them to James Elder, General Air-Brake Supervisor, Milwaukee,Wis.

Since the bulletins on "Piston Travel" and "Leverage" were issued, I have received a number of questions pertaining to brake beam hangers, such as, what effect does a vertical brake beam hanger have on the brake? What causes one wheel on a truck to slide? What is the correct angle for the brake beam hangers? etc. Instead of answering these questions through the medium of the "Question Box" I will endeavor to answer them in this Educational Bulletin.

When a train is in motion, the force applied to the brake shoe to bring each car to a stop is applied to the lower-most points of the truck, while the forces that are urging the truck forward are, first: the force due to motion applied at the center of gravity of the truck, and second: the force due to motion of the car body, which is applied to the truck at the center plate, far above the center of gravity. The rail pull holding the truck back while the car body surges ahead. This condition inevitably results in a tilting of the truck, with a reduction of the normal weight on the rear pair of wheels and a corresponding increase of weight on the forward pair of wheels of each truck. It will be quite clear that when the forces referred to are brought into existence by any application of the brake, the rear wheels of the rear truck will carry less weight than any other pair of wheels under the car.

A typical example of the bulletins issued periodically covering various subjects

losses incurred in dragging brakes, leaking air, etc. Much attention is given to this feature of the work because it requires mechanical precision and perfection. It is essential that definite maintenance regulations be established for work done on the repair tracks and shops and if this has been well established and systematized it is then a question of constant and proper inspection for service on the road. The training of inspectors for this class of work must be specific and in detail, note for example the air brake bulletin issued for March 15. Inspectors are directed to observe hand brakes, air and signal hose, piping, brake rigging clearances, couplings, piston travel and the necessity of cleaning brake cylinders and slack adjusters, dirt collectors, triple valves, retainers, etc., at proper intervals.

The period of service is closely checked to determine

the renewal requirements. Brake cylinders and reservoirs are inspected to see that they are kept tightly secured to the supports. The instructions as to adjusting brakes, piston travel, brake levers and other items of detail are set up specifically and fully systematized. When brake shoes are found to have a reddish color inspectors know that this indicates long application of brakes which usually heats the wheels and, therefore, requires a close wheel inspection as well, and an examination of the brake apparatus must be made in order to determine the cause of heating.

As to the inspection for cleaning air brakes, the A.R.A. rules are followed closely. Reports of cleaning are sent to a central office and when it is found that the same cleaning is necessary to be repeated within three months of the last date special investigation is made tracing back to the original point to determine the methods employed or the responsibility for lax work. A form (No. 665) showing the records kept by the general air brake supervisor on which is tabulated the work done at various points on the system, is illustrated on this page.

Wheel inspection

The inspection of wheels can be reduced to a specific and systematic arrangement and this plan is of great convenience. The organization of forces for intensive inspection of wheels should be specifically set up by localities.

We have found that practice desirable and efficient in the manner of placing responsibility not only for passing wheels in inspection which should have been removed, but preventing undue removal of wheels which should have continued in service. All wheels and axles removed are checked at specified points and on each axle is marked the symbol showing the nature of defects for which removal was made, giving the car initials, number, station and date. The system of symbols used is as shown below:

Symbol	Wheel defect
W 1	All right for service
W 2	Bracket cracked
W 3	Brake-burned
W 4	Burned from fire
W 5	Chill worn through
W 6	Flange broken
W 7	Flange chipped
W 8	Flange worn thin
W 9	Flange worn vertical
W 10	Hub burst
W 11	Hub worn
W 12	Large axle fit
W 13	Loose wheel
W 14	Plate cracked—front
W 15	Plate cracked—back
W 16	Rim broken
W 17	Rim chipped
W 18	Seamy
W 19	Shelled out
W 20	Shoulder worn
W 21	Slid flat
W 22	Tread cracked
W 23	Tread worn out
W 24	Wheel broken
W 25	Wheel condemned by remounting gage

Other reports are rendered to show wheels pressed off, mounted, gage readings, etc., with a complete record by wheel numbers. Axles are classified in somewhat the same manner as wheels to cover defects. [The final installment of this paper will appear in an early issue of the *Railway Mechanical Engineer*.—EDITOR.]

Form 665 Revised
Chicago, Milwaukee & St. Paul R.R.Co., Car Department
Repairing and cleaning air brake apparatus

________________ 192 _____

Mr. James Elder,
Gen. Air Brake Supvr.,
Milwaukee Shops.

Following is report of air brake work performed at __________ for the month of _________ 192__, in freight and coach yards, transfer, house and repair tracks:

	Passenger		Freight	
	Sys'm	For'n	Sys'm	For'n
1. Number of brake cylinders cleaned having last cleaning date less than 9 mo. frt., 6 mo. pass.				
2. Number of brake cylinders cleaned having last cleaning date from 9 to 12 mo. frt.				
3. Number of brake cylinders cleaned that had not been cleaned within 12 mo. frt. 6 mo. pass.				
4. Number of cylinder packings renewed				
5. Number of cars having brakes tested with air pressure while on repair tracks				
6. Number of air hose applied				
7. Number of angle cocks removed and exch.				
8. Number of retaining valves cleaned Number of retaining valves exchanged				
9. Number of freight cars repaired and delivered off repair track during month as shown on bad order report				
10. Number of slack adjusters cleaned				
11. Number of passenger triple valves changed				
12.				
Work performed in triple valve and air brake shops				
13. Number of triple valves passing final test over A.R.A. test rack				
14. Number of triple valves having repairs made to slide or graduating valves, piston ring or bushing				
15. Number of air hose mounted and tested under air pressure				
16. Number of angle cocks repaired				
17. Number of retaining valves repaired				
18.				

Whenever necessary to re-clean brake equipment, passenger or freight as per rule 60 due to being inoperative in less than 3 mo., car initial, number, last place and date of cleaning, also cause for brakes being inoperative to be shown below.

Record of incoming and outgoing air brake inspection of freight trains	Passenger		Freight	
	Sys'm	For'n	Sys'm	For'n
19. Number of arriving trains on which incoming test was made				
20. Number of arriving trains having less than 85 per cent effective brakes				
21. Number of cars set out for repair tracks due to inoperative brakes (brakes sticking or old air dates not considered)				
22. Number of cars set out due to old air dates				
23. Number of defective air hose replaced				
24. Number of cars with improper piston travel which were corrected				
25. Number of cars set out for damaged wheels or burnt brake shoes due to defective air brakes				

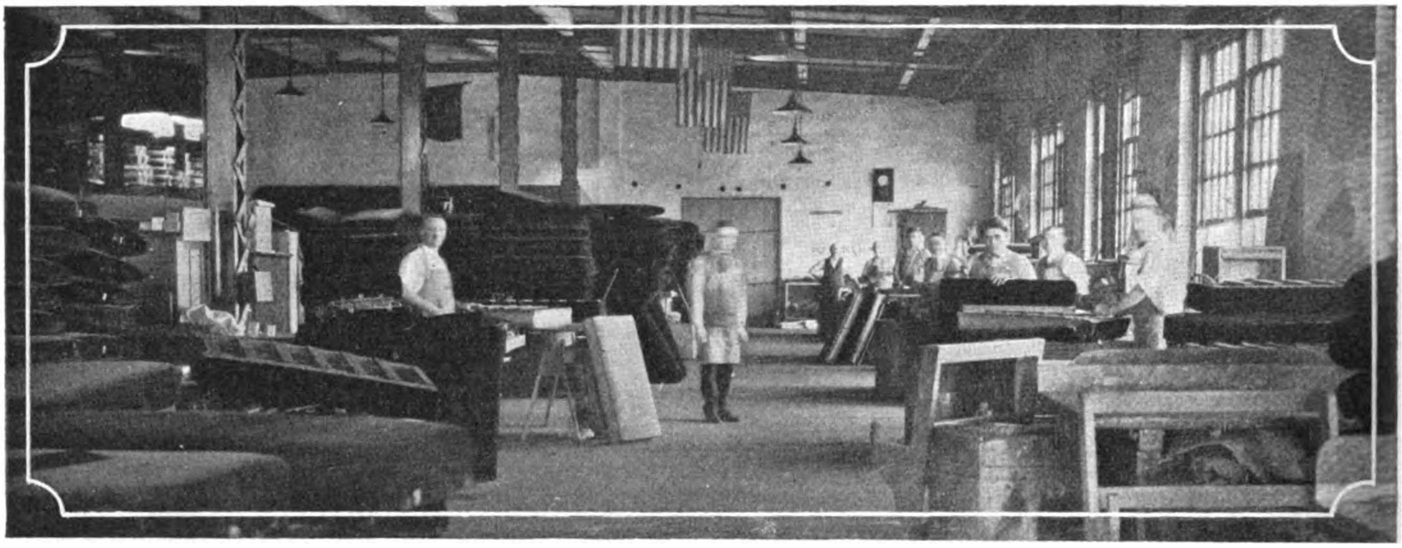
Record of cars found necessary to re-clean before being 3 mo. in service

Date	: Number and Initials :	Kind of triple	Last place and date of cleaning	Remarks

Checked by ________________ Foreman

Report of air brake equipment cleaned and repaired

THE MISSOURI PACIFIC has adopted a plan in its mechanical department whereby employees are invited to make suggestions to bring about greater efficiency and convenience in doing their work. Boxes are installed in the departments and blanks are provided for the employees. The suggestions are acted upon by two committees, one a production committee composed entirely of employees and an executive committee composed of three employees, the superintendent and the production engineer. The production committee first considers all suggestions, and, if they are considered worth adoption, passes them to the executive committee.



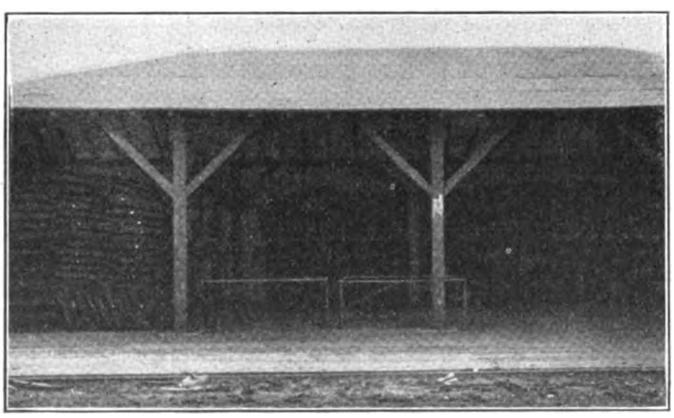
General view of the upholstering department at the North Billerica Shops of the Boston & Maine

Renovating interior trimmings of passenger cars

Proper location of tools and equipment has made possible the repair of upholstering by the progressive system

Part I

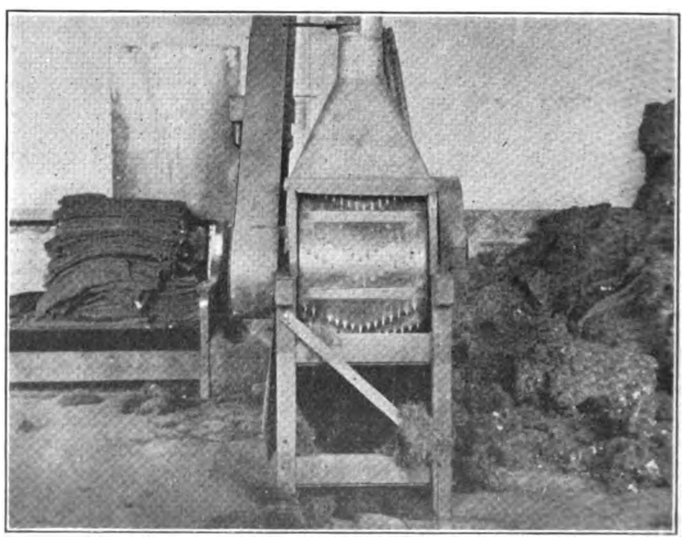
WHEN laying out the car department for the North Billerica shops of the Boston & Maine, considerable thought and careful planning was devoted to the upholstering and lacquering departments. These departments were planned and equipped to handle all of the interior trimmings of passenger cars on the system. The interior trimmings of from four to five cars are renovated



Shed where dust is blown from car seats and window blinds before they are taken to the cleaning room

in these departments every eight hour working day by a total working force of 25 men. In order to maintain this schedule, the work is routed through the departments, especially the upholstery shop, so that it will progress from one operation to the other in the same direction, thus eliminating any unnecessary handling of the work. The proper location of tools and equipment has made possible this system of progressive repairs.

The lacquering department has adopted the most modern methods available for cleaning and plating metal trimmings.



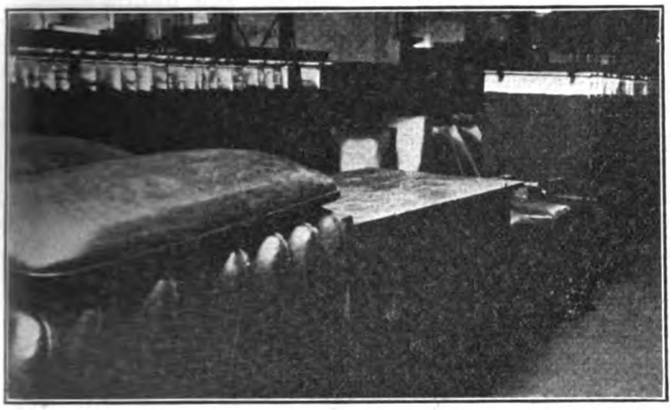
Machine for shredding hair used in car seats

The acid, washing and plating tanks are located in such a manner so as to insure a minimum lost motion in handling the work from one process to the other. Considerable study has been given to the protection of the workmen against the poisonous fumes of the chemicals used. The fumes are

carried away by a suction draft system leading from each acid containing vat.

The upholstering department

The upholstery and lacquer departments are located on the second floor of the paint shop which is in the same building in which the passenger cars are repaired. All the work is brought up to these departments on a freight elevator

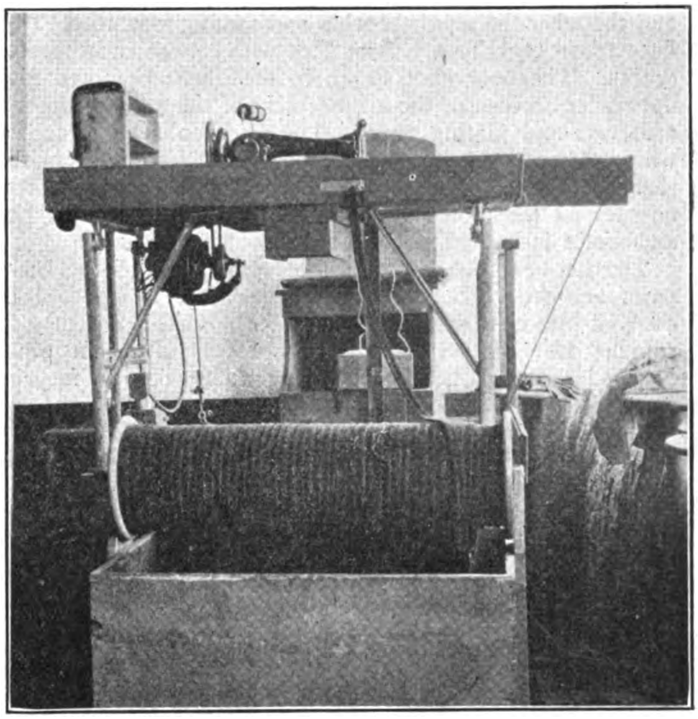


Pantasote seats and window blinds drying after receiving final coat of Imperial renovator

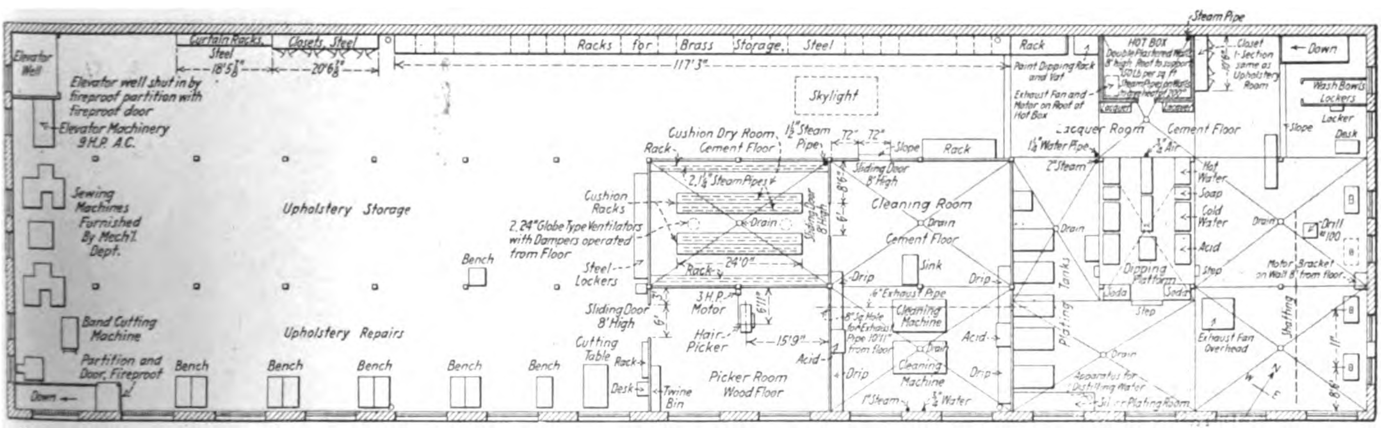
which is convenient to the shed where the dust is blown from the window blinds, seats and backs.

Located at the rear of the upholstery shop are the cleaning, drying and hair picking rooms. At the front of the shop are the repair benches, sewing machines and upholstery storage space. With this arrangement, the car seats and window blinds enter the cleaning room and pass in one direction through the various processes of renovation until they are complete, when they are either taken direct to the car for which they are intended or are placed in storage until needed.

The cleaning room is a large, well lighted room containing a cement floor properly sloped so that the water will run into two drains. On each side of the room, next to the wall and close to the windows is a sink with two sloping drip boards. These are used for washing and dyeing the plush seats. Another sink is located approximately in the center of the room which is used for washing by hand the window blinds and Pantasote seats. Cleaning machines are located between the two sinks for cleansing the plush seats. The two principal parts of these machines are the table and the swinging, revolving brush. The table is mounted on a movable carriage which can be moved back and forth, parallel to the center line of the brush spindle. The table has a motion transverse to the movement of the carriage. It has a vertical adjustment to take care of the various sizes of seats and the wear of the fiber brush, which is motor



Two-needle sewing machine with a special attachment for inserting two strands of No. 60 twine in binding for car seats and backs



Layout of the North Billerica upholstery and lacquer shops

driven and can be swung back and forth over the work on the table.

The drying room for the cushions is entered directly from the cleaning room. It contains six racks which have sufficient capacity to hold the seats and backs of five cars. Each rack has two 1¼-in. steam pipes passing through it. In the floor between the two main racks are located two 24-in. globe type ventilators with dampers. When in operation, this room is shut off from the cleaning room by a 6-ft. by 8-ft. sliding insulated steel door.

Next to the drying room is the hair picking room which is entered from the upholstering department. In this room is located a hair picking machine which separates the hair after it has been washed. The machine consists of a belt driven drum containing shredding teeth. The dust and fine

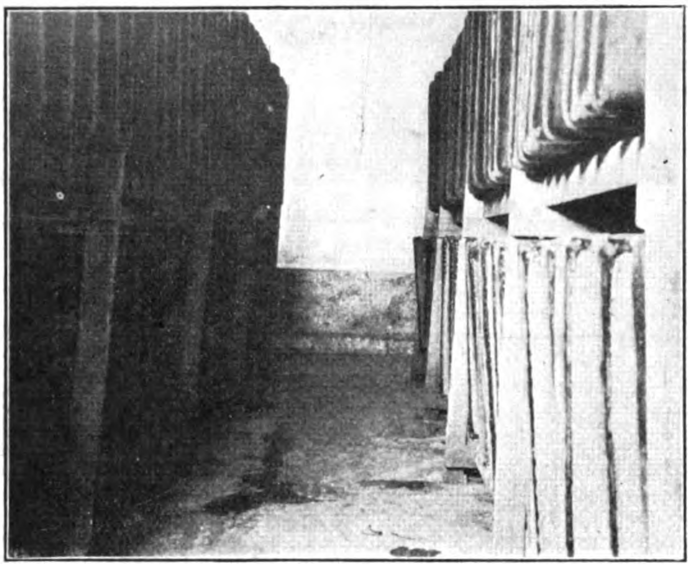
hair is carried off through a hood located over the drum.

The lacquer room

The lacquer or brass renovating room is practically divided into two sections, one containing the chemical vats and the other the repair benches and buffing machines. This department contains a cement floor with conveniently located drains. The floor plan shown in the illustration will give the reader an idea of the arrangement of the various wooden acid vats and plating tanks. The acid tanks are provided with exhaust pipes to carry off the gases coming from the chemicals used. The piping for this exhaust system terminates on the roof of the hot-box where the exhaust fan and motor is located.

The hot-box referred to is the room in which the brass parts are dried after being lacquered. It is enclosed in doubled plastered walls 8 ft. high. The roof is designed to support 150 lb. per sq. in. By means of steam pipes fastened to the walls, a temperature of 200 deg. F. may be obtained.

Located next to the west wall of the hot-box is the paint vat, in which car gates, locomotive headlight casings, car hand brake levers, etc., are dipped. The vat and its lid are made from sheet steel riveted together. Running from it is an inclined trough over which runs a monorail supporting a number of trolleys which are used for hanging the painted parts on so that they may thoroughly drip off before being placed in the hot-box.



Interior view of the drying room showing method of drying car seats and backs

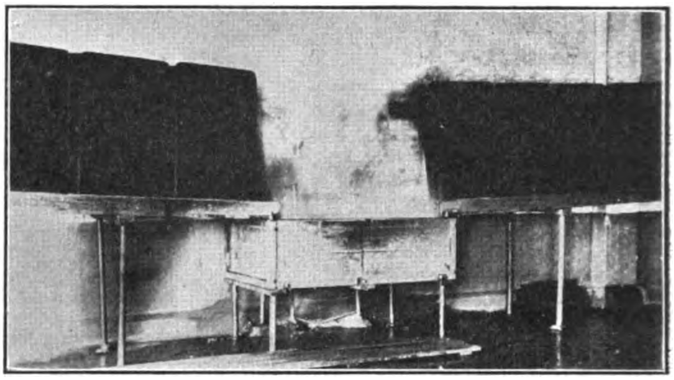
The silver plating room is located at the southwest corner of the lacquer room. This room is completely partitioned off from the rest of the department by a heavy wire screen. In this room are the silver plating tanks, assay scales under glass, an apparatus for distilling water and a heavy safe in which the bar silver is kept. The still is used to supply water for the Boston & Maine system. When the silvering tanks are not in use, they are covered over to keep foreign matter from the silvering solution.

Renovating car cushions and window blinds

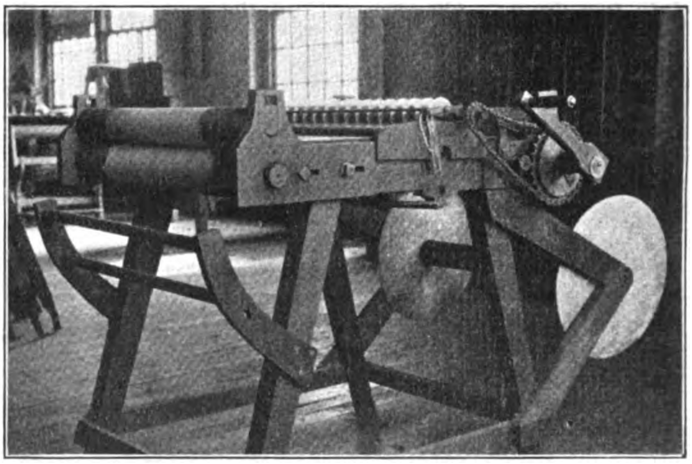
Before the passenger cars are placed on the repair tracks in the shop, the interior trimmings are removed. The metal fixtures and trimmings are taken direct to the lacquer room while the window blinds and the seats and backs are hauled on four wheel trucks to the blowing-off shed located at the southwest end of the paint shop. This shed, shown in the illustration, is entirely closed on two sides and partially on the side next to the paint shop. It contains two racks made from pipe, on which the cushions are placed while the dust is being removed. At a convenient distance from these racks are two air pipe outlets to which are attached suitable air hose for cleaning purposes. With this arrangement, the loose dust and dirt is thoroughly blown from the cushions and window blinds.

Cleaning the cushions and blinds

The cushions and blinds are then taken to the cleaning room. Here they are cleaned by the French Renovating Company's plush renewing process. Forty gallons of warm water is run into the cleaning sink to which is added one bottle of French cleaner. This amount will clean the seats and backs for one car, or a total of 76 pieces. They are thoroughly soaked in the cleaning solution and then placed on the sloping drip boards to drain off. They are then placed on the cleaning table shown in the illustration where they are thoroughly cleaned by the fibre brush which revolves at a speed of 1,700 r.p.m. This removes all dirt, soot and grease, so that the dye, which is next applied, may penetrate the fibre of the fabric. If the dirt were not thoroughly removed, before the application of the dye, both the dirt and the dye would be removed on the clothing of passengers after the cars were again placed in service. This process also thoroughly disinfects the cushions.



Plush seats draining off after being dipped in the dye solution



Hand operated machine with 15 circular knives for cutting plush cloth into strips for seat binding

The dye solution is prepared in a vat directly across from the cleaning sink. The cushions are again dipped and allowed to drain off, after which they are placed in the drying room. They remain in this room over night and then are taken to the repair benches.

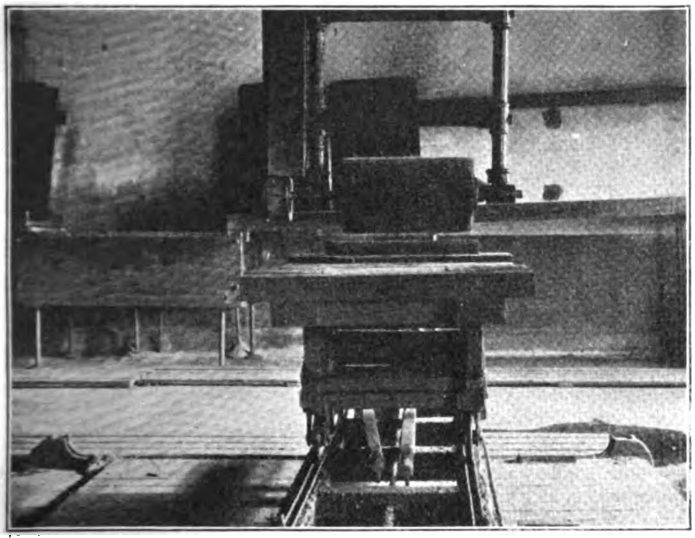
Pantosote seats and window blinds are scrubbed by hand with soap and water. They are then placed in the drying room, after which the Imperial renovator is applied by hand which leaves a dull finish. After the blinds are painted, they are hung on a specially designed rack to dry as shown in the illustration. The Pantosote seats are placed to dry in rows on the floor.

The cushions and blinds are cleaned on a piece work basis. One man can clean in a day the cushions from three cars while two men can clean those from five to six cars.

How repairs are made

After the seats and curtains are cleaned, they are given minor repairs or completely rebuilt. Such defects as worn or torn plush, burlap covering over the springs giving away, broken or worn out springs or a broken wooden frame keep the repairmen busy. When a seat is completely overhauled the hair contained in it is passed through the hair picking machine shown in the illustration, which tears it apart and restores its fluffy condition.

An interesting operation in connection with repairing the seats, is the method of making the plush binding which goes around the edge of the seats. Plush cloth 28 in. wide is



Machine for cleaning plush seats and backs after they have been dipped in the cleaning solution

passed through a hand operated machine containing 15 evenly spaced circular knife blades which cut the plush into strips 1⅞ in. wide. The machine shown in the illustration is mounted on a wooden frame which has at each end a set of wooden rollers, covered with sand paper, for the purpose of pulling the cloth through the machine. The trunnions of the upper roll run in rectangular slots. On the trunnions are wooden caps upon which are placed a spring which allows the top roll to be opened in order to start the plush through the machine. These springs also serve the purpose of compressing the top roll on the plush so that the abrasive paper will grip the cloth. The arbor holding the cutting blades is turned by means of a hand operated sprocket wheel and chain. The blades may be readily removed for sharpening.

The ends of the strips are sewed together and are then ready for the following operation. The plush band is sewed in a two needle motor driven sewing machine placed on a suitable table which is mounted on a raised platform on which the operator sits. The plush strip is contained in a box underneath the platform and is fed up to the machine. The illustration of this machine shows two balls of No. 60 twine leading up to the needles of the machine. This is fed through a special attachment which forms the double beading of the plush band. The band measures ⅞ in. wide when finished. These two machines, along with additional sewing machines and cutting tables, are located at the west end of the shop. On these machines the window blinds are repaired or new blinds made to replace the old ones. In this shop are made all the blinds for the Boston & Maine system.

The operations in the lacquering department will be described in the concluding part of this article, in the January issue.

Decisions of the Arbitration Committee

(The Arbitration Committee of the A.R.A. Mechanical Division is called upon to render decisions on a large number of questions and controversies which are submitted from time to time. As these matters are of interest not only to railroad officers but also to car inspectors and others, the Railway Mechanical Engineer will print abstracts of decisions as rendered.)

Repairs occasioned by one shopping not consolidated in same bill

Maine Central car No. 3763 was shopped by the Boston & Maine at the East Fitchburg, Mass., shops on December 12, 1922; a wheel change having been made and also two journal bearings applied on that date, charges for which were included in the January, 1923, bill, supported by the proper billing repair cards. Other repairs were made and charges included in the February, 1923, bill, also supported by the proper billing repair cards.

The Maine Central claimed that the Boston & Maine should have withheld the bill for the wheel change until such time as the bill for the balance of the repairs to the car were completed and the two bills consolidated to reach that company as a complete charge for repairs to the car in accordance with Rule 93. The Boston & Maine claimed that Rule 93 did not cover the case in question, its interpretation of the rule being that one single bill must be made each month, but that the rule does not require all of the repairs made to a car to be included in the same bill. The contention was that, inasmuch as the repairs were continuous and the car was not released for service until all repairs were completed, the fact that part of the expense of repairs were included in the month of January and the balance of the repairs in February, in no way released the Maine Central from its obligation to pay the bill presented in the February, 1923, account.

The Arbitration Committee in rendering a decision in this case, stated that: "It is important that all proper charges for repairs occasioned by the same shopping of the car be consolidated in the monthly bill to enable proper check of all charges, overlapping labor items, etc. The circumstances in this case, however, do not justify cancellation of the subsequent charge. This decision has no bearing on previous decisions with reference to charges omitted, reopening accounts, etc."—*Case No.* 1314, *Maine Central vs. Boston & Maine.*

Charges rendered on authority of defect card

The Southern Pacific removed one pair of cast iron wheels from El Paso & South Western car No. 20369 on account of one wheel being loose on the axle, and applied one pair of new rolled steel wheels which were standard to the car. A bill was rendered against the car owners on authority of copy of defect card issued by the Chicago, Rock Island & Pacific and billing repair card, the charges for wheel centers and service metal of the steel wheels being based upon A. R. A. Rules 98 and 101, effective February 21, 1922, the date of the defect card, instead of the rules as changed by Supplement No. 1 to

the 1921 Rules, effective May 1, 1922. The Chicago, Rock Island & Pacific had removed a pair of steel wheels from this car and applied a pair of cast iron wheels. Credit was allowed the car owner for the difference in value of the wheels applied and those removed and defect card was issued as required by the rules. The car owner contended that the defect card authorized A. R. A. prices at the time the defect card was issued only for such items as the defect card authorized the car owner to bill the company that made the improper repairs. It further contended that the repairs were not made by the Southern Pacific on account of improper repairs, but on account of the car owner's defect in accordance with Rule 81, and that the billing repair card and Rule 98, not the defect card, authorized the charge against the car owners for wheel centers and service metal. The steel wheels applied should have been furnished at current A.R.A. prices as under Rule 98, the defect card being only for the protection of the car owner. The Southern Pacific maintained that the defect card was its only authority for a charge against the car owner under Rule 98 and that if, therefore, the defect card actually performed such function, it was entitled to charge prices in effect at the date of the card or at the same rates as credit allowed by the Chicago, Rock Island & Pacific when making the wrong repairs. The Southern Pacific further stated that the principle that the date of the defect card governs has been so long established, that railroads have not questioned it in recent years.

The Arbitration Committee rendered a decision sustaining the contention of the Southern Pacific and referred to the decision rendered in connection with case No. 1273.—*Case No.* 1316, *El Paso & South Western vs. Southern Pacific.*

Car and engine replacer clamp

FREQUENTLY a car and engine replacer will not stay in position when the wheel is being moved up and onto the rail. The clamp shown in Fig. 1 has been designed to overcome this difficulty. Holes for the clamp

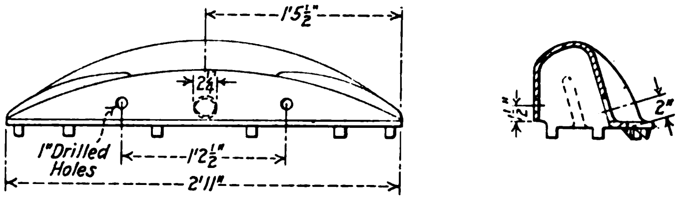


Fig. 2—Drawing showing the location of the holes in the replacer for the clamp

are drilled in the replacer as shown in Fig. 2. The clamp is made in two lengths as shown in Fig. 1, the shorter of which is used for holding the replacer against a standard rail. The method of holding the replacer to the rail with the clamp is shown in the drawing in the lower right hand corner of Fig. 1. The extension clamp is designed to be used for derailments at frogs and switches where it is impossible to fasten the hook of the shorter clamp on the flange of the outside rail. The extension is provided with a number of notches on which the extension clamp slide can be adjusted. The replacer is held securely to the rail by the replace clamp wedge which is inserted in the 3⅜-in. by 7/16-in. slot in the clamp. The replacer equipment is carried on the side of the tender.

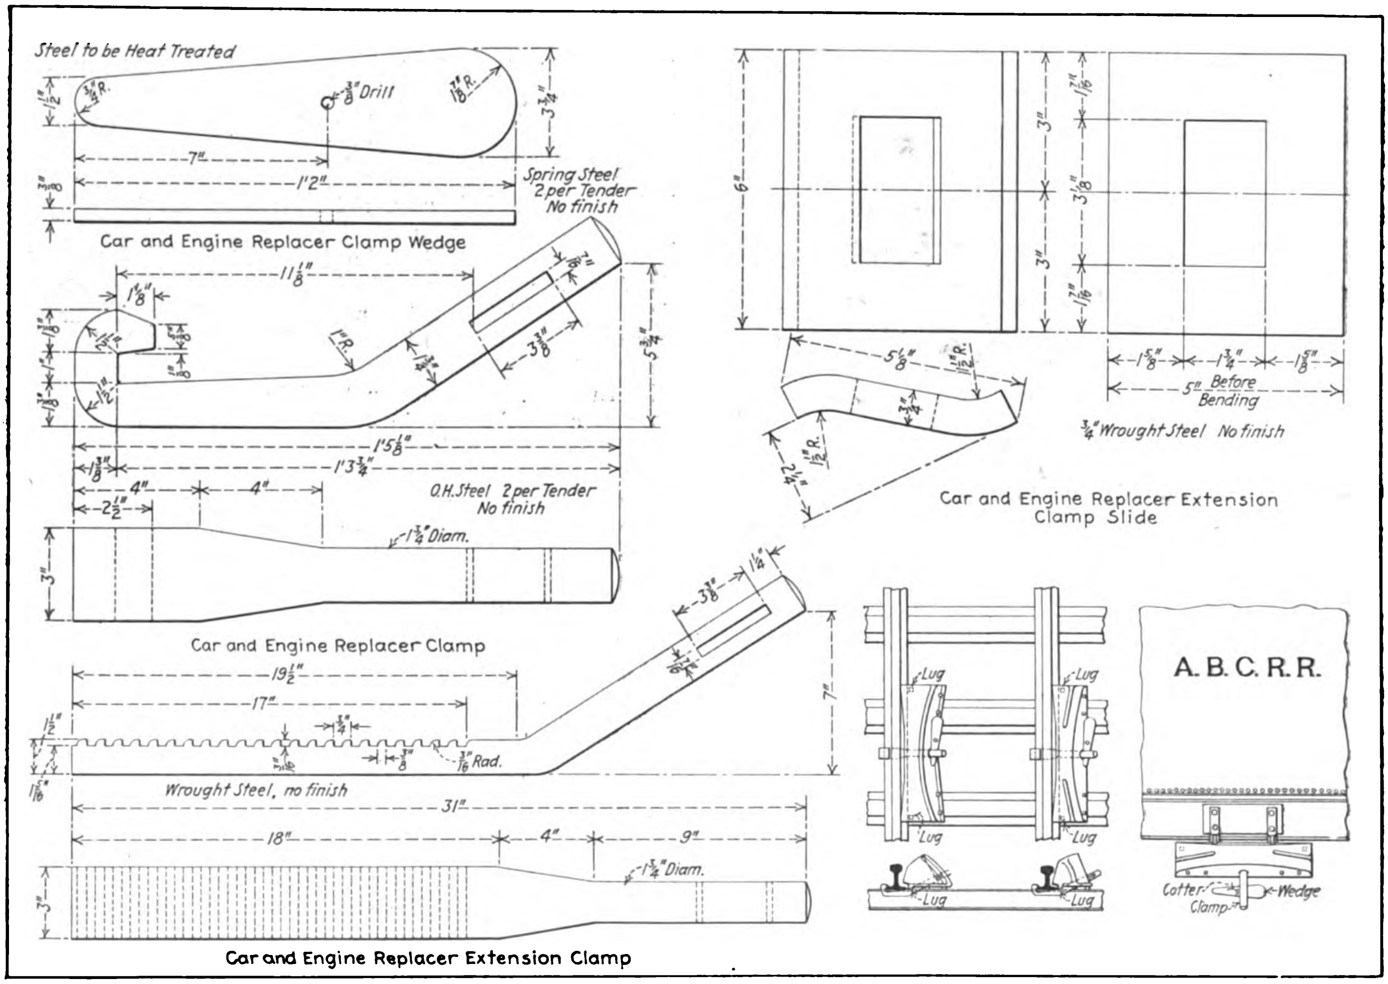

Fig. 1—Drawing of the details of the replacer clamp and the application to the rail

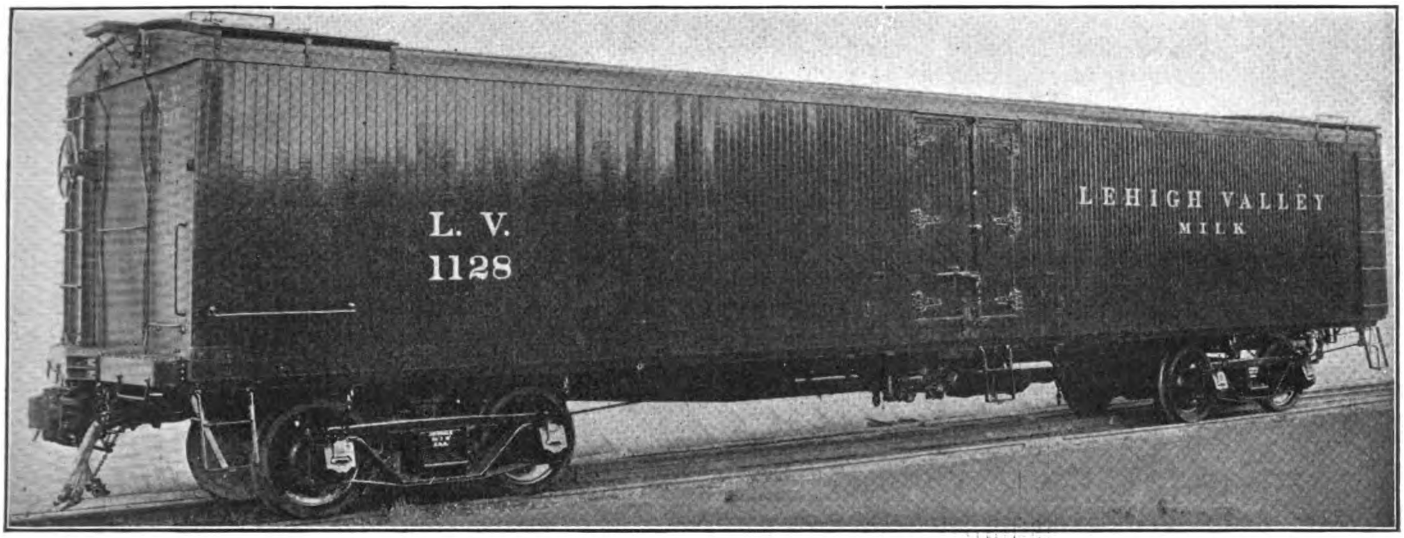


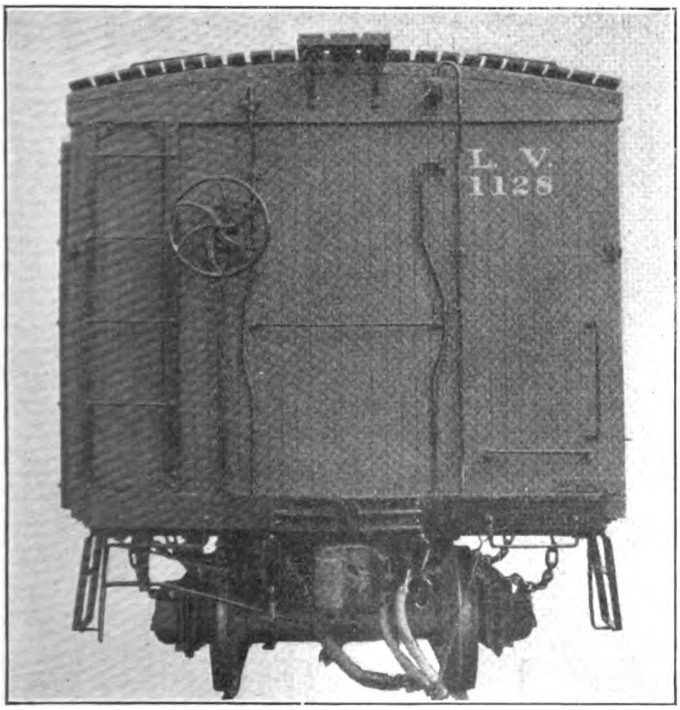
Large capacity milk cars recently built for the Lehigh Valley

New type milk cars for the Lehigh Valley

Departure from conventional design has effected increase in loading capacity—Unique truck construction

THE Lehigh Valley has recently placed in service 25 milk cars, the design of which differs materially from previous equipment used in that class of traffic. These cars were built at the Berwick plant of the American Car & Foundry Company in the early part of 1924.

The change in design has particularly affected the arrangement of the ice bunkers. In previous milk cars the bunkers, four in number, were located at each side of the end door vestibules and extended from floor to roof. In the new cars the end doors have been eliminated and an ice bunker built across each end of the car. The bottom of the bunkers is at a height of 27½ in. from the floor which permits the loading of milk cans underneath. The car body as a whole has been designed with the idea of providing maximum loading capacity and, aside from the change in ice bunker arrangement, the inside width has been increased 6 in. so that eight milk cans may be placed in a row across the car. The side doors have been arranged to swing outward instead of into the car which allows for additional loading space. These changes have served to increase the individual car capacity to a total of 370 40-quart cans which represents an increase of 40 cans over the capacity of previous cars. The ice capacity has been increased from 5,880 lb. to 9,000 lb.



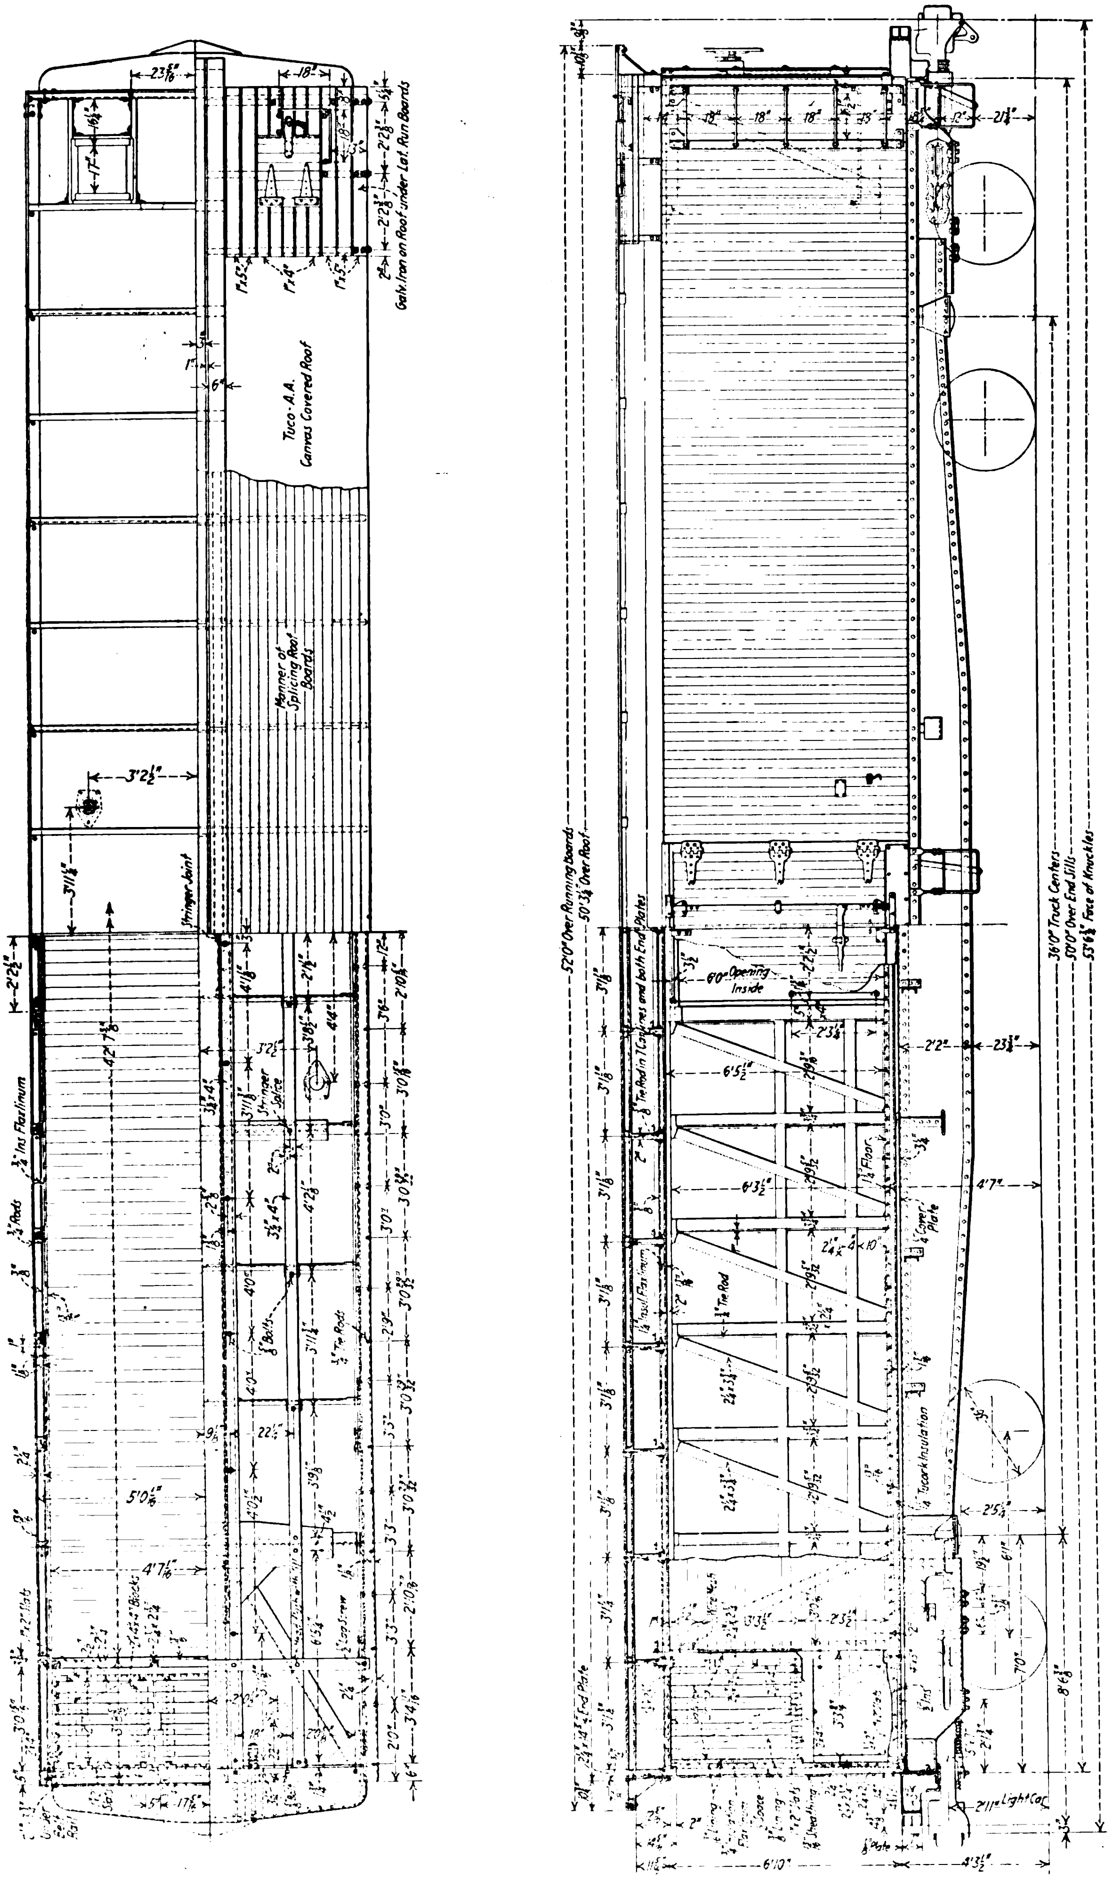
End view of car showing location of retainer, train signal and conductor's brake valves

Principal dimensions and weights

Length over body end sills	50 ft. 0 in.
Length inside	49 ft. 4⅛ in.
Length between bunkers	42 ft. 7⅜ in.
Width inside	9 ft. 2⅛ in.
Width at eaves	10 ft. 1⅞ in.
Total capacity of ice bunkers	9,000 lb.
Distance from center to center of trucks	36 ft. 0 in.
Truck wheel base	6 ft. 1 in.
Net capacity of car, including ice	85,500 lb.
Light weight of car complete	68,400 lb.
Loaded weight of car	153,900 lb.

Underframe construction

These cars have a steel underframe and wooden superstructure. The underframe is of the fish-belly type with double center sills, the depth of these sills at the middle of the car being 26 in. The center sills are of plate and angle girder construction with 5/16-in. web plates reinforced by 3½-in. by 3½-in. by ⅜-in. angles on the outsides of the top chord and by the same size angles on the



Side sectional elevation and plan view of Lehigh Valley milk car

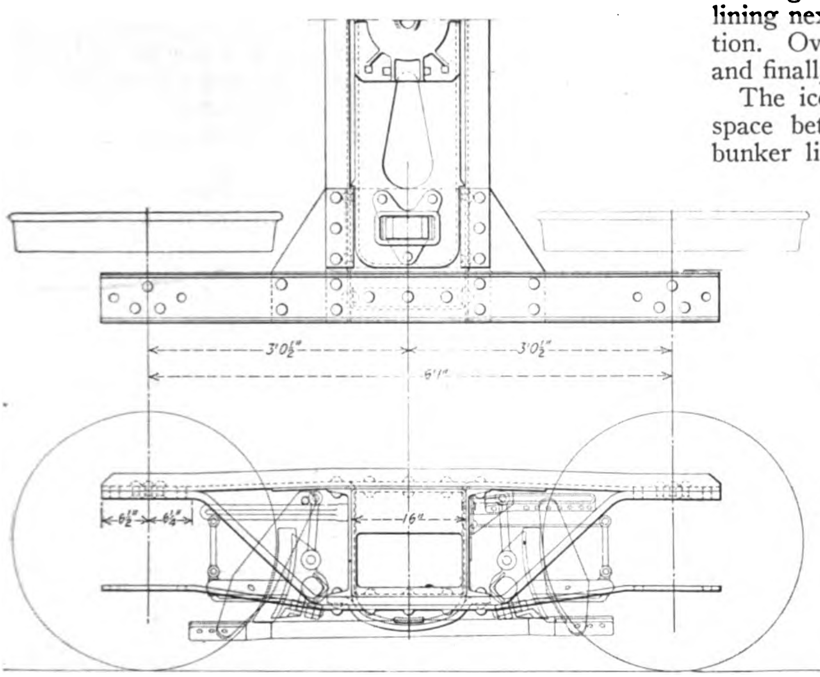
inside and outside of the bottom chords. A 21¼-in. by ¼-in. top cover plate extending the full length of the underframe serves further to reinforce the center sills. The side sills consist of two 8-in., 11.5-lb. channels, to each of which is riveted a 3-in. by 3½-in. by ⅜-in. angle for supporting the wood side sills. The cars are equipped with built up extended end sills as shown in one of the illustrations. The body bolsters, cross-bearers and diaphragms are of conventional design. The underframe construction follows closely that adopted as U.S.R.A. standard design for refrigerator cars.

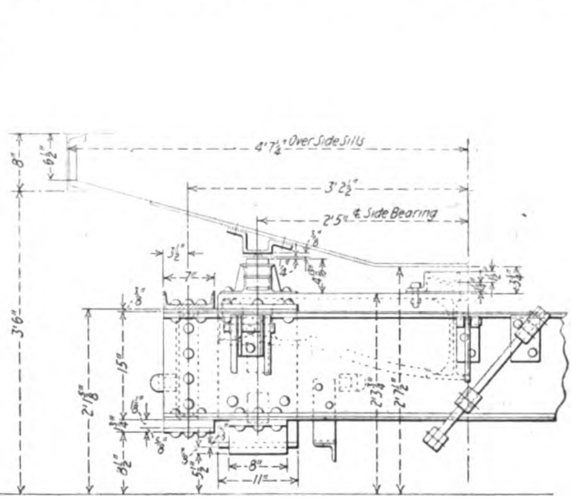
Car body and trucks

The design of the super-structure provides excellent ventilation. The construction of the body framing follows the usual practice with 2¼-in. by 3¾-in. side posts and diagonal braces. Vertical, transverse and longitudinal tie rods are provided.

The floor construction consists of a 13/16-in. false floor laid over floor stringers, then a 1¼-in. layer of Tucork insulation over which is laid 1¾-in. tongue and grooved flooring. The sides of the car have a 13/16-in. inside lining next to which is a ¾-in. layer of Flaxlinum insulation. Over this is a ⅜-in. lining, then a 2¼-in. air space and finally the outside sheathing, which is 13/16-in. thick.

The ice bunkers are further insulated by a ½-in. air space between the inside body lining and a 13/16-in. bunker lining. The inside of the bunkers is lined with galvanized iron over which is secured 1-in. by 2-in. slats. Two icing hatches, with 17-in. openings, have been provided for each bunker.

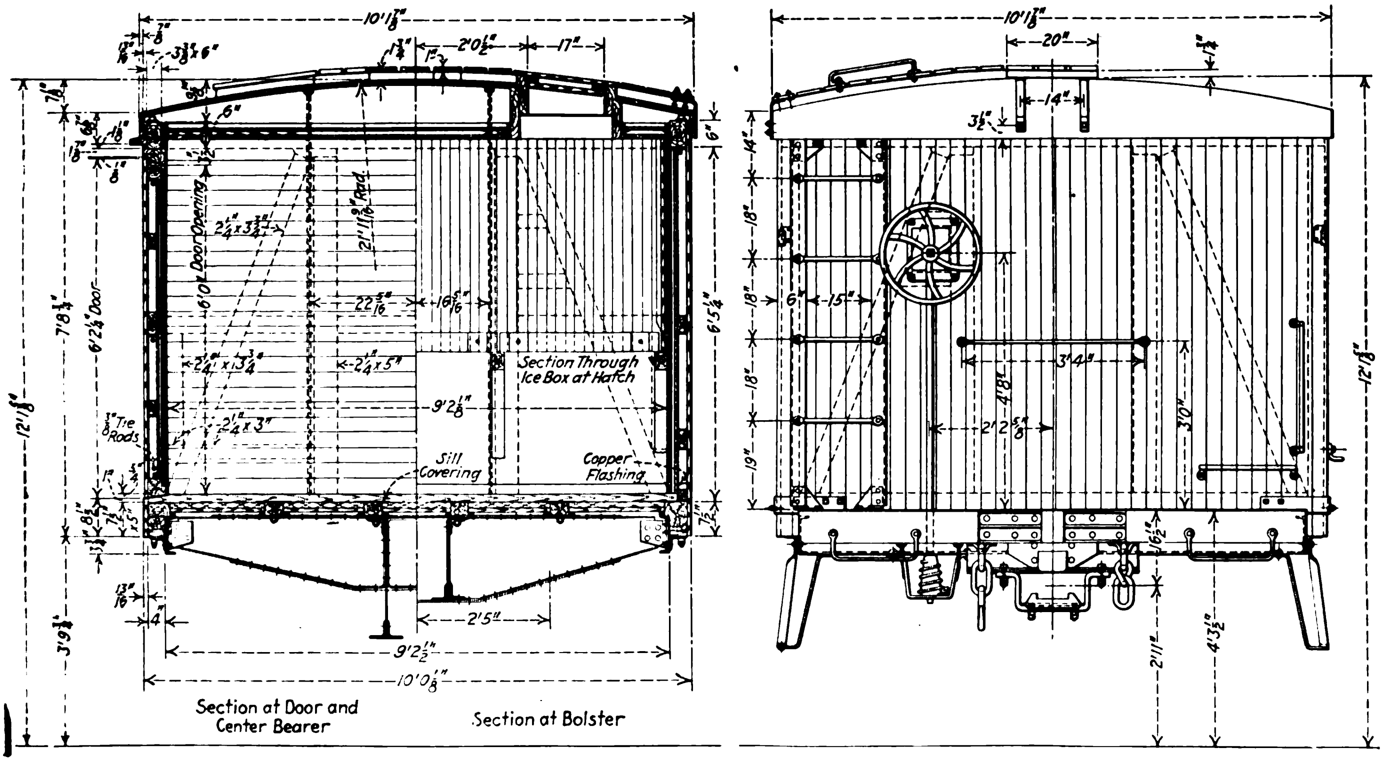




The truck frame is built up principally of standard structural shapes

The end doors have been eliminated in this design and double side doors, swinging outward, provide an inside opening of 4 ft. 5 in. by 6 ft. A Miner door locking device is used on these doors.

The ceiling, which consists of ⅜-in. and 13/16-in.

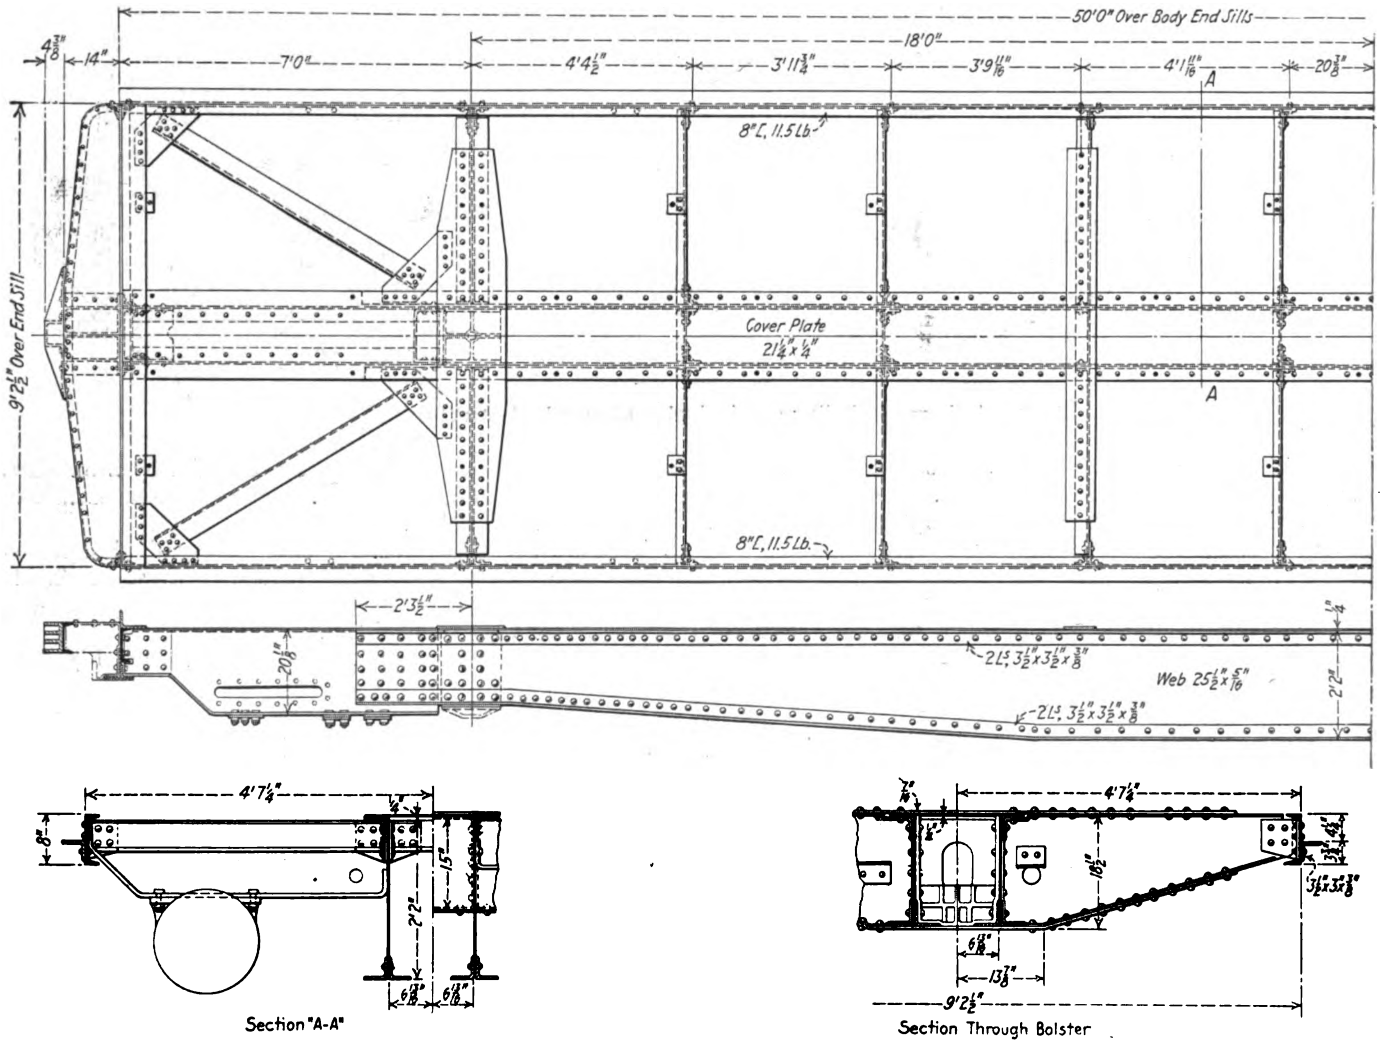


End elevation and cross sections

wood courses with a 1¼-in. layer of Flaxlinum between, is beneath the carlines. The roof sheathing is covered with Tuco A-A canvas. The roof on these cars has been considerably flattened as compared with the conventional oval type roof ordinarily found on milk cars. Running boards of the box car type have been provided the full length of the car.

The cars are carried on trucks with 5½-in. by 10-in. journals and 36-in. wheels. These trucks are unique because of their simple construction. They are of the modified arch bar type, in which the top arch bar consists of a 7-in. channel to which the ends of the 1⅛-in. bottom arch bar is riveted. The column castings and spring plank are replaced by transoms consisting of 15-in. channels, spaced 16 in. apart, which are rigidly secured to the arch bars and reinforced by pressed steel end plates, through which are cut the window openings to accommodate the ends of the full elliptic springs. These springs rest in malleable iron seats supported by yokes of ⅝-in. by 11-in. steel plate, which are flanged over and riveted to the tops of the transom channels. These plates, which also form wearing strips for the ends of the bolster, are reinforced below the spring seats by ⅞-in. by 8-in. plates riveted to the bottom channel flanges.

Westinghouse UC brake equipment and train signal equipment, Bradford draft gear and solid shank couplers with a Chaffee centering device comprise part of the car equipment.



Details of construction of the underframe and body bolsters

Hooks, cables and chains for wrecking service

It is the usual practice to include in wrecking equipment various kinds of hooks and arrangements of chains and cables in order to save time and labor when clearing up wrecks. A few examples of this type of equipment are shown in the drawing. These devices are not only convenient to have in the tool car of the wreck train, but they are also handy to have as part of the crane equipment in locomotive erecting shops and shops where car repairs are handled.

The arrangement of two hooks and chains shown in the upper left hand corner of the drawing is designed primarily for lifting trucks and various kinds of equipment on which it is better to take an inside hold. The chain is ¾-in., hand forged and is designed to carry a safe load of 10,000 lb. These chains are proof tested with a load of 11,160 lb. and have an approximate breaking load of 33,800 lb.

The arrangement of the two hooks and cables shown in the top center of the drawing is made of 1¼-in. bright monitor plow steel cable of six strands, 37 wires to the strand, with a hemp core. The end link and hooks are designed for the same factor of safety as the cable. This device is convenient for such work as lifting cabs and similar parts which are light but bulky to handle. The

working load of each cable used straight is 16,500 lb.

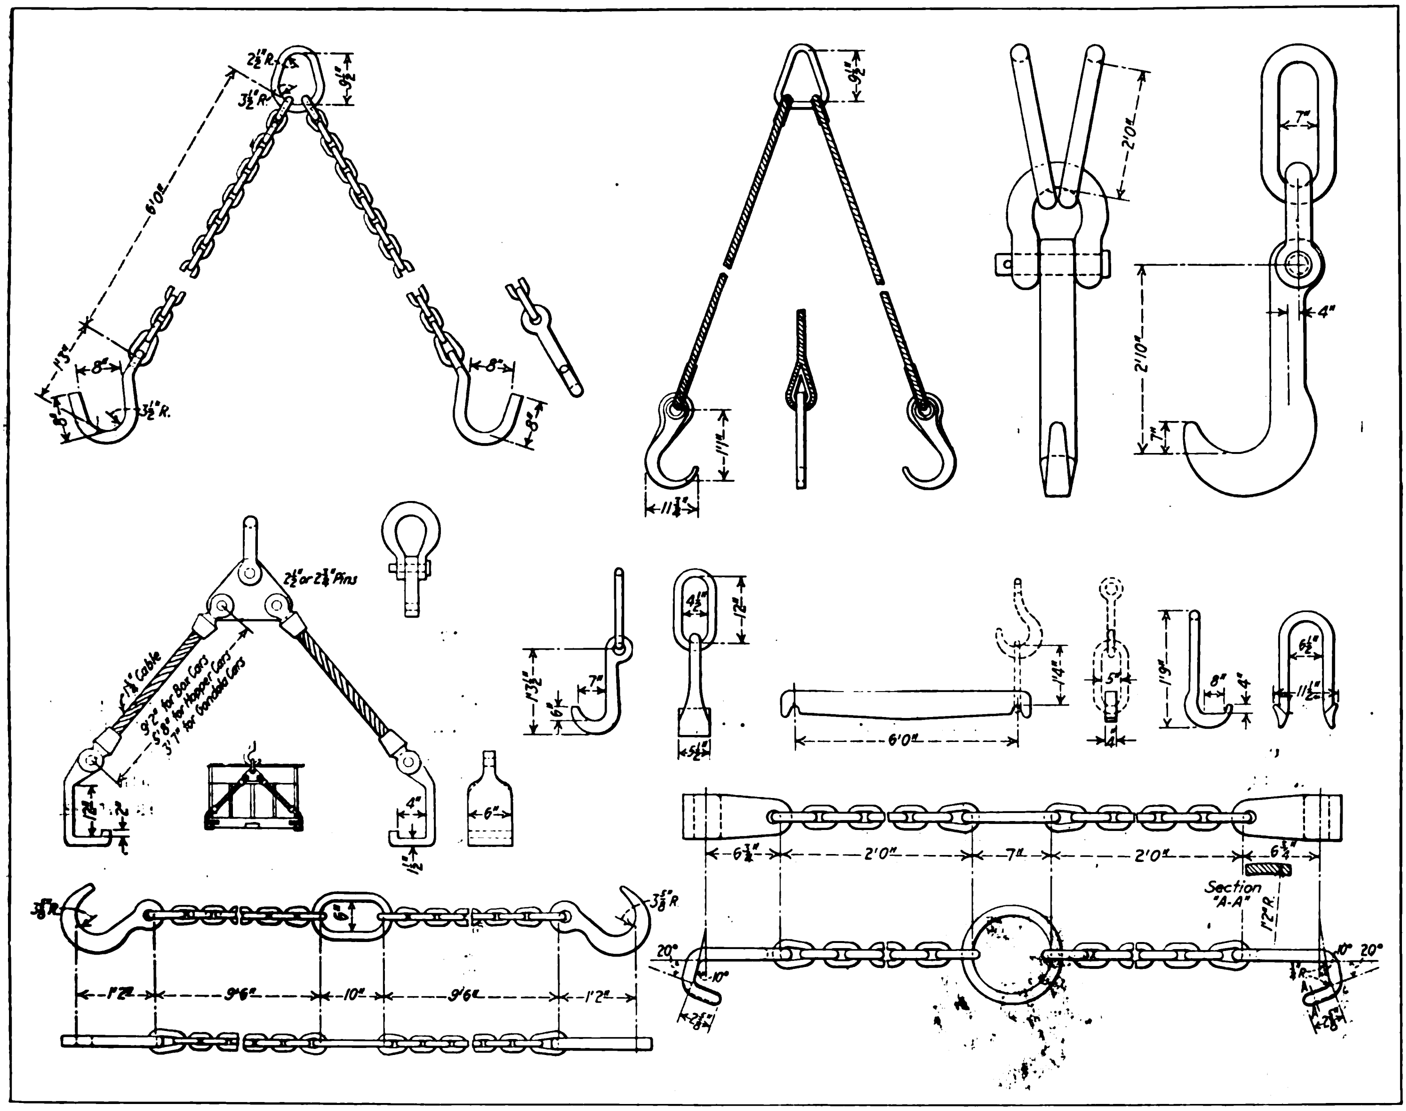
The crane hook shown in the upper right hand corner of the drawing is a fire box door hook. It is designed for heavy lifting, the hook, chains, pin and links having a working load of 100 tons with a factor of safety of five. The design of the hook gives it an exceptionally wide grip and at the same time permits it to hold a chain or cable without danger of slipping off.

The cable and hook arrangement shown at the left center of the drawing is designed especially for handling car bodies. It cannot be used for cars having concealed end sills. The method of application is shown in the small drawing. The design of the hook may be varied to suit the different classes of cars which have to be lifted with a crane.

The arrangement of chains, link and hooks shown in the lower left hand corner of the drawing is intended for general wrecking and crane service. It is designed for a safe load of 16,000 lb. and is proof tested with a load of 20,460 lb. The approximate breaking load is 62,000 lb.

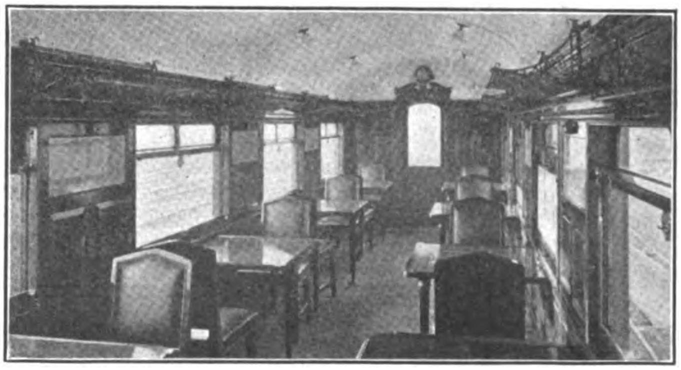
The chains, link and hook shown in the lower right hand corner are made of ¾-in. hand forged iron and are designed for a safe load of 10,000 lb. They are proof tested for 11,160 lb. and have an approximate breaking load of 33,800 lb. The enlarged link and hooks should have as high a factor of safety on the chain.

The double hook shown at the right center of the drawing can be slipped into difficult places and a chain or cable hook slipped through the loop. It is of sufficient strength to carry a load of 25 tons with a factor of safety of five. This hook is proof tested with an actual working load of 125,000 lb.

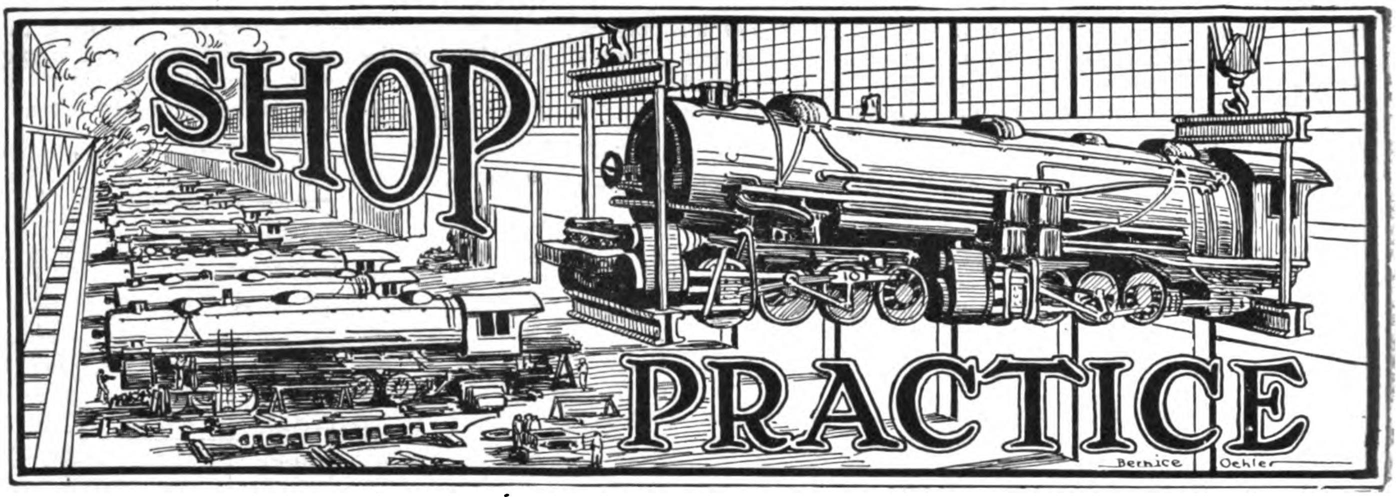


Details of a number of hook, chain and cable arrangements which have proved useful in crane and wrecking service

The hoisting hook and link shown at the left of the lifting beam is also designed for a working load of 25 tons with a factor of safety of five.



Interior of dining car used on the Siamese State Railways

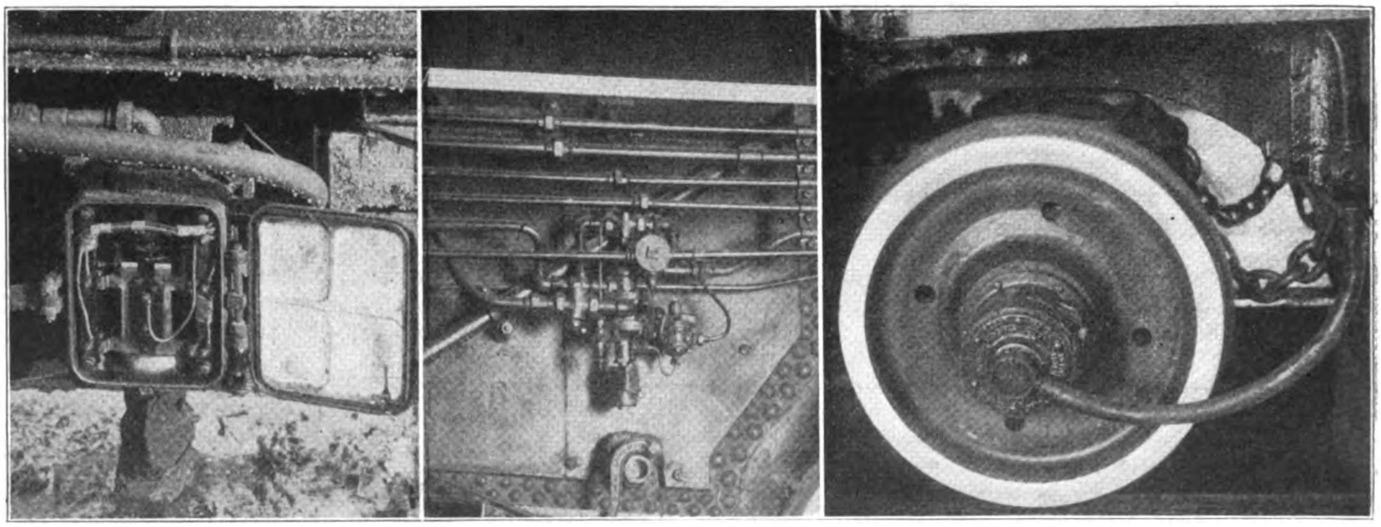


Maintaining train control equipment on locomotives

By E. Wanamaker

Electrical engineer, Chicago, Rock Island & Pacific, Chicago

THE equipment or devices necessary to an automatic train control system include roadside equipment which properly lies within the province of the signal department, and locomotive equipment which comes under the jurisdiction of the mechanical department. The chief mechanical officer is in a position to combine and utilize the skill of the electrical engineer, the mechanical engineer, the air brake engineer, and all others familiar with locomotive operation and maintenance. Familiarity with the many peculiarities of locomotive equipment and devices is a prime requisite.



Open shoe box, electro-pneumatic valve and speed controller—parts which must be maintained

Train control supervisor should be appointed

In order to co-ordinate successfully the efforts of all these in the mechanical department, it is highly advisable, if indeed not absolutely necessary, to appoint a supervisor of automatic train control. This man should preferably be one who has had considerable experience in locomotive mechanical, electrical, and air brake work, as well as some experience in engine service. He will then be better qualified not only to co-ordinate the efforts of those in the mechanical department, but to secure the co-operation of those in the signal department and at the same time enlist the necessary support of the division transportation officers. The successful operation of automatic train control depends quite largely on the skill and fidelity of the division officers functioning under the supervision of the automatic train control supervisor insofar as automatic train control is concerned.

The following paragraphs refer to automatic train control as applied to 165 miles of double track between Blue Island and Rock Island, Ill., on the Chicago, Rock

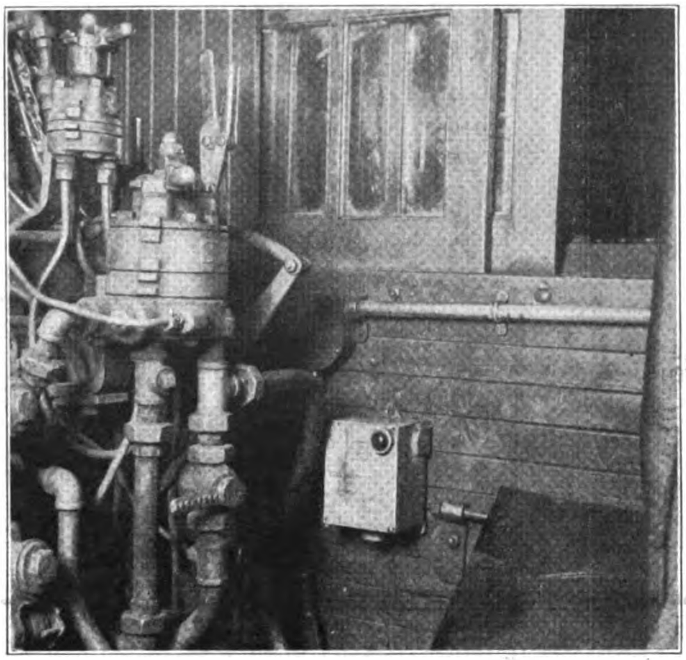
Island & Pacific. The system as now installed is of the intermittent electrical contact type, with 240 ramps installed and 103 locomotives equipped.

Automatic train control operation

Last February the operating rule requiring a train to stop at an automatic stop signal indicating stop, after which it may proceed through the stop block at a speed not to exceed eight miles an hour, was changed so that on all locomotives equipped with the automatic train control in operation the engineman may, upon reducing his speed to below 15 miles an hour, pass the stop signal without stopping and proceed, thus eliminating the stop at the stop signal.

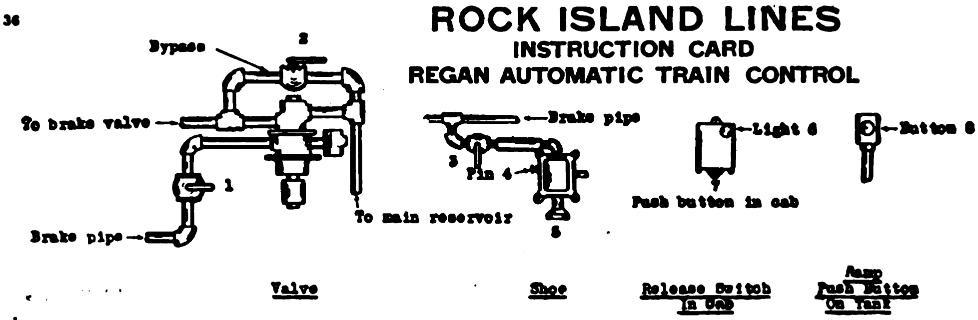
As long as the signals are all clear there is no action of the automatic train control device. If approaching and passing a caution signal above a certain prescribed speed (in the case of a passenger train this speed is 30 miles an hour and for a freight train 25 miles an hour) an automatic brake application will result. This will reduce the speed of the train to within the prescribed limit, and upon arriving at that speed an indicator light is shown in the cab, which is the engineer's indication that he may release the brakes. Upon so doing he can proceed but only at the prescribed limit or speeds below. If he should not be alert for some reason or other and fails to operate the release, then the train will be stopped. Upon continuing through the caution block, if he should happen to exceed the caution limit, another application will result, necessitating a second operation of the release.

Upon approaching the stop signal, and if he should pass it above the prescribed speed, which is 15 miles an hour for both passenger and freight service, an automatic application of the brakes will result and the same releasing operation must be carried out as explained for the caution signal. However, if he should pass this stop signal below 15 miles an hour (having operated a secondary push button which is on the tank and inside the gangway) he can pass over the ramp without an application. If that button is not pushed while he is running below the prescribed speed of 15 miles an hour he will get an application, no matter at what speed he is running,



Cab indicator and release button

whether it be one, five or ten miles an hour. After he has passed the stop signal, if he should exceed the speed of 15 miles an hour or reach that speed at any time, he will get an application which will necessitate a release. If the next signal is clear, his high speed is restored and he can proceed at unlimited speed.



FORM M. P. 36

ROCK ISLAND LINES
INSTRUCTION CARD
REGAN AUTOMATIC TRAIN CONTROL

1. TO CUT DEVICE OUT OF SERVICE: Close cock 1 so that handle is in line with pipe and open cock 2 on bypass so that handle is crosswise with pipe. In case of heavy leak of air at shoe box also close cock 3 so that handle is in line with pipe.

2. TO PLACE DEVICE IN SERVICE: Open cocks 1 and 3 so that handle is crosswise with pipe and close cock 2 on bypass so that handle is in line with pipe.

3. DOUBLE HEADING: When double heading, on rear engine Raise shoe stem 5 to full height; pull out locking pin 4, give it one-quarter turn and see that it has entered the slot full length.

4. OPERATION:

(a) The train control apparatus does not interfere with the proper observance of rules governing air brake operation.

(b) CAUTION SIGNAL will enforce speed throughout the block not to exceed 30 miles per hour for passenger trains and 25 miles per hour for freight trains. To avoid unnecessary application of the brakes, speeds should be maintained below these limits.

(c) STOP SIGNAL: At a stop block, ramp push button number 8 on tank must be pushed in before shoe engages ramp, and held in so long as shoe is on ramp. If stopped with shoe on ramp, button 8 must be pushed in and held in until shoe is off ramp.

(d) A stop signal will enforce speed not to exceed 15 miles per hour throughout the block for both passenger and freight trains. To avoid unnecessary application of the brakes, a speed should be maintained below that limit.

(e) RELEASE SWITCH IN CAB: Whenever devico makes brake pipe reduction, place brake valve in lap position until train is running below prescribed speed; then when indicator light 6 is displayed, push the button 7 which will extinguish the light, and proceed to fellow prescribed rules of proper air brake operation as though you had made the application yourself.

(f) IN CASE OF IMPROPER OPERATION: Should the device improperly apply the brakes, it must not be cut out of service until the ramp next ahead has been passed. The only exception to this rule will be permitted when, with the train at stop, it is impossible to release the brakes after pushing button 7.

(g) Report any improper working of the device to the Train Dispatcher and on work report.

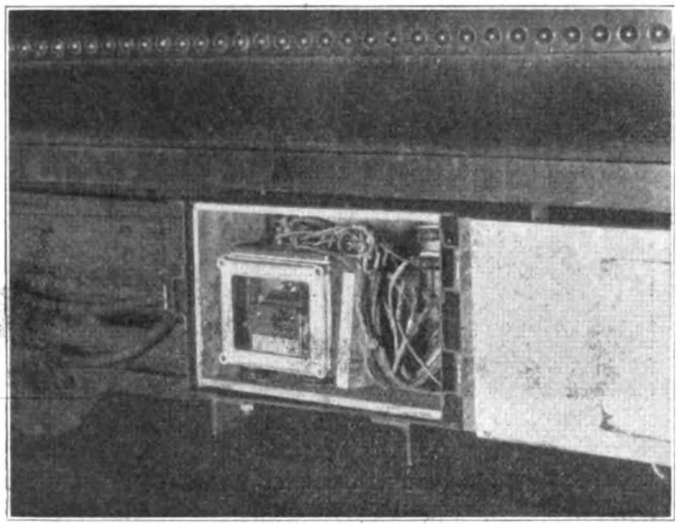
Card placed in the cab for the instruction of enginemen regarding train control operation

The roadside apparatus used is a ramp located at each signal, the energy supply to the ramp being from a roadside battery controlled by the signal circuits. The loco-

motive apparatus consists of the shoe mechanism located on the No. 1 tank truck; an indication selector or relay and storage battery; the speed controller on the No. 1 engine truck wheel; an electro-pneumatic reservoir and brake valve, with an exhaust control valve and suitable cocks arranged so as to cut the apparatus out in case it should be necessary; release switch; and tank button, all suitably connected by conduit and wire.

The electrical engineer has general supervision

The automatic train control is supervised by the electrical engineer who acts more or less as the directing and consulting engineer in connection therewith. The supervisor of automatic train control, reporting directly to the superintendent of motive power of the first district, also works in direct contact with the superintendent's office. A clerk is employed in the superintendent's office to follow in detail the operation of each locomotive, compile information and data, and quickly transmit to the supervisor of automatic train control any irregularity of operation that shows up, for his immediate attention. This clerk is one of the most important links in train control operation. He should be a man of considerable ability. He is charged with the responsibility of interpreting the reports from the various maintenance points and train dispatcher and following them up for corrective action when necessary.



Relay box—One reason why maintainers must understand electrical circuits

Automatic train control locomotive maintainers are located at the various locomotive terminals on the division, of which there are five maintenance points, two at Chicago, one at Peoria, Ill., and two at Rock Island, Ill., the western terminus of the division. In general the regular electrical maintenance men at enginehouses and back shops absorb most of the work so that comparatively few maintainers are needed and the working hours of these men are arranged to meet the requirements of the engines dispatched. In other words it is not always necessary to have a maintainer and helper on each shift at each of the maintenance points. The work of these men is arranged so as to utilize fully the available man power.

The maintainers report to the roundhouse foremen, who are responsible for the locomotives getting out on time and in satisfactory condition, both as to mechanical features and electrical features. Therefore, it is highly important, if not the most important duty of the supervisor of automatic train control, to see that good relations exist between the maintenance forces and the roundhouse authorities, and to act in accord with the roundhouse forces; to make of himself a good influence on the division, looked up to and respected by every operating officer concerned in both the transportation and mechanical departments as well as soliciting the unqualified support of the enginemen. The degree of success he makes in this direction is an important factor in the smoothness, quickness and intelligence with which the train control is maintained and operated. He must become well acquainted with the enginemen, firemen, trainmen and conductors; he must so conduct himself that these men will look to him for information and advice and depend upon him implicitly in train control matters.

The train control apparatus is maintained in a similar manner to any other locomotive appliance; that is, the engineman, upon arrival at a terminal fills out in a space provided on his engineman's work report, the condition of the automatic train control apparatus. If some repairs are necessary a work slip is made out from this work report the same as for any other part of the locomotive, and handed to the train control maintainer. The train control maintainer makes such inspection and repairs as are deemed advisable and reports back to the foreman, signing the work report accordingly. At the end of each day, another form called "The Automatic Train Control Inspection Report," is filled out, giving a record of all locomotives arriving at that particular terminal, the condition on arrival, and any remarks considered necessary to explain the condition of the train control equipment. This form also gives a record of all locomotives departing from the terminal and the condition in which they were dispatched. It is mailed to the superintendent's office for the files of the automatic train control clerk, one copy being retained in the roundhouse foreman's office. In

Semi-annual inspection report forwarded to the electrical engineer's office

this way a complete and accurate record of the operation of the automatic train control is compiled.

In addition, a report form called "The Record Card" is carried on each locomotive. Any repairs made are noted on this report form each time a locomotive enters a locomotive terminal and at the end of the month the card is removed and mailed to the electrical engineer's office in order that he may have a complete history of the operation of each locomotive at all times.

Thorough knowledge of air brakes essential

To understand, operate and maintain automatic train control intelligently it is imperative that the electrical engineer, train control supervisor, and maintenance forces be thoroughly familiar with the theory of application, maintenance and operation of the air brake systems, not only on the locomotive but upon all rolling stock. They must have an intimate knowledge of locomotive operation and maintenance. They should also have sufficient knowledge of the operation of the signal system upon which the train control has been superimposed to have an understanding as to the control of the roadside element by the signal.

The reservoir and exhaust control valve, which is the air appliance of the automatic train control equipment, is inserted in the air brake lines of the locomotive, and unless the maintainer has sound knowledge of the air brake system, it is easy for him to become confused, resulting in confusion of installation and operation of the air brake equipment of the locomotive as well as of the automatic train control system. For instance, a defective feed valve has caused violent fluctuations of the train line air gage on the locomotive, resulting in the cutting out of the automatic train control by the engineman, and it becomes necessary for the train control forces to be able to detect and explain satisfactorily to the engineman what his trouble actually was. The train control organization must also know the effect of air brake applications upon moving trains, particularly freight trains, and the effects of various reductions and rates of reduction upon the slack action of the trains, as they will be called upon from time to time to discuss these things with enginemen in order to bring about a more complete understanding of train control and its operation.

They must understand locomotive conditions as they develop in operation in order to handle the train control equipment properly. For instance, locomotive tender truck wheels develop flat spots occasionally and begin to pound so severely that the train control attachments become disturbed. They loosen up and the supervisor or maintenance men must pick out these cases for correction by the roundhouse forces. They must be acquainted with all of the government requirements as to clearances, arrangement, etc., that are wrapped about the maintenance of locomotives, so that the train control will not interfere in any way with these requirements. They must work hand in hand with the air brake repairmen and engine inspectors in order that complete co-ordination with air work may result. Their operations must be so conducted as to create a feeling of good fellowship among all concerned.

Train control record card 8½ in. by 11 in. in size which is carried on each locomotive

Maintainers need working knowledge of signals

The mechanical department automatic train control maintainers should have a working knowledge of that

part of the signal system that controls the roadside elements; that is, they should have a general understanding as to how the different indications are transmitted to the ramp in accordance with the signal indication. This is necessary in order that they can interpret such operations as reported applications of the brakes at a clear signal, etc., particularly where it is the only signal encountered on the trip, at which such an application was received. After inspecting the train control equipment and finding it to be in good condition, it should be possible for them to report to the train dispatcher that the signal in question probably has defective roadside apparatus.

Inspections and repairs of the indication selector, release switch and magnet are reported on one of the forms illustrated, being filled out semi-annually and forwarded to the electrical engineer's office.

The general instructions for automatic train control operation and maintenance are contained in a 38-page pocket size book of rules and instructions issued to all concerned. Electrical engineer's circulars are issued from time to time as necessary, giving detail instructions for the maintenance of the automatic train control equipment. Some important detail instructions for enginemen are contained in an instruction card, illustrated. One of these cards for ready reference is placed in the cab of each locomotive equipped with automatic train control.

Train control assists mechanical and operating men

The results of the operation of train control are particularly interesting and important to the mechanical department. It is permissible for trains hauled by locomotives equipped with automatic train control in operating condition to pass an automatic stop signal indicating "Stop" without bringing the train to a full stop, as a reduction to below the low prescribed speed limit of 15 miles an hour, and the continuous control of this speed through the red block, has obviated such a necessity. All mechanical men, traveling engineers, road foremen of equipment, etc., fully realize the importance of not bringing a train to a stop except when absolutely necessary. The elimination of unnecessary stops results in economy of fuel, reduces the number of drawbars pulled out and lessens wear and tear on equipment, such as draft gear, drawbars, knuckle pins, brake riggings, etc., all of which helps to reduce operating and maintenance costs.

The automatic train control clerk in the division superintendent's office is constantly in close touch with the entire train control situation through the chief dispatcher, also directly by telephone or telegraph with the shop and roundhouse foremen, and in daily contact with the trainmaster. This close contact, together with the regular form reports, including emergency or trouble wire reports, enables the automatic train control clerk to keep a close check on each individual locomotive and signal equipped with automatic train control, handling any trouble for immediate correction. At the end of the month he makes an analysis sheet from his daily records kept for each locomotive, etc., and from this analysis sheet forms his monthly report for the chief operating officer and the Interstate Commerce Commission.

Jig for planing the boiler radius on cylinder saddles

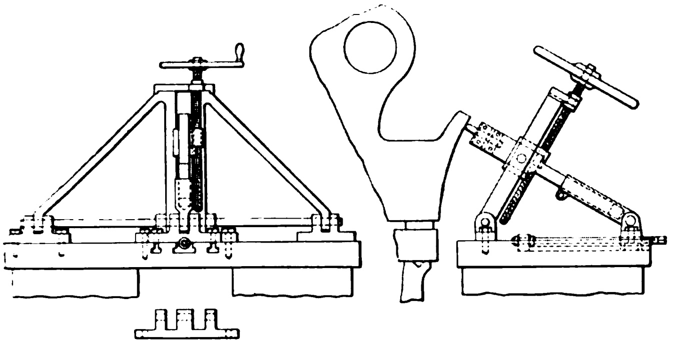
By C. G. Williams

ONE of the numerous problems of railroad shop work is the replacement of cylinders in cases where the originals have been worn out, broken or where replacement has become necessary in order to eliminate the old slide valves. The main item is the cost of finishing the saddles to fit the radius of the boiler. This operation has been performed in various ways, from chipping with a hammer and chisel or by using an air hammer, to planing slots to the layout lines on a planer and then chipping out the bridges with a hand chisel and sledge. The finishing has then been done with an air hammer or by attempting to follow the radius with a planer tool. This is a tedious and inaccurate job and costs money.

The Hoisington, Kans., shops of the Missouri Pacific has devised a practical and quick method for doing this work by the use of the fixture shown in the sketch. This fixture is placed on a heavy face plate, 8 ft. by 3 ft. 6 in., and 8 in. thick. It is placed on two concrete pillars set parallel with the bed of the planer which is used to plane up the backs of the cylinders and the plate is located about two inches lower than the top of the planer bed. This permits the center of the pin to go through the end of the radius bar about two inches higher than the bed of the planer and also allows the machinist to use two-inch parallels under the back of the

cylinder. The radius bar is then set to the radius of the smokebox and the saddle is planed to fit.

No provision was made in the original fixture to allow for lengthening the radius bar to suit the various radii, other than the slight amount that the yoke might be raised, or the cylinder set back from the edge of the planer bed, because the fulcrum was fixed. The writer has suggested an improvement in the drawing which will give a variable fulcrum by sliding the base of the radius bar by the use of a screw.



Sketch showing the construction of a jig for planing the radius on cylinder saddles

This improvement has been recommended by the shop officers to be incorporated in the original fixture so that it can be used for planing cylinders on the largest power now in use on this road. Another improvement is the graduation of the sliding member of the radius bar so that the radius may be determined directly from the bar and not by the use of a tram.

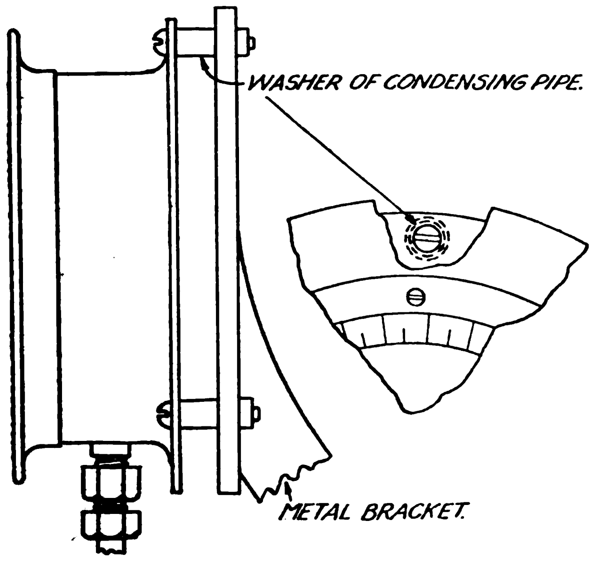
With this fixture it is possible to plane a pair of cylinder saddles to the correct boiler radius in five hours.

Method of applying gages to eliminate vibration

By Frank Bentley

Machinist, Chicago & North Western, Missouri Valley, Iowa

THE two common methods of securing air and steam gages, though expedient for fastening the gages in place, are not very permanent. If wooden washers or clips are used between the gage casing and the metal bracket, they are prone to split, which results in a loose, rattling gage. More particularly is this the case when the location of the gage subjects it to heat and vibration. If it is to be installed on a wall or wooden surface, the usual practice is to make a block near in size to the diameter of the back of the casing. This is, of course, fastened to the wall and the gage to the block, to permit free access to the connecting nipple. If the block is not carefully made an untidy job is the result, in addition to the liability of splitting, as several screws are applied in putting the two pieces in place.



A neat, permanent and easy method of fastening gages

The illustration shows a simple way of fastening gages which is neat, permanent, and easily done. Short pieces of old lubricator condensing pipes are sawed off, squared on a file, and used to block out the gage. It is held against these pieces by the casing screws or bolts. The small pieces of the brass condensing pipe do not protrude over the circumference of the casing or body. They are light and take paint or bronze readily, and will not break or crack under heat or vibration. They can be used to secure the gage to a wooden surface of any kind without splitting it. They can be cut any desired length, and afford a strong back support for a fairly large gage.

Locomotive valve setting chart

A CONVENIENT form for keeping a record of the valve setting on locomotives is shown in the drawing. This form can be drawn on a tracing in the drafting room from which blue print copies may be made. The chart is

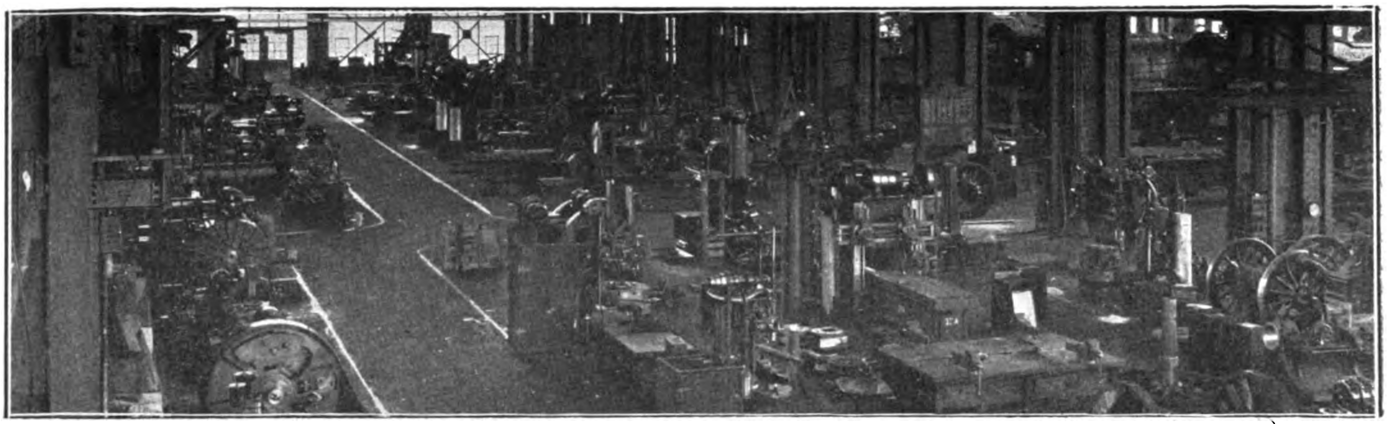
A convenient form for keeping a record of the valve setting of locomotives

filled out by the mechanic who sets the valves and duplicate copies for the mechanical engineer and master mechanic are typewritten. This record is valuable in checking cases where locomotives have not been working properly and readjustments of the valve gear are desired. It is also convenient to have such a record available for purposes of comparing locomotives with others of the same class.



The year's purchases of machine tools

Lists from 85 roads indicate a $14,000,000 expenditure; Demand likely to be greater in 1925

By L. R. Gurley

USING as a basis figures submitted by a group of railroads representing over 50 per cent of the track mileage in the United States, Canada and Mexico, it has been estimated that during the past year the railroads of North America spent approximately $14,400,000 for machine tools. Such budget figures as are available indicate that the railroads of the same territory will spend about $17,000,000 for shop machinery in 1925, which will exceed last year's expenditures by $2,600,000. The rapidly rising business barometer indicates that this figure may even be exceeded if the financial situation of the roads proves stronger in 1925 than in 1924.

On page 101 of the January 3 issue of the Railway Age will be found an article on "Machine Tools Purchased During 1924" which contains two tables giving in total numbers the various types of machines purchased by approximately 100 railroads of North America. These figures show that the railroads purchased 337 lathes, 178 drill presses, 127 planers, shapers and slotters, 80 boring mills, 50 milling machines, 240 grinding machines, 96 bolt and pipe cutting and threading machines, 51 portable boring facing and turning machines, 78 power presses, 54 hammers and forging machines, 108 boiler shop machine tools, including punches and shears, 64 flue shop machines and 146 wood working machines. The lists of machine tools here shown give in detail the size and capacity of the individual tools, as well as the name of the builder or dealer from whom they were purchased.

As might be expected, the lathe leads all other types of machine tools in the number purchased. Of the total of 337 lathes purchased, 209 are engine lathes. It is interesting to note that 93 turret lathes were purchased, which seems to indicate a real growth in the extent to which work is being put on a production basis. The indispensable drill press ranks next in importance to the lathe. From the data submitted, it was found that the smaller, belt driven, drill presses are being replaced by powerful, high-speed, motor driven machines. The last 15 years has witnessed an immense increase in the size of locomotives which has led to the adoption of large steel castings, some of alloy steel, and alloy steel forgings. Twist drill manufacturers have developed high-speed drills to handle these materials effectively, and it is being realized that it is false economy to use machines which will not pull these drills.

During the past few years considerable has been written and said about the place the grinding and milling machines would take in the railroad shops. A machine tool expert of one of the largest railroads of the country recently stated that in future years milling and grinding machines will rank in importance next to the lathe and the drill press. The railroads purchased 240 grinders of which 50 were precision machines and the remainder, tool and floor grinders. They also purchased 50 milling machines. These figures indicate a well defined trend in the direction of the above forecast.

The railroads purchased 80 boring mills of which 64 were of the vertical and 16 of the horizontal type. The latter apparently is used to handle a variety of general work while the former is used for production work.

It is evident that the slotter is being replaced by tools of other types. Only 13 are included in the lists. The planer and the shaper, however, hold places of importance in the purchases of the railroads. The lists include 40 planers and 74 shapers.

A total of 78 power presses were purchased during the past year. The presses shown in the accompanying lists are divided between those of high capacity for wheels and comparatively light bushing presses. Again, the increase in the size of locomotives has resulted in increasing the pressures required for forcing off and on wheels, crank pins and bushings which can not be efficiently done on presses that were installed 15 or 20 years ago to handle the smaller class of rolling equipment in use at that time.

The flue and boiler shops were equipped with a considerable number of new machines during 1924. Flue welders, mainly the electric type, received considerable attention as a necessary addition to a modern flue shop. The flanger and forming rolls with a scattering of riveters constituted the bulk of the purchases.

In spite of the tendency to change wooden cars to steel construction, 146 units of woodworking machinery were bought during the past year. Wooden passenger cars are fast disappearing, but it will be many years before all freight cars are built of steel. Consequently, the demand for woodworking machinery will continue.

A few of the large railroads of the country declined to report while others sent in no reports of any kind. Still others reported no purchases during 1924.

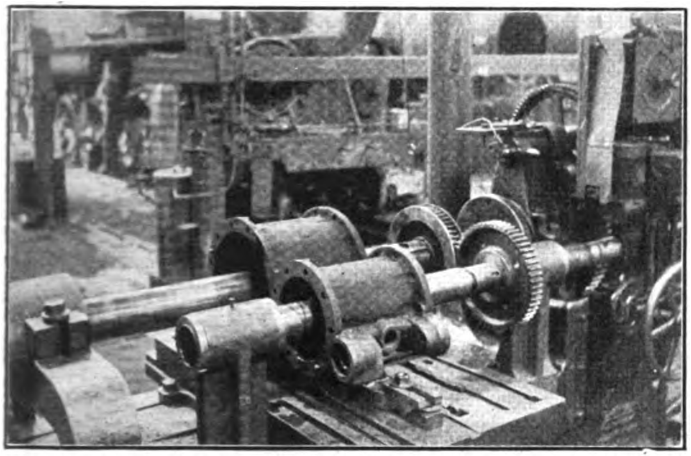
Boring bar for compound pump cylinders

By E. A. Murray
Shop Superintendent, Chesapeake & Ohio, Huntington, W. Va.

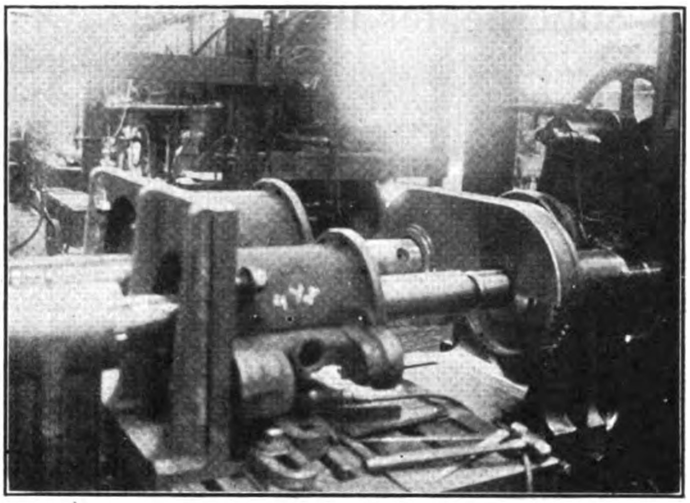
MANY original devices have been developed from time to time in railroad repair shops for reboring the cylinders of cross-compound air pumps. The majority of these boring bars, however, are designed to bore only one



General arrangement of boring bars with gear cover and angle bracket removed

of the two cylinders at a time. The drawing and illustrations to this article show the details as well as the operation of a boring bar which has been designed for handling this work in the Huntington shops of the Chesapeake & Ohio, and it differs from many others in that it performs the operation of boring both cylinders at one time.

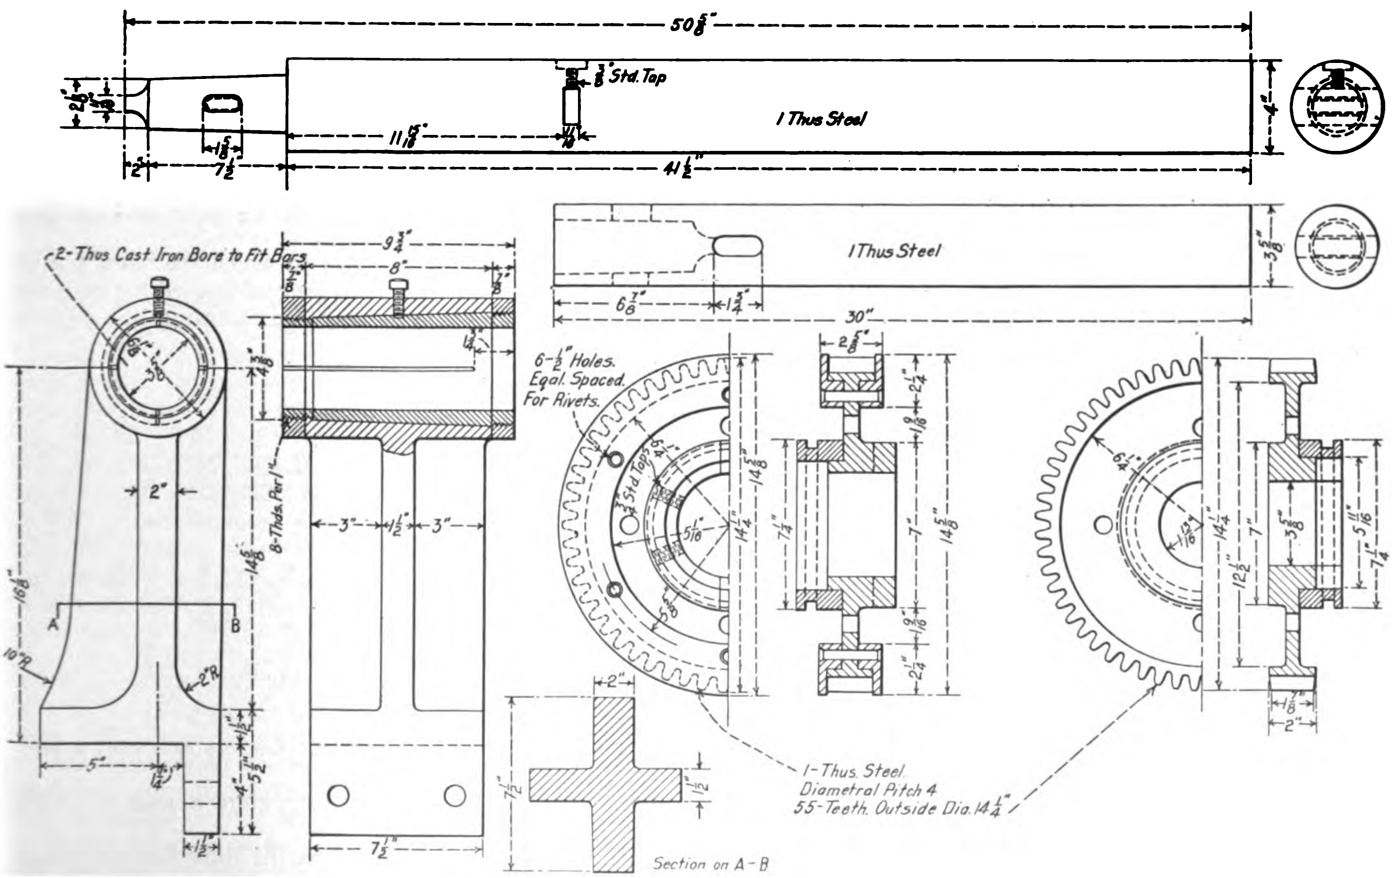
The device as a whole is simple to construct and to apply. It is intended for application to a horizontal boring mill, and consists of two parallel boring bars, one of which is



The cylinder casting is bolted to an angle bracket on the machine bed

driven from the spindle of the boring mill and the other, in turn, is driven by a flanged gear on the main bar which meshes with a gear on the auxiliary bar. Both bars are suitably supported by bearing brackets fastened to the table of the machine. The function of the flanged gear is to transmit to the auxiliary bar both the revolving motion for making the cut and the horizontal motion for the feed.

In actual practice the air pump cylinders are bolted to an



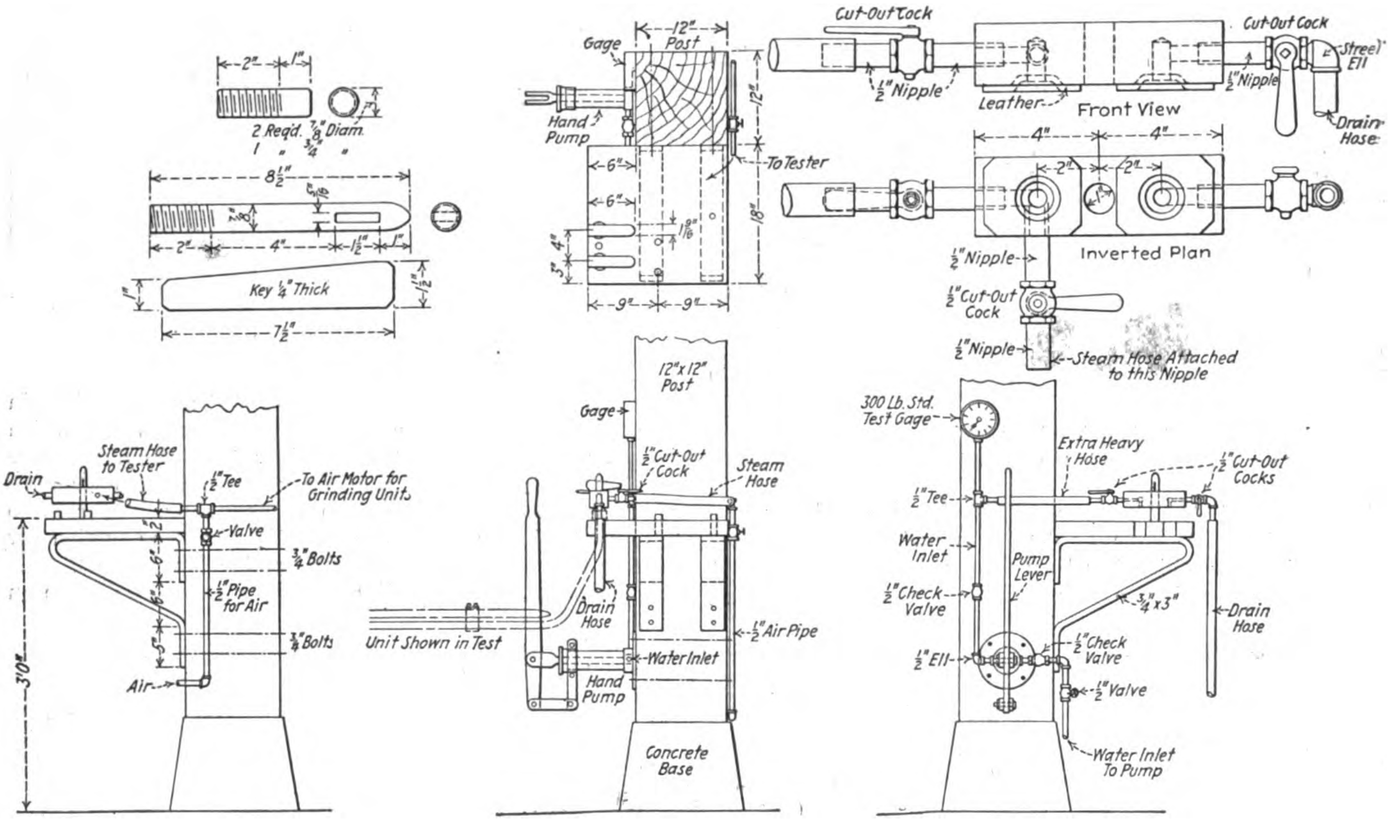
Details of construction of boring bars, gears and bracket

angle plate on the machine bed after which the bars are lined up to bore both cylinders at one operation. It has been found possible to reduce the time required on this job by about 50 per cent by the use of this device.

Superheater unit test rack

IN the drawing accompanying this article is shown a remarkably simple yet efficient device developed for testing superheater units. It was designed and constructed at the Minneapolis shops of the Chicago, Milwaukee and St. Paul.

As shown in the drawing, the rack rests on a bar iron bracket which can be fastened to a convenient column in the shop. On the bracket is a block with two slots for the unit pipes. This block, or table plate, is stationary and a ⅞-in. bolt with key slot is screwed into it. The superheater unit is inserted in the slots in the table plate, the cap is slipped down over the key bolt on to the ball joints of the unit and a tapered key is driven into the slotted bolt with a slight hammer blow which forces the cap down on the joints. Pressure is applied by means of a small hand pump conveniently located for the operator to handle. Valves and cut-out cocks are so arranged that the units may be filled with water and pressure pumped up for hydrostatic test and when the test is completed the water and scale can be blown out into a drain.



Constructional details of test rack for superheater units

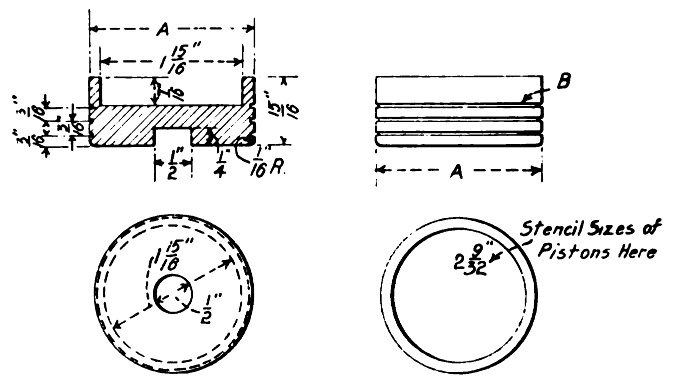
THE LOCOMOTIVES inspected by the Bureau of Locomotive Inspection in November numbered 5,143, of which 2,366, or 46 per cent, were found defective and 283 were ordered out of service, according to the Interstate Commerce Commission's monthly report to the Senate on the condition of railway equipment. Of 98,723 freight cars inspected by the Bureau of Safety 3,582 were found defective and of 1,773 passenger cars 15 were found defective. During the month 38 cases, involving 253 violations of the safety appliance acts, were transmitted to various United States attorneys for prosecution.

Reducing valve piston repairs

By Frank Bentley

A GREATER part of the efficiency of the steam heat reducing valve depends on the main valve piston. If properly repaired when required, it will be kept off of the engineman's report slip as well as off the repair bench.

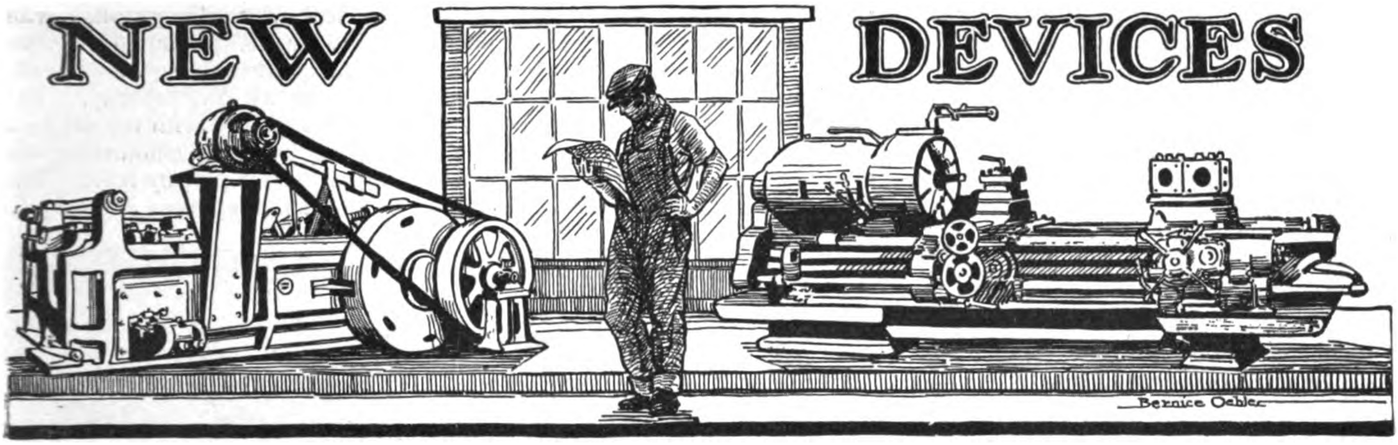
In order to prepare for the winter months a number of odd size stock pistons are made up early in the fall. The sizes in 1/32 in. are stenciled on the piston in the hollow portion of the top. The valve body is, of course, held on a mandrel as the cylinder is trued up. A piston of the proper diameter is selected for the size to which the worn portion is bored out. The removed pistons can be used for cylinders which true up to smaller sizes. By following this practice



Method of maintaining pistons for Leslie steam heat valves

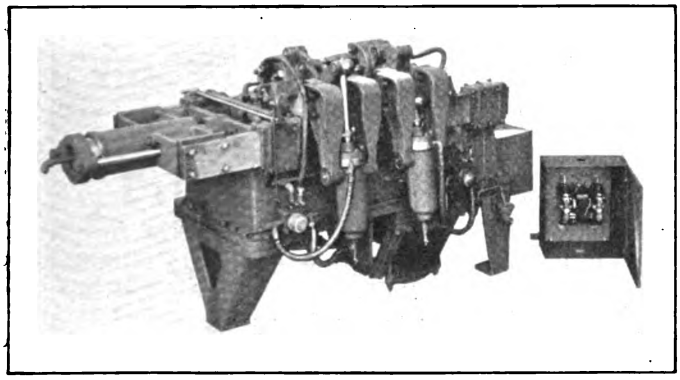
a small stock of pistons will keep quite a number of the reducing valves in working order.

When making up stock pistons the dimension *A* should be made up in sizes of 2 9/32 in., 2 5/16 in., 2 11/32 in., and 2⅜ in. The grooves *B* should be 1/32 in. square.



Electric butt welder with a water-cooled transformer

THE three accompanying illustrations show the No. 92 electric butt welder manufactured by the Federal Machine & Welder Company, Warren, Ohio. The machine is supplied with a remote control, magnetically operated switch, so designed that the metal

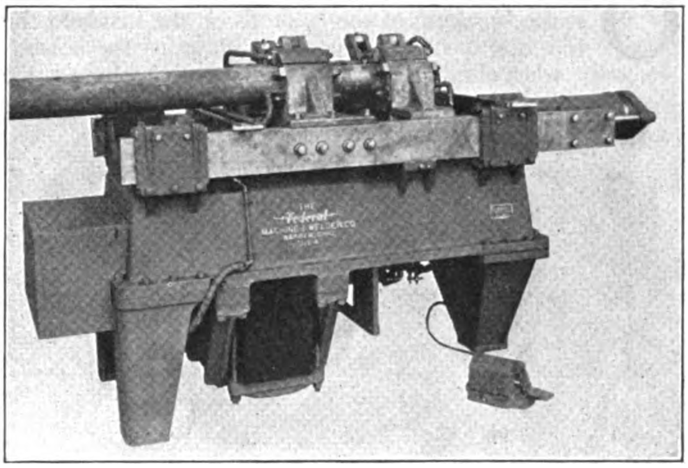


Rear view showing air cylinders and remote control switch in steel box

contacts are readily removed and replaced with slight expense. The switch has asbestos-wood flash plates, to prevent the arc from blowing out from the contacts when the circuit is open under heavy load and is also supplied with magnetic blow-outs, which extinguishes the arc. The switch is mounted on a heavy slate base, which is installed in a steel box, having a door arranged for locking to avoid tampering with the switch. A small shunt switch is supplied as part of the regular equipment. This is mounted directly on the operating lever, or at a convenient point on the welding machine.

The machine is supplied with a cylinder of the proper dimensions to give pressure capacity at the welding jaws of 3,000 lb. per sq. in. up to the given capacity of the machine, or the cylinder will have a capacity to apply 13,400 lb. pressure at the welding jaws, when supplied with 1,800 lb. pressure on the hydraulic line.

The transformer consists of heavy cast copper secondaries entirely surrounding the core and insulated from it with bakelite strips. Each section of these secondaries is supplied with a water cooling pipe which extends through its entire length. The secondaries are divided into three sections which are placed between four primary coils. The primary coils are wound with copper ribbon, the turns of which are insulated from each other with oiled muslin and asbestos ribbon. The coils complete are covered throughout with asbestos tape to make them fire and water proof. The insulation between the primary and secondary coils consists of a flexible material made up of asbestos fibre 1/8 in. thick, which has a break-down test of 20,000 volts. The entire set of transformer coils is mounted on the transformer core which is machined in sections, and the coils can be readily removed, in case it is desirable to dismantle the transformer. The core is made of high silicon, non-ageing transformer steel, having a low core loss. The entire equipment is air cooled. If the welders are equipped with a 100 k.v.a.



Welding a locomotive superheater tube in a Federal butt welder

capacity transformer it will have sufficient capacity to weld continuously 4½ sq. in. of metal.

The transformer is mounted under the movable main platen or slide in such a manner that it is impossible for dirt, flash or refuse coming from the weld to get in the windings of the transformer. It has been found that with the transformer located directly underneath the gap between the movable slides, the flash or throw-up from the weld falls directly on it and the strong magnetic pull induced by the secondary under the flow of the immense amperage has a tendency to pull the metallic dust into

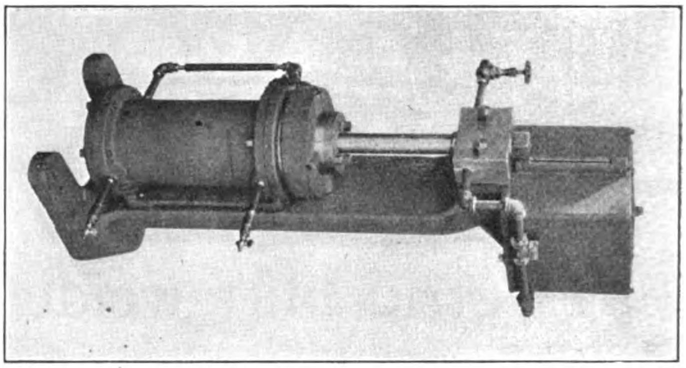
the windings, finally resulting in burn-outs or short circuits. It is claimed that this difficulty has been entirely eliminated in this machine as the transformer is not located under the slides and is further protected by a heavy slate slab, which extends directly from the under slide of the platen down nearly to the floor. The only parts of the electrical secondary that are exposed to the throw-off from the weld, are three heavy copper secondary connections, which extend to the left hand stationary electrode.

The welding machine has a three point bearing, that is, two legs on one end and one on the other. The four legged construction, unless very carefully installed, throws a twist in the machine, resulting in a binding of the slides and unsatisfactory work due to improper alinement.

The main movable platen or slide is carried on two heavy steel bars which extend the full length of the machine, giving a bearing between the sliding contacts of approximately 5 ft. 6 in. and at the same time placing the main bearings at the extreme ends of the machine where they are entirely out of the way of dirt and flash which is thrown off at the weld.

The transformer being supported directly under the movable slide and not enclosed in an oil-cooled case, is readily inspected and accessible for blowing out of whatever dirt may accumulate after long use. The main bearings which are of heavy steel construction are located at the outer ends of the machine and are easy to adjust and are arranged for proper lubrication by means of the Alemite system. An Alemite grease gun to lubricate all of the moving parts is supplied with the welder.

The machine is constructed with dies of the circular pattern design, held in position by wedge shaped clamps. The dies are located in holders which are supplied with water-cooling pipes. The water is permitted to flow through these holders at all times when doing heavy work, or handling the machine up to its full capacity. The pressure in clamping the pipe is applied with the aid of a toggle lever and air operating cylinder, eliminating the labor necessary in clamping large size pipe by hand. The actual pressure applied when clamping tubes is approximately 16 tons on each clamp. The circular shape of the dies provides proper alinement at all times.



Hydraulic intensifier used with the butt welder

The construction of the machine is such that the disposition of the frame to buckle is a remote possibility. The operating cylinder is so installed that a straight pull is applied to the moving platen and this, with the aid of the long bearing, eliminates the tendency to spring the bed plate.

Universal truck column anchor

One frequent source of trouble with arch bar trucks is the breaking of the columns on the inside at the top, due to repeated hammer blows of the bolster. Moreover, when the brakes are hung from the columns, the ears or support brackets are not infrequently worn through by the hanger pins or broken off.

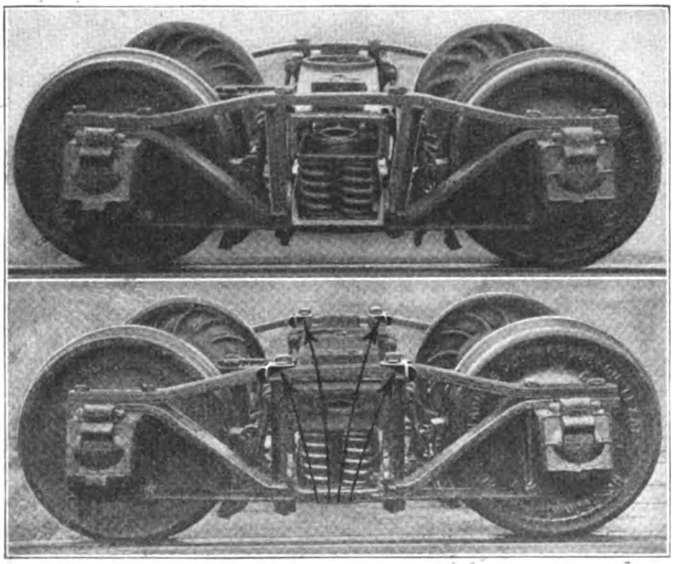


Fig. 1—Arch bar truck with broken columns (above); Same truck with broken columns held in place by Universal truck column anchors (below)

The cost of renewing truck columns when broken is considerable, depending on the weight and material from which they are made. Their period of usefulness is said to be greatly extended by the application of Universal truck column anchors, developed recently by the Universal Draft Gear Attachment Company, Chicago. By the use of these anchors the truck columns are supported at the top from the outer face and even if broken out on the inner face they are still serviceable. In fact, the defective columns, when supported at the top with these anchors, are said to be stronger than new columns without the anchors. In cases where the brake hanger bracket has been broken off, the truck column anchor is provided with an integral brake hanger support, thus making a permanent repair and retaining the old column.

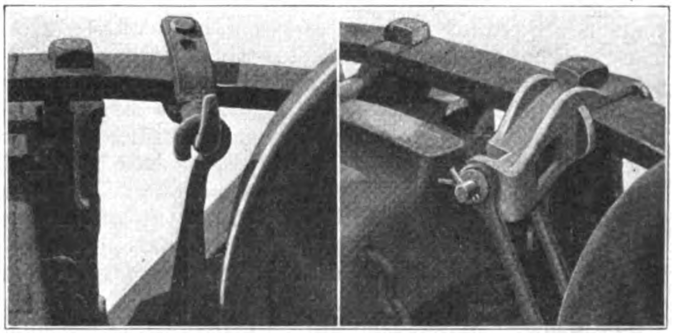

Fig. 2—Temporary repairs in case of broken brake hanger bracket (left) and permanent repairs (right) by means of Universal truck column with integral brake hanger bracket

In the upper part of Fig. 1 an arch bar truck is illustrated with all four columns broken out on the inner face as described. The same truck, fitted with Universal truck column anchors, by means of which necessary repairs are made and the old columns retained, is shown in the lower half of the illustration.

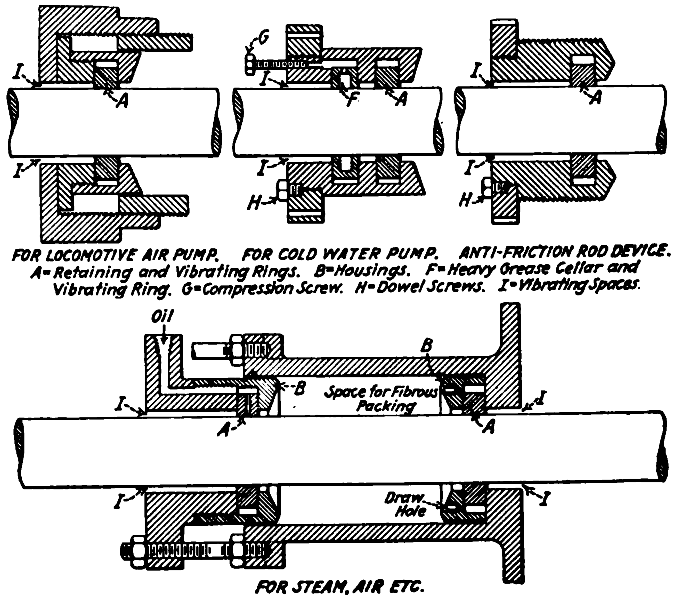
A truck with temporary repairs in case of a broken brake hanger bracket is illustrated at the left in Fig. 2, and at the right, the method of making permanent repairs by means of a Universal truck column anchor with integral brake hanger bracket which provides a permanent rigid support for the brake beam.

Packing gland provides for improper alinement

THE two main sources of packing troubles are improper alinement of machinery and improper adjustment of the compression gland by the operator. Few operators use calipers in making adjustments. Where calipers are not used, the operator invariably puts more tension on one adjustment nut than on the other, which results in a scored rod and cut packing. In trying to overcome this condition, the workman will apply more pressure in the gland. Unnecessary pressure is applied to the rod and more power is required to operate the machinery and, with this condition, the packing must be frequently renewed and eventually the scored rod must be removed or turned which undoubtedly increases the cost of packing gland maintenance.

In an effort to overcome these conditions William S. Sudekum, Nashville, Tenn., has developed and patented a packing gland to take care with an anti-friction rod device of improper alinement. Referring to the illustration showing the application of the device to steam, air and other glands, it will be noticed that the fibrous packing is cut at an angle of 45 deg. The object is to obtain a perfect fit with the least possible compression. The glands are bored no less than ¼ in. larger than the piston rod to prevent them from coming in contact with the rod.

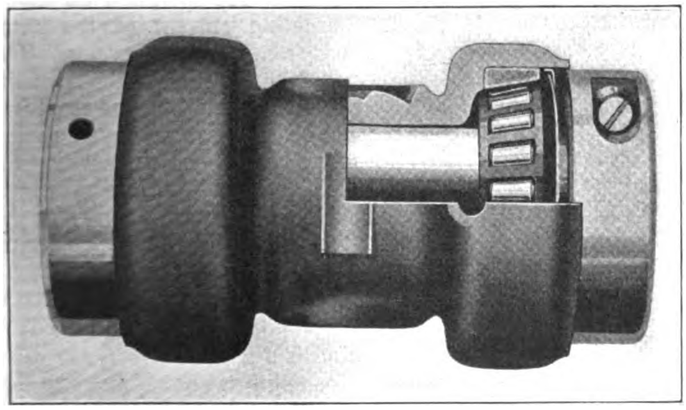
The retaining or vibrating rings are turned ¼ in. smaller than the bore in the housing in order that the rings may have the same amount of vibrating space as the rod. The packing is lubricated through the feed oil cup which is said to be economical as the vibrating rings will distribute the oil on the rod properly and without waste.



A method of packing piston rods which overcomes improper alinement of machinery and adjustment of the compression gland

Roller bearing for line shaft hangers

THE Dodge Manufacturing Corporation, Mishawaka, Ind., has placed on the market a line shaft bearing embodying the Timken tapered roller bearing, as well as several new features of construction.



Line shaft hanger bearing equipped with Timken tapered roller bearings

The special requirements that must be met by any appliance used in power transmitting service, such as ruggedness, simplicity, interchangeability and reliable lubrication, have been given the most careful consideration in the design and manufacture of this bearing. It consists of only five parts; two Timken tapered roller bearings mounted on a ground and slotted steel tube and fitted to an accurately machined housing. The ends of the steel tube are threaded to receive clamping collars designed to secure accurate adjustment of the bearings on the tube. This adjustment is made at the factory and need not be altered by the user.

The mounting of the tapered roller bearings, as described, insures full utilization of the bearings for both radial and thrust loads. It also adds to the ruggedness of the assembly and is of particular value in resisting the side weave of heavy driving belts. The method of fastening the steel tube or sleeve to the shaft permits its use on any commercial shafting. This fastening is accomplished by simply setting up the screws in each of the two clamping collars.

The sleeve on which the bearings are mounted extends from end to end of the housing. Liberal grease compartments are provided inside of the housing and outside of the tube. The outer ends of the bearings are protected against dust by special metallic grease seals which eliminate friction at this point and prevent dust working in or

the lubricant from working out. These grease seals take the place of felt washers or packing.

The erection of this lineshaft bearing is very simple. It is only necessary to slip the bearing over the shaft and set up the clamping screw in each of the split clamping collars. To remove it, in order to make any necessary repairs, the screws in the collars are loosened and the bearing slipped off the shaft.

Quartering gage with vernier attachment

PAGE 1407 of the June 11 issue of the Daily Railway Age contains a description of the improved quartering gage manufactured by The Ashton Valve Company, Boston, Mass. Since then the instrument has been further improved by the addition of a vernier attachment and an outside revolving casing. The gage can be used for testing crank pins for quartering in any position of the drivers without removing them from the frames; for checking the quartering of crank pins before setting the eccentric or crank arms of the valve motion; and it can be used to advantage when applying new axle to old wheel centers.

Each space upon the dial indicates one degree. Each space upon the vernier scale is six minutes or .1 degree shorter than one space on the dial scale. Thus, when the line marked zero on the vernier scale coincides with the line marked zero on the dial scale, the instrument is standing horizontally. When the dial is moved so that the graduation or line on the vernier scale next to the zero line coincides with the graduation next to the zero graduation on the dial scale, the included angle of the center line of the instrument and the horizontal center line has changed .1 degree or six minutes. To read the setting of the instrument, read directly from the dial scale, the number of whole degrees between the zero line, and the zero line of the vernier scale. Then count in the same direction, the number of graduations from the zero of the vernier scale to a graduation that coincides with a graduation on the dial scale; multiplying this number by six gives the number of minutes to be added to the number of whole degrees.

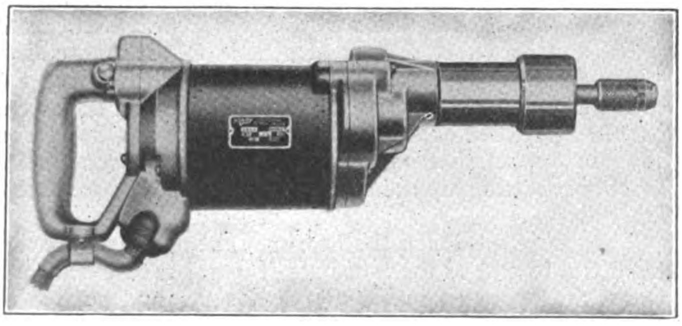
A table on the casing of each gage gives the linear variation corresponding to one degree of angular variation for the different strokes from 18 in. to 32 in. Provision has been made for suspending the gage from the crank pin by the use of a coil spring or strap.

Ashton locomotive driving wheel quartering gage provided with a revolving casing and vernier scale

Electric friction head screw driver

AN electric screw driver, the driving head of which is equipped with a disc type friction clutch, which is regulated automatically by pressure applied by the operator, has been placed on the market by the Hisey-Wolf Machine Company, Cincinnati, Ohio.

It is equipped with ball bearings throughout and designed with the company's universal motor for operation on direct current, or single phase alternating current of the same voltage, and for any frequency from 25 to 60 cycles. The quick-cable external connector is a feature which permits cable repairs and renewals without dismantling the machine. The switch is fitted to the handle grip. The clutch casing is of convenient size and serves as an end grip when the work requires. The screw slot finding attachment, which may be secured with the machine, is intended to prevent the driving bit from slipping out of the screw slot and marring the surface of the work. These are made in three sizes with bits 5/16 in., 3/8 in. and 7/16 in. diameter. Two screw driving bits are furnished with the machine.



Friction head screw driver fitted with a slot finding attachment

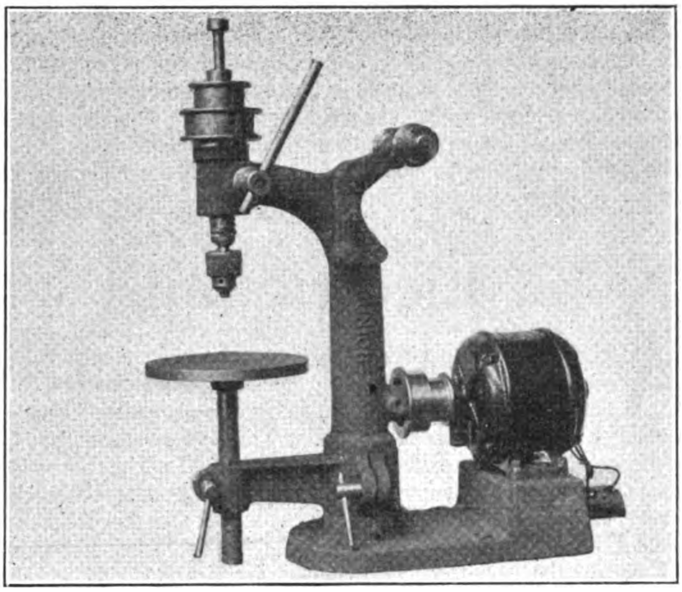
The capacity of the machine is for driving screws up to No. 14, 2½ in. long, in soft or solid wood. When suitable lead holes are provided, larger wood and lag screws up to 5/16 in. in diameter by 4 in. in length can be driven. These machines can also be used for setting up nuts to 3/8 in. in metal and wood. They are 15½ in. long and 3¾ in. in outside diameter. The no load speed of the spindle is 525 r.p.m. The net weight is 9½ lb.

Motor driven bench drill

When the Buffalo Forge Company, Buffalo, N. Y., first put its Junior 10 in. bench drill on the market it was driven by a motor through a pinion and gear which resulted in a noisy operation. In order to overcome this defect, the machine has been redesigned with a ¼-hp., 1,750 r.p.m. motor with the belt drive pulleys keyed to the motor shaft. This gives a quiet, positive power transmission and also saves space. The spindle runs in a large bronze bushing, and is provided with a No. 2-A Jacobs chuck. Two speeds are provided and the shifting from one speed to the other is accomplished without using tools as the idler works with a snap socket.

The machine has a substantial cast iron frame and a finished circular table movable in both horizontal and vertical positions. The normal driving speed is 550 r.p.m., although it can be driven as high as 3,000 r.p.m. and still remain in balance.

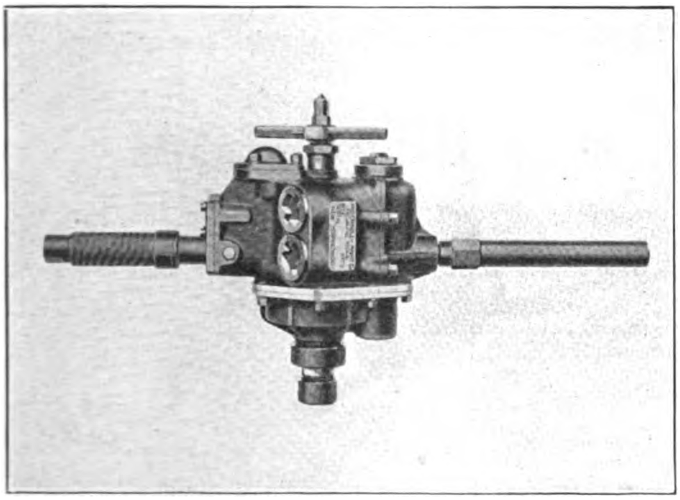
The height of the drill is 27½ in. with an 8-in. diameter table. It can drill holes up to ⅜ in. and to the center of a 10-in. circle. The travel of the spindle is 8½ in. and the greatest distance from the table to the spindle is 8 in. It also has a vertical movement of 3½ in. The net weight is 66 lb.



Buffalo Forge 10-in. Junior bench drill

Pneumatic drill provided with a speed governor

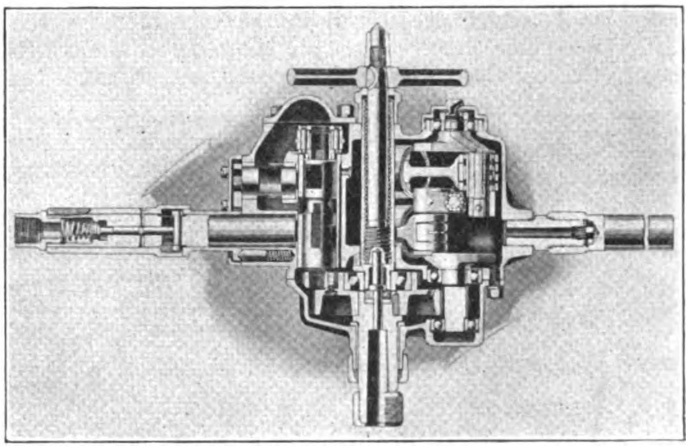
The Ingersoll-Rand Company, New York, has recently added to its list of pneumatic tools a four cylinder pneumatic drill equipped with a speed governor to eliminate the racing of the machines when running free. This governor is set so that the machine will do the maximum amount of work at the proper working speed. In addition to the governor, the valve mechanism consists of one valve of a gear timed construction. This valve is balanced at all times and there is, therefore, practically no wear on the valve or on the valve bushing.



Ingersoll-Rand reversible pneumatic drill

All the cylinders have special steel liners, fitted into the steel casing, which are easily removed and renewed. With this construction, it is said to be practically impossible to dent the cylinder liner as the wall of the casing on the outside protects it, there being a chamber between the casing wall and the cylinder proper.

The crank pins are fitted with sleeves which are held stationary so that all of the wear takes place on the sleeve instead of the crank pin. Therefore, if a crank pin bearing becomes worn, instead of renewing the entire crank shaft, it is only necessary to renew the one sleeve. The crank pin bearings are lubricated from the inside of the crank pin out, instead of by revolving in a grease-filled crank case. It has been found that the centrifugal force of a high speed crank shaft throws the grease away to such an extent that the crank pin usually receives very little lubrication. With this method, the centrifugal force aids lubrication by throwing the grease from the inner part of the crank shaft out through the crank pin bearings.



Sectional view of pneumatic drill equipped with a speed governor

A helical type of gearing is used for the crank pinion and the main driving gear. With this type of gearing, there are always two teeth engaged instead of only one as with the spur gear type. This considerably reduces the tooth pressure on the gears. The crank pinion is also

renewable. A new method of venting the casing through the crank shaft is used, which gives a better venting for the casing and still will not throw out the grease which is used to lubricate the machine.

The dead handle is screwed onto a stud which is set into the crank cap of the drill. This eliminates the wear which occurs when a dead handle is screwed directly into the crank cap proper as it is necessary to take out the dead handle frequently in order to properly lubricate the drill. The drill is fitted with a new type reversible throttle which has a rotating reverse throttle in addition to a poppet throttle. This is said to give excellent service and eliminate leaking. The throttle is fitted with a spring center with notches for the full forward speed, full reverse and dead center and is very easily regulated by the operator.

The crank parts can be completely assembled outside of the drill case and then inserted in the case. This feature saves time and assembling and assures the work being properly done. It avoids lost time from working on small parts if the crank has to be assembled in the case.

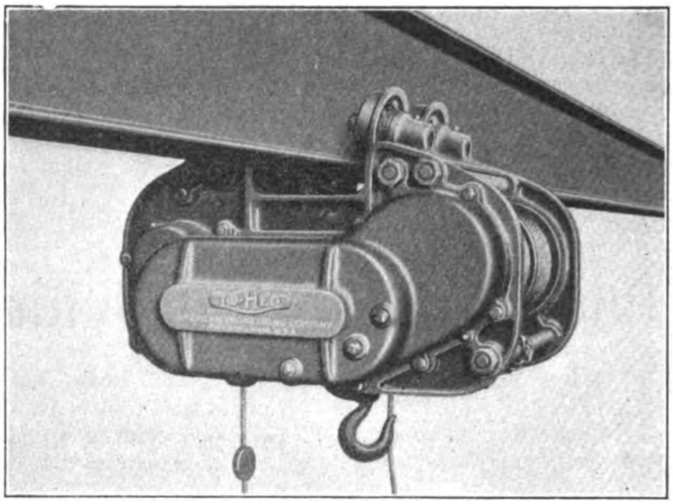
Electric hoist with low headroom

An electric monorail hoist designed to operate in a minimum headroom has been placed on the market, in half-ton and one-ton sizes, by the American Engineering Company, Philadelphia, Pa. This hoist retains many of the features that distinguish the other "Lo-Hed" hoists made by the same company, but is smaller and is intended for general utility use where a light, handy electric hoist is needed.

Like all the "Lo-Hed" line, this hoist is able to draw the load hook up until it almost touches the rail, which makes it available for use in places where, because of low headroom, no other hoist could be used. It gives additional clearance and safety for bulky loads and makes it possible to pile materials higher than could be done by any other means, thus increasing the capacity of storage spaces by utilizing the space almost up to the ceiling.

Automatic holding and lowering brakes are provided and a safety device checks the hoist at the upper limit of travel and throws off the current. High duty roller bearings and automatic lubrication give a high efficiency. A factor of safety of five makes overloads possible in emergency.

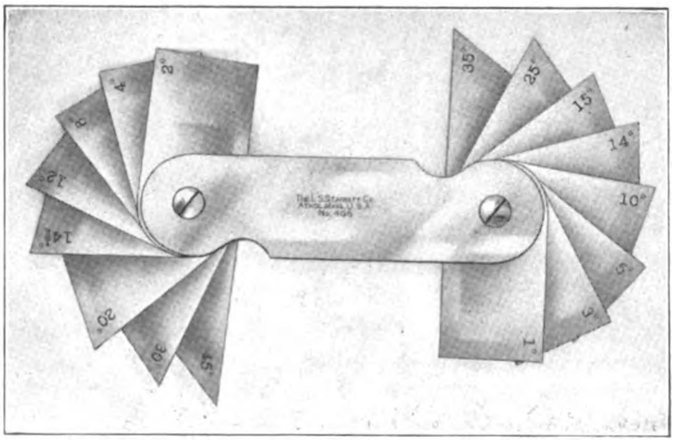
These hoists are furnished for either direct or alternating current. All working parts are completely accessible and the motor can be removed for repairs in a few minutes without touching the load on the hook.



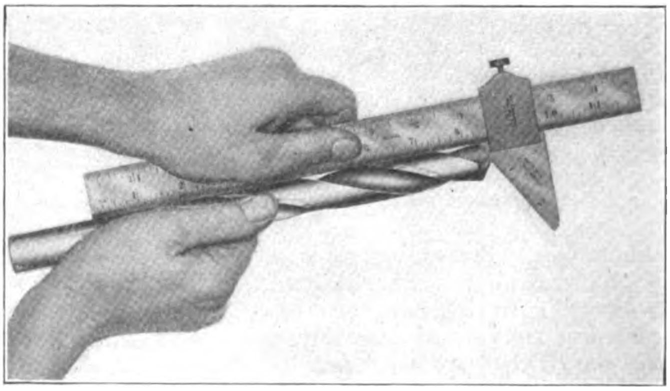
A view of the Lo-Hed Hoist showing gear and drum

Hand tools adaptable to railway shops

The accompanying illustrations show four hand tools which are useful in the tool room or the machine shop. The angle gage contains 16 leaves, the ends of which are ground on an angle to most frequently used, including 14½ deg., one-half the Acme Standard. The gage is about 9/32 in. thick, 11/16 in. wide and 4-3/16 in. long. It includes angles from 1



Angle gage No. 466 includes angles from 1 to 45 deg.

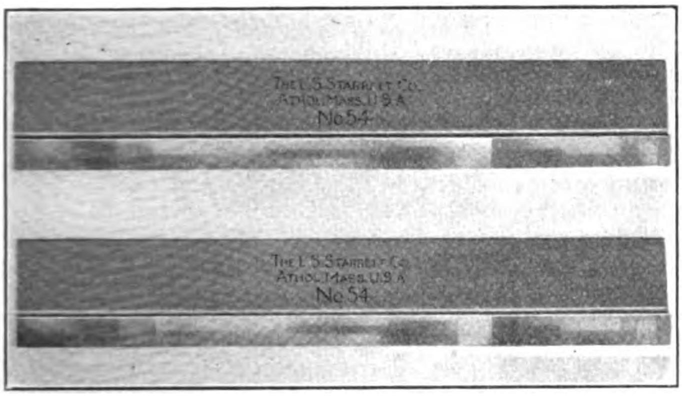


Drill point gage No. 22 designed for assisting in grinding drill points accurately.

degrees. The leaves are made from spring tempered steel and their two sides, as well as the angle edge, are ground. The gage embodies a combination of angles to 45 deg. It is especially useful to inspectors and toolmakers.

The drill point gage has been designed for the specific purpose of assisting in grinding drill points accurately.

The method proposed for sharpening the cutting edges is to do one at a time. For satisfactory results, each lip must not only be the same length, but must also have the same angle in relation to the axis of the drill. Experience has determined that for ordinary drilling purposes a 59-deg. angle has advantages. When the lips or cutting



Tool steel, hardened and ground hold-downs

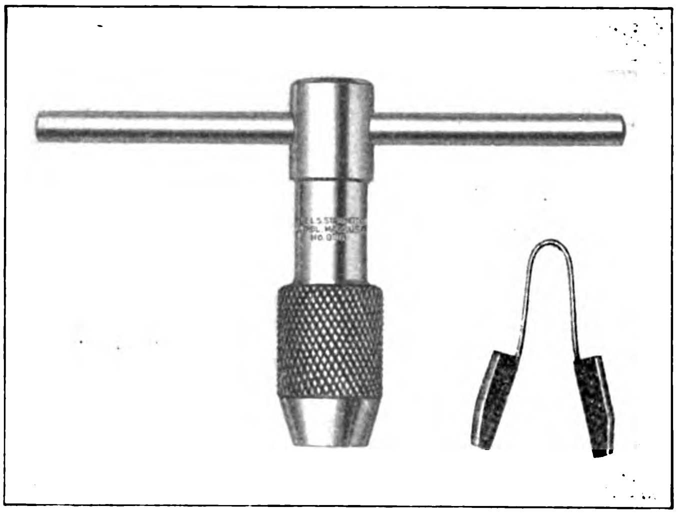
edges are the same, then it follows that the "dead center" will be located on the drill axis.

The use of this gage should effectively eliminate not only the breaking away of the cutting edges, splitting the drills and drilling oversize holes, but also break-downs from straining the machine bearings.

The blade furnished has sixty-fourth and thirty-second graduations on one side and sixteenths and eighths on the other. The angle part lies in the plane of the blade and, being adjustable, may be clamped to any point in its length. It may be also used as a square, depth gage, or book rule. The blade is 12 in. long.

The hold downs are used to hold work down flat as on a machine platen or in a vise where a small amount is removed from a surface, and where other methods of clamping are inconvenient. Work can be securely held without distortion. The contact edges are slightly tapered so as to force the base of the work to the bed of the machine. They are made of tool steel, hardened and ground.

The T-handle tap wrench is used for holding taps to be turned with the hand, and is also useful for holding drills, reamers and other small tools. The body is centered, enabling the workman to start the tap straight when using it on lathe centers or in an upright drilling machine. Its unique construction permits the jaws to conform to the



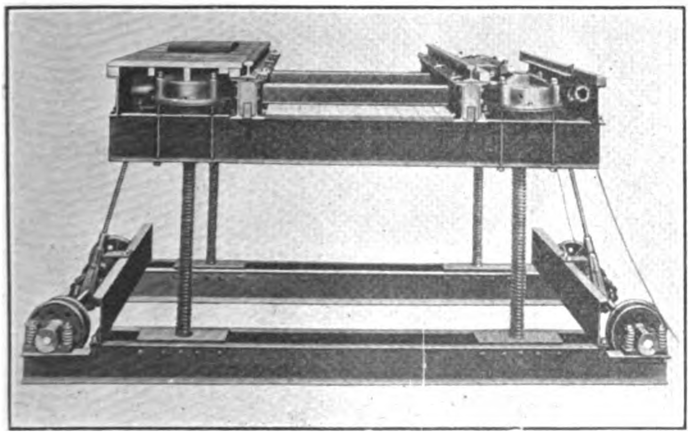
A T-handle tap wrench known as tool No. 93

piece to be held, making it rigid and less apt to become loose. The jaws and the knurled clamping nuts are heat-treated to withstand any ordinary use.

These tools are manufactured by the L. S. Starrett Company, Athol, Mass.

Whiting screw-type electric drop table

The Whiting Corporation, Chicago, has developed a new screw-type electric drop table which may be designed to perform any dropping operation on wheels or other parts of locomotives or cars. Particular



Whiting self-contained electric drop table for enginehouses

advantages in the design of this drop table are safety, secured by the worm and gear type drive now used on over 100 Whiting hoists; ample, reliable power by means of electric motor drive; the absence of air or water lines, a feature of importance particularly in the northern states; and the provision in a single unit of a drop table for driving wheels and tender truck wheels.

The new drop table consists essentially of a truck with four stationary screws, the table being built on top. Wheels and axles are provided at each end of the truck, being inserted in roller bearings to permit easy lateral movement. The boxes are spring supported so that when the full locomotive weight is received, the springs will deflect. This in turn seats the screws on the rails, passing the weight directly onto the foundation of the pit track.

The table rails are reinforced and supported by beams. The load is carried to the driving units by means of transverse channels. The driving units consist of worms and worm wheels with roller thrust bearings. The latter are 14 in. in diameter and contain 56 rollers. The driving motor is mounted on the table, thus making it safe from flood. The control is a matter of choice but the push button type with extension cord gives the most flexibility.

The pit is rectangular in cross section and may be constructed straight or in conformity with the enginehouse circle. Channels are set in the wall to guide the table and insure its being correctly positioned. Sockets are pro-

vided for the power plug, from which a flexible cable leads to the hoisting motor.

In operation the power is turned on and the table run up until the locomotive weight is relieved from the locking bars. These bars are thrown out, a single lever performing the operation, and the table and load are then dropped to the low position. The entire unit is moved laterally by ratchets, the use of roller bearings making it possible to do this with one hand.

In dropping locomotive drivers, it is not necessary to take the locomotive weight on jacks before starting, as the new table has a capacity of 50 tons. Neither is it necessary to spot the locomotive closely as the entire rail section drops. As there are no heavy rail beams to be moved out of the way, one mechanic and a helper can do the work. In replacing the drivers with a drop pit, they are first lifted into position, the rail beams moved in place and a scaffold erected. With the drop table, the operator can stand in the table pit and come up with the drivers. The shoes can be placed first and held by shims. The pedestal binders can be set on blocks and fitted with wedges. In this way all the operations can be performed at once, saving time.

If the table is of sufficient length, two pairs of drivers or tender truck wheels can be dropped in a single operation. On the other hand, a single pair of tender wheels can be removed by just running them out on the table and blocking under the spring seat. Trailers may be handled, or a cradle casting can be blocked on the table and dropped without using extra blocks and tackle.

Boosters are readily removed on the drop table, a difficult operation on a drop-pit jack because of the shifting weight. This is due to the overhanging weight of the booster engine and the spring weight, which drops to zero after a few inches. The Whiting drop table has four legs and any shift of weight does not affect it. In addition, spring work is said to be done quickly and easily without disturbing any box packing. To renew a spring the table is raised two inches above the rail and the spring rigging blocked. The table is then dropped, taking the weight off the spring. It can then be readily removed. The same method can be employed in spring equalization.

Truck or trailer brasses also can be replaced readily. After blocking the box, the table can be dropped a few inches. On account of the self-locking worm drive, it is then safe to remove and replace a brass.

A self-contained centrifugal oil-extractor

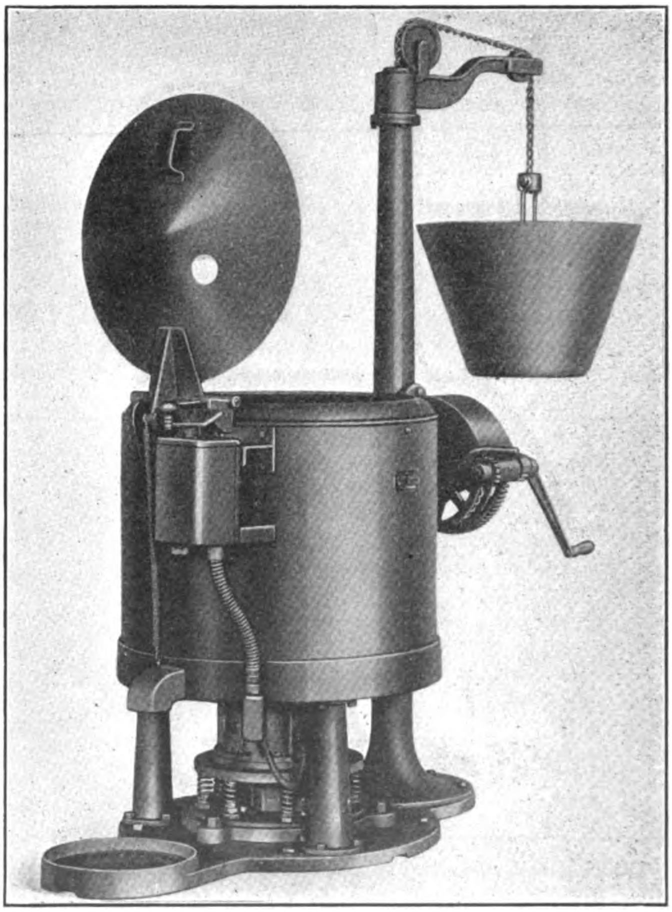
AN entirely self-contained centrifugal oil-extractor electrically driven, eliminating belt, countershaft or motor stand, quarter turn pulleys, mechanical brake and rubber bumpers has recently been designed by the Curtis Machine Company, Worcester, Mass., and is being sold by the Crescent Washing Machine Company, New Rochelle, N. Y.

The motor is equipped with Timken bearings. The bearing at the lower end of the motor carries the radial loads only, while the upper bearing carries the radial loads and also the thrust load of the pan assembly, the spindle and the chip load. The weight of the entire assembly comprising the motor and pan is carried by a pivot bearing in the base of the machine. By means of a unique compensating feature in the application of the motor unit all vibration, common to this type of machinery, is transferred direct to the base of the machine.

The motor is of the squirrel cage type, specially designed to meet the requirements of this type of machine. It can be run on 220-volt, 440-volt or 550-volt, 60 cycle, three phase a.c. current. It has a speed of 1,165 r.p.m. and is mounted directly upon the spindle of the machine. The motor is controlled by a drum type controller conveniently mounted on the drum of the machine. The running or forward position is positive while the reverse side is spring actuated and is arranged for braking. The machine may be accelerated under full load in 10 seconds and stopped in 12 seconds.

An automatic safety lock is applied to the cover hinge. This device prevents the operation of the machine except when the cover is in the closed position, and at the same time prevents the splashing of oil.

The pan is filled with machine chips, or other material from which the oil is to be extracted, and then placed in position on the spindle by means of the hoist. The pan cover is then secured in place by means of the spindle nut and the machine run for from three to five minutes at a speed of 1,200 r.p.m. The resulting force acting upon the load is the equivalent of about 350 times gravity. The chips, being confined to the pan, are thus separated from the oil which leaves through various small openings between the pan and the cover and then finds its way to the spout in the base of the machine. For efficient handling the chips should first be gravity drained and an extra pan provided so that one may be loaded while the other is extracting.



An entirely self-contained oil extractor for removing oil from machine cuttings

General News

Locomotive and train cost statistics dispensed with

The Interstate Commerce Commission has amended its order relating to the compilation of monthly operating statistics, to annul the requirement of the reports of locomotive and train costs, selected accounts, except as to the reports to complete the twelve months of 1924.

Simultaneous application of M. C. B. couplers to all rolling stock in Japan

On some day in June, 1925, yet to be determined, the standard M. C. B. automatic coupler will be placed in service simultaneously on all the rolling stock of the Imperial Japanese Government Railways, replacing the manual type with side buffers now in use.

Wage statistics for September

The total number of employees reported by Class I railroads for the month of September, 1924, was 1,801,296, a decrease of 144,621, or 7.4 per cent as compared with the number reported for the same month of 1923, according to the Interstate Commerce Commission's monthly bulletin of wage statistics. The total compensation decreased $14,557,938 or 5.7 per cent. A comparison of the returns for the months of August and September, 1924, shows that in September the employment increased 0.7 per cent and the total compensation increased 0.5 per cent.

A. F. of L. condemns enginemen's brotherhood

The action of the chairman of the Brotherhood of Locomotive Engineers, in refusing to pay the union scale of wages in the brotherhood's mines in West Virginia and in replacing union miners with non-union workers, was condemned by the American Federation of Labor in resolutions adopted at the annual convention at El Paso, Tex., on November 22. The committee on resolutions reported to the convention that it had found there had been a strike in effect in four mines of the company in West Virginia since April 1, due to the failure of the company to renew a wage agreement; that the officers of the United Mine Workers of America had made repeated efforts to reach an agreement with the Brotherhood; that the miners and their families have been evicted from company houses and strike breakers have been employed.

In commenting on the adoption of the resolution, John L. Lewis, president of the Miners' Union, declared that "the refusal of the Coal River Collieries to deal with the United Mine Workers has been a scandal in the entire organized labor movement."

The convention also denounced the United States Railroad Labor Board and endorsed the Howell-Barkley railroad labor bill now pending in Congress.

Southern Pacific enginemen vote for strike

Although 90 per cent of the engine service employees on the Southern Pacific have voted in favor of a strike, there is little likelihood of such action being taken, at least for some time. William Sproule, president of the Southern Pacific, has made arrangements with the Brotherhood of Locomotive Engineers and the Brotherhood of Locomotive Firemen & Enginemen, representing the employees, to hold an early joint conference. The strike vote was taken as a result of the refusal of the management to renew direct negotiations with the brotherhoods on their request for general wage increases. The Southern Pacific was only one of the large number of western railways which participated in the dispute on the question before the Railroad Labor Board, but was picked out by the brotherhood executives as the road on which concerted efforts to secure acquiescence to their demands might best be made. The decision of the Labor Board which awarded a wage increase to the employees of 5 per cent on condition that they accept a number of changes in working rules apparently has not affected the situation on the Southern Pacific. Developments are being watched with great interest by the other roads involved in labor board decisions since the attitude of the brotherhoods toward the decision will be made known by the steps they take in the Southern Pacific case.

Higher wages will not necessitate higher rates

The Railroad Labor Board has denied the petition of the managers representing the Western Railways that the settlement made by the Southern Pacific with its enginemen and firemen be set aside. This petition averred that the proposed advance in wages would tend to necessitate general increases in freight rates. The board holds that there is no sufficient ground for this contention. The board considers only the increase on the Southern Pacific and compares only with that company's earnings. The board ignores the fact, presented by the managers, that the engine service brotherhoods had already gone to one other road with the demands that were made on the Southern Pacific; this as the first step in a campaign to have the Southern Pacific agreement apply generally to the western roads. The engine service brotherhoods were given until January 1 to agree to the provision of the Labor Board's decision in the case which ordered wage increases of six per cent, accompanied by changes in working rules which the brotherhoods violently opposed. There is no expectation among the western managements that this decision will receive any consideration whatever from the brotherhoods. If they ignore the decision, as is expected, the Board's finding provides that the same wage rates and working rules that have been in effect shall be continued.

A. R. A. to investigate power brakes

The American Railway Association has completed plans for a complete study and exhaustive investigation of power brakes and appliances for operating power brake systems. The investigation, the cost of which will be borne by the American Railway Association, will be conducted by Harley A. Johnson, assistant general manager of the Chicago Rapid Transit Railway, who, as director of research, will employ such assistants as may be necessary for conducting the work.

The American Railway Association, after conferences with the

Data from Car Service Division reports.

director of the Bureau of Safety of the Interstate Commerce Commission, has agreed on the following plan:

1. Steps will be taken to obtain appliances, which, it is claimed, meet the views of the Interstate Commerce Commission, as indicated in its preliminary report and conclusions. If the plans or specifications for such appliances are available and the appliances are not yet being manufactured, steps will be taken by the director of research to secure such appliances, even to the extent of entering into an agreement to have such appliances made.
2. As soon as such appliances have been obtained they will be given exhaustive tests on the test rack at Purdue University, Lafayette, Indiana, which rack will be completely prepared and brought up to date for the purpose of this investigation.
3. Following the completion of the rack tests such devices will be given road tests, to develop whether or not they meet road conditions safely in service.
4. This program will be carried out with all dispatch and as promptly as the devices for these tests are available.

The investigation will also embrace such further study as may in the judgment of the director of research throw further light upon this problem.

Court news

EMPLOYERS' LIABILITY.—The Kentucky Court of Appeals holds that neither a machinist in defendant's roundhouse, injured while engaged in setting valves on engines nor the railroad was engaged in either interstate or intrastate commerce, so that the state Employers' Liability Act, which only applies when railroad and injured person are "engaged in commerce," was not applicable.—Idol v. L. & N. (Ky.) 261 S. W. 878.

WRONGFULLY DISCHARGED EMPLOYEE MUST MINIMIZE DAMAGE BY TRYING TO OBTAIN OTHER EMPLOYMENT.—The Mississippi Supreme Court holds that a servant engaged for a specified time and wrongfully discharged must make reasonable exertion to prevent loss by obtaining other employment, and if he enhances his damages by wilfully or negligently remaining out of employment the increased loss must fall on him.—Batesville-Southwestern v. Vick (Miss.) 90 So. 7.

AGREEMENT REQUIRING SHIPPER TO INSPECT CARS HELD INVALID.—The Louisiana Supreme Court holds that a clause in a bill of lading requiring the shipper to inspect the carrier's own cars and assume the risk of defects therein is invalid because (1) it requires the shipper to assume a risk arising from the carrier's own negligence in failing to inspect; (2) shifts the burden of proof to the shipper, and (3) requires an unskilled person to make an inspection which only an expert can make.—Coustaline v. L. R. & N. (La.) 98 So. 81.

EVIDENCE OF DEFECTIVE COUPLER.—The Federal Safety Appliance Act makes the duty to maintain couplers in such condition that they will always couple automatically by impact absolute, and the Mississippi Supreme Court holds that where plaintiff's testimony showed that because of the use of a nail instead of a cotter pin in the drawhead, a coupling could not always be made by the ordinary use of the lift lever, the nail catching on a part of the drawhead, there was sufficient evidence of a defective coupling appliance and a violation of the act, though it was not shown that the injured employee attempted to use the lift lever.—Yazoo & M. V. v. Cockerham (Miss.) 99 So. 14.

Ask extension of time for train control

Petitions for a postponement of the effective date of the Interstate Commerce Commission's order of June 13, 1922, as modified by its order of July 18, 1924, requiring installations of automatic train control, have been filed with the commission by the Lehigh Valley, the Cincinnati, New Orleans & Texas Pacific and the Southern.

In the petition of the C. N. O. & T. P., and the Southern, it is stated that 35.5 miles between Ludlow and Williamstown, Ky., have been equipped with the auto-manual type of inductive train control and that the equipment is now ready for inspection by the commission, and that this has been asked for; and that, until this installation and its performance under actual operating conditions have been inspected and observed by the commission's representatives and a report made, the petitioners hesitate to go forward on a major scale with the work of equipping the remaining mileage required by the order. Therefore, further time is asked in which to comply with the mandate of the order, and it is stated that if the present installation is approved the roads will proceed as rapidly as possible to equip the remaining mileage as required by the order.

The Lehigh Valley petition asks for a postponement of the effective date for six months. It says that a contract has been made with the General Railway Signal Company for the installation of the auto-manual system between Easton, Pa., and Newark, N. J., and that the full roadside equipment has been installed between Phillipsburg and Flemington Junction, N. J., over 20 miles, while ten locomotives have been equipped. This, the petition says, constitutes a bona fide effort to secure and install a device that will comply with the commission's order, and warrants additional time to complete the work.

The Delaware & Hudson Company has petitioned the commission to be exempted from the order of June 13, 1922, contending that its financial condition does not warrant such expenditures when other improvements are needed. The company says it has made serious efforts to install the automatic train control, but that its experiments to date do not justify such an expenditure as the commission contemplates. Experiments have been made with many systems of automatic train control on three miles of road, but the device needs further development.

The railroad further says it has ordered all material for the installation of automatic train control, beginning at Rouses Point, N. Y., and extending southward for one division. It declares that this will be installed and tested as soon as possible.

Labor Board decisions

INTERPRETATION OF INTERMITTENT SERVICE RULE.—A decision on questions raised in regard to the meaning and intent of the Intermittent Service Rule of Decision No. 630 has been made by the Railroad Labor Board. The rule in question reads as follows: "Where service is intermittent, 8 hours actual time on duty within a spread of 12 hours shall constitute a day's work. Employees filling such positions shall be paid overtime for all time actually on duty or held for duty in excess of 8 hours from the time required to report for duty to the time of release within 12 consecutive hours, and also for all time in excess of 12 consecutive hours computed continuously from the time first required to report until final release. Time shall be counted as continuous service in all cases where the interval of release does not exceed one hour." In answering questions raised in regard to the rule, the Labor Board decides that the meal period provided for in other rules of the decision cannot be considered as a part of the period of release under the Intermittent Service Rule. The board also decides that a carrier is within its rights in applying Rule 49 to a position or positions without first reaching an agreement with the representatives of the employees as to whether the rule is applicable, the employees if they disagree with the management to take up the matter in accordance with the provisions of the Transportation Act. In interpreting the language of the rule reading:

FREIGHT CAR REPAIR SITUATION

1924	Number freight cars on line	Cars awaiting repairs			Per cent of cars awaiting repairs
		Heavy	Light	Total	
January 1	2,279,363	118,653	39,522	158,175	6.9

November	75,954	1,304,924	1,380,878

"Intermittent service is understood to mean service of a character where during the hours of assignment there is no work to be performed for periods of more than one hour's duration and service of the employees cannot otherwise be utilized," the board rules that whether the carrier is the sole judge as to whether or not there is work to be performed and if the service of the employees can otherwise be utilized shall be determined by the actual conditions in every case. The board rules also that it is not permissible to place an employee under the provisions of this rule by assigning his work to other employees so as to make it possible to allow him the period of release prescribed by the rule. Finally, the board rules that it is not permissible to place an employee on an intermittent service assignment where it can be shown that there is work to be performed during the period of release, even though the work can just as well be accomplished in a 12-hr. spread. An opinion dissenting from the decision of the board on the last two questions was rendered by Messrs. Elliott, Baker and Higgins, board members representing the railways.—Interpretation No. 3 to Decision No. 630.

Meetings and conventions

Mechanical division meeting in 1925

At a meeting of the General Committee, Division V—Mechanical A. R. A., held in New York, December 11, it was decided that the annual meeting of the Division for 1925 be a strictly business meeting, and that it be held in Chicago during the week commencing June 15.

It was decided at the meeting that the attendance at the Chicago meeting be restricted to the members of the General Committee of Division V, members of the various committees of Division V, and the voting representatives of the railway members of Division V, American Railway Association.

Later in the day of September 11, the General Committee of Division V met the Executive Committee of the Railway Supply Manufacturers' Association and announced the decision. J. J. Tatum, chairman of Division V, emphasized the fact that inasmuch as no exhibit of railway supplies and machinery would be held in 1925, it was to be hoped that in the following year a mechanical convention would be held with a larger and better exhibit than ever and a large attendance of railway supply men.

The following list gives names of secretaries, dates of next or regular meetings and places of meeting of mechanical associations and railroad clubs.

AIR-BRAKE ASSOCIATION.—F. M. Nellis, Room 3014, 165 Broadway, New York City. Next meeting May 5-8, Los Angeles, Cal.

AMERICAN RAILROAD MASTER TINNERS', COPPERSMITHS' AND PIPEFITTERS' ASSOCIATION.—C. Borcherdt, 202 North Hamlin ave., Chicago.

AMERICAN RAILWAY ASSOCIATION, DIVISION V.—MECHANICAL.—V. R. Hawthorne, 431 South Dearborn St., Chicago.

DIVISION V.—EQUIPMENT PAINTING DIVISION.—V. R. Hawthorne, Chicago. Business meeting to be held in Chicago during week commencing June 15. No exhibit of railway supplies and machinery will be held.

DIVISION VI.—PURCHASES AND STORES.—W. J. Farrell, 30 Vesey St., New York.

AMERICAN RAILWAY TOOL FOREMAN'S ASSOCIATION.—G. G. Macina, 11402 Calumet ave., Chicago.

AMERICAN SOCIETY OF MECHANICAL ENGINEERS.—Calvin W. Rice, 29 W. Thirty-ninth street, New York. Railroad Division, A. F. Steubing, Bradford Corp., 23 West Forty-third street, New York.

AMERICAN SOCIETY FOR STEEL TREATING.—W. H. Eiseman, 4600 Prospect Ave., Cleveland, Ohio.

AMERICAN SOCIETY FOR TESTING MATERIALS.—C. L. Warwick, 1315 Spruce St., Philadelphia, Pa.

ASSOCIATION OF RAILWAY ELECTRICAL ENGINEERS.—Joseph A. Andreucetti, C. & N. W., Room 411, C. & N. W. Station, Chicago, Ill.

CANADIAN RAILWAY CLUB.—C. R. Crook, 129 Charron St., Montreal, Que. Regular meetings second Tuesday in each month, except June, July and August, at Windsor Hotel, Montreal, Que.

CAR FOREMEN'S ASSOCIATION OF CHICAGO.—Aaron Kline, 626 N. Pine Ave., Chicago, Ill. Meeting second Monday in month, except June, July and August, Great Northern Hotel, Chicago, Ill.

CAR FOREMEN'S ASSOCIATION OF ST. LOUIS.—R. E. Giger, 721 North 23rd street, E. St. Louis, Ill. Meetings, first Tuesday in month, except June, July and August, at the American Hotel Annex, St. Louis.

CENTRAL RAILWAY CLUB.—H. D. Vought, 26 Cortlandt Street, New York, N. Y.

CHIEF INTERCHANGE CAR INSPECTORS' AND CAR FOREMEN'S ASSOCIATION.—A. S. Sternberg, Belt Railway, Clearing Station, Chicago

CINCINNATI RAILWAY CLUB.—W. C. Cooder, Union Central Building, Cincinnati, Ohio. Meetings second Tuesday, February, May, September and November.

CLEVELAND STEAM RAILWAY CLUB.—F. L. Frericks, 14416 Adler Ave., Cleveland, Ohio. Meeting first Monday each month at Hotel Cleveland, Public Square, Cleveland.

INTERNATIONAL RAILROAD MASTER BLACKSMITHS' ASSOCIATION.—W. J. Mayer, Michigan Central, 2347 Clark Ave., Detroit, Mich.

INTERNATIONAL RAILWAY FUEL ASSOCIATION.—J. B. Hutchinson, 6000 Michigan Ave., Chicago, Ill. Next annual convention May 26-29, Hotel Sherman, Chicago.

INTERNATIONAL RAILWAY GENERAL FOREMEN'S ASSOCIATION.—William Hall, 1061 W. Wabash St., Winona, Minn.

MASTER BOILER MAKERS' ASSOCIATION.—Harry D. Vought, 26 Cortlandt St., New York, N. Y. Next convention May 19-25, Hotel Sherman, Chicago.

NEW ENGLAND RAILROAD CLUB.—W. E. Cade, Jr., 683 Atlantic Ave., Boston, Mass. Regular meeting second Tuesday in month, except June, July, August and September, Copley-Plaza Hotel, Boston, Mass. Next meeting January 13. Paper on the Preservation of Forest Products will be read by Herman Von Schrenk, consulting timber engineer, New York Central.

NEW YORK RAILROAD CLUB.—H. D. Vought, 26 Cortlandt St., New York. Meeting third Friday of each month except June, July and August at 29 West Thirty-ninth St., New York.

NIAGARA FRONTIER CAR MEN'S ASSOCIATION.—George A. J. Hochgreb, 623 Brisbane Building, Buffalo, N. Y. Regular meetings, January, March, May, September and October.

PACIFIC RAILWAY CLUB.—W. S. Wollmer, 64 Pine St., San Francisco, Cal. Regular meetings second Thursday in month, alternately in San Francisco and Oakland, Cal.

RAILWAY CLUB OF GREENVILLE.—F. D. Castor, clerk, maintenance of way department, Bessemer & Lake Erie, Greenville, Pa. Meeting last Friday of each month, except June, July and August.

RAILWAY CLUB OF PITTSBURGH.—J. D. Conway, 515 Grandview Ave., Pittsburgh, Pa. Regular meeting fourth Thursday in month, except June, July and August. Fort Pitt Hotel, Pittsburgh, Pa.

ST. LOUIS RAILWAY CLUB.—B. W. Frauenthal, Union Station, St. Louis, Mo. Next meeting January 9. Paper on Railway Problems will be presented by Harvey Rubey, professor railway engineering, University of Missouri.

SOUTHEASTERN CARMEN'S INTERCHANGE ASSOCIATION.—J. E. Rubley, Southern railway shops, Atlanta, Ga. Next meeting January 13 and 14, Ansley Hotel, Atlanta, Ga.

TRAVELING ENGINEER'S ASSOCIATION.—W. O. Thompson, 1177 East Ninety-eighth St., Cleveland, Ohio. Annual meeting September, 1925, Chicago.

WESTERN RAILWAY CLUB.—Bruce V. Crandall, 189 West Madison St., Chicago. Meetings third Monday in each month, except June, July and August. Annual meeting May 23, Edgewater Beach Hotel, Chicago.

Supply Trade Notes

The Link-Belt Company, Chicago, has moved its St. Louis office to 3638 Olive street.

B. B. Phillips has resigned as general manager of the Gifford-Wood Company, Hudson, N. Y.

M. T. Lothrop has been appointed vice-president of the Timken Roller Bearing Company, Canton, Ohio.

T. R. Talbot, manager of the St. Louis district of the Republic Iron & Steel Company, has resigned.

The Link-Belt Company, Chicago, has opened a warehouse and office at 5938 Linsdale avenue, Detroit, Mich.

The Pawling & Harnischfeger Company, Milwaukee, Wis., has changed its name to the Harnischfeger Corporation.

The Wine Railway Appliance Company, Toledo, Ohio, will construct a plant in that city to cost approximately $150,000.

The corporate name of the Zapon Leather Cloth Company, Wilmington, Del., has been changed to the Zapon Company.

The Mid-West Engineering Company, Chicago, has moved its sales office to the Steger building, 28 East Jackson boulevard.

Johns-Manville, Inc., will establish a plant in New Orleans, La., the first unit of which will be equipped and in operation by April.

Samuel Hale, formerly vice-president of the Interstate Iron & Steel Company, Chicago, died at Santa Fe, New Mex., on October 25.

Charles H. Bromly has been appointed manager of the lubrication and filtration division of S. F. Bowser & Co., Ft. Wayne, Ind.

C. J. Thompson, district sales manager of the Osgood Company, with headquarters at Chicago, has been transferred to New York.

The Joyce-Cridland Company, Dayton, Ohio, has opened an office in the Railway Exchange building, St. Louis, Mo., in charge of R. C. O'Brien.

The Chicago Varnish Works, Chicago, Ill., will in the future be operated under the name of E. I. du Pont de Nemours & Co.—Chicago Works.

The Cleveland Twist Drill Company, Cleveland, Ohio, plans the construction of one, two and four-story plant additions to its factory at Cleveland.

T. E. Beddoe has been appointed industrial sales engineer of the Cutler Hammer Manufacturing Company, with headquarters at Philadelphia, Pa.

J. B. Marks, purchasing agent of the Colorado Fuel & Iron Company, with headquarters at Denver, Colo., has also been appointed assistant to the president.

Benjamin P. Lane has been appointed local manager of the newly opened branch office and warehouse of the Sullivan Machinery Company at Los Angeles, Calif.

W. S. Campbell has been appointed manager of domestic machinery sales in the eastern district for Joseph T. Ryerson & Company, Inc., with headquarters at Jersey City, N. J.

J. F. Kroske has been appointed manager of pneumatic tool sales for the Ingersoll-Rand Company, in the Pittsburgh territory. Mr. Kroske's headquarters are at Pittsburgh, Pa.

The Linde Air Products Company has opened a branch office at Salt Lake City, Utah, in charge of R. L. Strobel and another office at Seattle, Wash., in charge of C. E. Rheim.

The Union Metal Products Company will expend $500,000 for the remodeling of its plant at Hammond, Ind., which it recently acquired from the Keith Railway Equipment Company.

D. E. Sawyer, formerly general sales manager of the Pollak Steel Company, New York, has been appointed vice-president of the Wanner Malleable Castings Company, Hammond, Ind.

Martin H. Schmid, metallurgical engineer of the United Alloy Steel Corporation, has been appointed assistant general manager of sales of the alloy division, with headquarters at Canton, Ohio.

P. Blair Lee, who has been engaged in special work for the vice-president and general manager of Birdsboro Steel Foundry & Machine Company, Birdsboro, Pa., has been appointed works manager.

The Southwark Foundry & Machine Company, Philadelphia, Pa., has discontinued its Cleveland office. This office is now located at 100 East South street, Akron, Ohio, in charge of F. H. Smith.

The Dallas office of the Franklin Railway Supply Company, under the supervision of S. D. Rosenfelt, district manager, have been moved to the Boatmen's Bank building, 314 North Broadway, St. Louis, Mo.

N. C. Failor Company, 30 Church street, New York, and G. A. Pabst, 106 South Jefferson street, Chicago, have been appointed direct sales representatives of the Stockbridge Machine Company in their respective territories.

C. S. Price, First National Bank building, Hazelton, Pa., has been appointed district representative for northeastern Pennsylvania of the Conveyors Corporation of America, Chicago. E. F. Elliott is associated with Mr. Price.

The Gibb Instrument Company, Bay City, Mich., has changed its name to the Gibb Welding Machine Company. The company is now engaged exclusively in the manufacture of electric welding and heating machines. There has been no change in organization.

Glen D. Evans, for many years connected with the J. F. Buhr Machine Tool Company, but more recently chief engineer of the Climax Engineering Company, at Los Angeles, Cal., has again joined the Buhr organization in the capacity of chief engineer.

T. R. Langan has been appointed manager, transportation division in the New York office of the Westinghouse Electric & Manufacturing Company to succeed A. J. Manson recently promoted to manager, heavy traction division of the railway sales department at East Pittsburgh, Pa.

The American Car & Foundry Company has sold to a Canadian syndicate its stockholdings in the Canadian Car & Foundry Company. It is understood that two or three Canadian men will replace the American Car & Foundry representatives who were elected to the directorate at the time of the stock purchase in 1920.

O. M. Bostwick, New York representative of the publicity department of the General Electric Company and formerly advertising manager of the Sprague Electric Works, has resigned. After a short vacation, it is expected that Mr. Bostwick will resume his activities in the technical publicity field in New York City.

The U. S. Metallic Packing Company, Philadelphia, Pa., has taken over the entire business of the Locomotive Lubricator Company, of Chicago, manufacturers of the Schlacks system of force feed lubrication. W. J. Schlacks, C. W. Rudolph and O. H. Neal, formerly of the Locomotive Lubricator Company, have become affiliated with the U. S. Metallic Packing Company.

The Milburn Sales Company, distributors in the Philadelphia territory for the Alexander Milburn Company, Baltimore, Md., makers of oxy-acetylene welding and cutting apparatus and portable carbide lights, has taken over the Metropolitan New York district with headquarters at 309 Fifth avenue. E. P. Boyer, D. Keyser and other assistants will be in charge of the New York City office.

E. A. Thornwell has been appointed representative of the Premier Staybolt Company, Pittsburgh, Pa., in the southeastern district, with headquarters in the Candler building, Atlanta, Ga., and E. B. Corbett has been appointed representative in the southwestern district, with headquarters at the corner of Sawyer and Winter streets, Houston, Tex. The company was previously without representation in these districts.

J. B. Odell, manager of the New York telephone distributing house of the Western Electric Company, New York, has been appointed assistant to the president of the company. Mr. Odell

has been in the service of the Western Electric Company since 1904. He served in 1909 as head of the equipment division of the telephone department at New York, and the following year became assistant manager. He later was manager at Richmond, Va., before becoming manager of the New York house.

The Hopp-Patterson Company has been organized under the laws of Illinois to engage in selling industrial equipment and supplies in Chicago. The organizers are J. H. Hopp, former vice-president of the Charles C. Kawin Company, and J. B. Patterson, district manager of the P. H. & F. M. Roots Company, Connersville, Ind. The equipment to be handled by the new company includes steam and centrifugal pumps, conveying and transmission equipment and air compressors.

A. A. Corey, Jr., president of the Vanadium Corporation of America, New York, announces that an arrangement has been made with the United States Ferro Alloys Corporation for the merging of that concern with the Vanadium company. The plan involves the acquisition of complete control of the operations and affairs of the Alloys company immediately, but the corporate organization will be maintained. Mr. Corey, president, and L. K. Diffenderfer, treasurer of the Vanadium Corporation have been elected also president and treasurer respectively of the United States Ferro Alloys Corporation.

A. H. Weston, sales engineer of the T. H. Symington Company, with headquarters at New York, has been elected vice-president in charge of sales of the Car Devices Company, with headquarters at Richmond, Va. Mr. Weston obtained his early mechanical training in the motive power department of the Baltimore & Ohio and the Western Maryland and was for several years mechanical engineer for the Atlantic Coast Line. He left railroad service to enter the employ of the T. H. Symington Company as mechanical engineer and for the past ten years has been sales engineer for the same company, with headquarters at New York.

Arthur J. Manson, manager of the transportation division, railway department, of the New York office of the Westinghouse Electrical & Manufacturing Company, has been appointed to the position of manager of the heavy traction division, railway department, at Pittsburgh, Pa., effective November 1. After graduating from the Massachusetts Institute of Technology in 1905, he entered the company's engineering apprentice course and assisted in the building and testing of the first electric locomotive for the New York, New Haven & Hartford. In the spring of 1907 he was assigned to the electrification work on this road and aided in the inauguration of the electric service. In this position he instructed the steam enginemen in their duties as electric enginemen. Mr. Manson was associated with the preliminary test conducted by the Pennsylvania Railroad on Long Island prior to the decision as to the system to be used in the Pennsylvania tunnels entering New York City. Later he became associated with F. H. Shepard, director of heavy traction, entering the New York office of the Westinghouse Company. He assisted Mr. Shepard in connection with the Pennsylvania contract for power house, substation and locomotives for the Pennsylvania New York tunnel electrification. In 1910 Mr. Manson entered the sales department of the New York office following construction, subway and elevated work. In 1920 he was made manager of the transportation division of the New York office which position he held at the time of his recent appointment. During the time when Mr. Manson was manager of the transportation division he wrote and published a book entitled Railway Electrification.

A. J. Manson

Trade Publications

Thermaload starters.—Bulletin No. 106, descriptive of the thermaload starter for small alternating current motors, has been issued by the Monitor Controller Company, Baltimore, Md. An alternating current contractor combined with a thermal relay are the essential parts of this starter.

Electric equipment for cranes.—A 35-page bulletin, No. 48732, descriptive of electric equipment for cranes, has been issued by the General Electric Company, Schenectady, N. Y. Particular reference to crane motors and control, brakes, etc., is made and information is given on operating characteristics.

Hammers.—The Blacker "B" hammers, designed especially for tool dressing and general utility jobbing work, are described in an 8-page illustrated brochure issued by the Blacker Engineering Company, Inc., New York. The hammer travels over the anvil face performing hand forging and smithing operations without helpers.

Arches.—A 50-page catalogue showing the adaptability of its arches to all types of boilers and stokers, industrial furnaces and oil stills, has been issued by the M. H. Detrick Company, Chicago, Ill. The application of the Detrick sectional supported wall to pulverized fuel furnaces is described for the first time in this catalogue.

Electric tools and shop equipment.—Drills, bench and pedestal grinders, tappers, screw drivers, socket wrenches, post and bench drill stands, etc., are among the electric tools and shop equipment illustrated and described in the attractive 32-page catalogue, No. 8, recently issued by the Black & Decker Manufacturing Company, Towson, Md.

Bolt heading machine.—The Ajax Manufacturing Company, Cleveland, Ohio, has just issued bulletin No. 50, which is well illustrated and tells the complete story of the new heavy duty continuous motion heading machines for making bolts and rivets. This new machine contains some important improvements which should interest those who have anything to do with machinery of this type.

Turret lathes.—The No. 4 Universal turret lathe, which permits independent operation of two tool carrying units, the cross slide carriage and the hexagon turret slide and saddle, is fully described in a 12-page illustrated brochure issued by the Warner & Swasey Company, Cleveland, Ohio. Quick change of set-up from one job to another is provided and measuring, due to positive stops, is eliminated.

Exhaust steam injectors.—A 23-page illustrated booklet giving description and instructions for the installation and operation of the Elesco exhaust steam injector, has just been issued by the Superheater Company, New York. The theory and advantages of the injector are also briefly covered and test results from the New York, Ontario & Western and foreign roads are given on inserts in the back of the book.

Superheater dampers.—An 8-page bulletin, No. 3, descriptive of superheater dampers, designed to regulate the flow of gases through the large flues when the throttle is open or closed, has been issued by the Superheater Company, New York. Cross-sectional drawings show the damper conditions with different link lengths, also the general arrangement of damper cylinder and rigging and method of pipe lagging for road locomotives.

Expansion boring tools and reamers.—A complete description of the various types of expansion boring tools and reamers is given in catalogue No. 24, which contains 71 well illustrated pages and has just been issued by the Davis Boring Tool Company, St. Louis, Mo. The catalogue contains much valuable information pertaining to where and how to best apply these tools in order to obtain the maximum service from them. The last few pages contain illustrations showing all the various types of tools manufactured by this company and explains for what work they can be best adapted.

Personal Mention

General

C. W. Dysert has been appointed mechanical engineer of the Southern Pacific, Louisiana Lines, with headquarters at Houston, Tex., succeeding J. S. Netherwood.

R. L. Ettenger, formerly consulting mechanical engineer of the Southern, has been promoted to assistant vice-president, mechanical, with headquarters at Washington, D. C.

J. T. Leach, assistant master mechanic of the Eastern division of the Pennsylvania, has been promoted to master mechanic of the Wheeling division, succeeding P. M. Cheesman.

B. M. Swope, master mechanic of the St. Louis division of the Pennsylvania, with headquarters at Terre Haute, Ind., has been transferred to the Buffalo division, succeeding F. J. Huston.

P. M. Cheesman, master mechanic of the Wheeling division of the Pennsylvania, with headquarters at Mingo Junction, Ohio, has been transferred to the St. Louis division, succeeding B. M. Swope.

J. S. Netherwood, mechanical engineer of the Southern Pacific, Louisiana lines, has been promoted to assistant superintendent of motive power and equipment of the Louisiana lines, with headquarters at Algiers, La., succeeding B. M. Brown, whose promotion to chief assistant superintendent of motive power of the lines in Texas and Louisiana was reported in the December issue of the *Railway Mechanical Engineer*.

R. H. Bates has been appointed mechanical engineer of the Chicago Great Western, with headquarters at Oelwein, Iowa. He was born on June 11, 1889, at Altoona, Pa., and graduated from the Williamson Trade School in 1909, attending Northwestern University in 1921 and 1922. He entered railway service as a draftsman in the mechanical engineer's office of the Pennsylvania, with headquarters at Altoona, Pa., in August, 1909, and served in that position until September, 1911, when he was appointed draftsman on the Northern Pacific, with headquarters at St. Paul, Minn. He returned to the Pennsylvania as a draftsman, with headquarters at Ft. Wayne, Ind., in June, 1913, serving until October, 1917, when he entered the United States Army, serving in France from February, 1918, to March, 1919, with the Meteorological Division, Signal Corps. In May, 1919, he re-entered the service of the Pennsylvania lines west as chief draftsman, Northwest System, with headquarters at Pittsburgh, Pa., serving in that position until March, 1920, when he was promoted to motive power inspector, with headquarters at Chicago, which position he held until July, 1920. From September, 1920, to July, 1921, he served as senior mechanical engineer of the Interstate Commerce Commission, Bureau of Valuation, with headquarters at Chicago. He was employed as a car designer and checker of the American Car & Foundry Company, with headquarters at Chicago and New York, from March, 1922, to March, 1923, on the latter date being appointed chief draftsman of the Standard Stoker Company, which position he held until August, 1924, serving as acting mechanical engineer in charge of research and development work from January until June, 1924. On October 8, 1924, he was appointed to his present position as mechanical engineer of the Chicago Great Western, with headquarters at Oelwein, Iowa.

Master Mechanics and Road Foremen

M. A. Vaugh has been promoted to assistant road foreman of engines of the Cincinnati division of the Pennsylvania.

Vernon Hathaway has been promoted to assistant road foreman of engines of the Columbus division of the Pennsylvania.

J. McDonough, division master mechanic of the Atchison, Topeka & Santa Fe, with headquarters at Chicago, has retired.

G. R. Miller has been appointed master mechanic of the Slaton division of the Panhandle & Santa Fe, with headquarters at Slaton, Tex., succeeding W. W. Walker.

G. S. Emrich, assistant master mechanic of the C. & P. division of the Pennsylvania at Cleveland, Ohio, has been transferrred to Akron, Ohio, as assistant master mechanic of the Akron Division.

F. T. Huston, master mechanic of the Buffalo division of the Pennsylvania, with headquarters at Olean, N. Y., has been transferred to the Renovo division, with headquarters at Erie, Pa., succeeding J. B. Kapp, transferred.

John P. Morris, general foreman of the Atchison, Topeka & Santa Fe, at Shopton, Iowa, has been promoted to master mechanic of the Illinois division, with headquarters at Chicago, succeeding J. McDonough.

A. R. Sykes, assistant mechanical inspector of the Missouri Pacific, with headquarters at St. Louis, Mo., has been promoted to master mechanic of the newly created Little Rock division, with headquarters at McGehee, Ark.

E. A. Koschinske has been appointed superintendent of the locomotive shops of the Delaware, Lackawanna & Western at Scranton, Pa., succeeding J. R. Lancaster, resigned. Mr. Koschinske, who was born on February 21, 1888, at Scranton, entered the employ of the Delaware, Lackawanna & Western, in July, 1903.

W. W. Walker, master mechanic of the Slaton division of the Panhandle & Santa Fe, with headquarters at Slaton, Tex., has been transferred to the Pecos division of the Atchison, Topeka & Santa Fe, with headquarters at Clovis, New Mex., succeeding M. H. Haig, whose death was announced in the December issue of the *Railway Mechanical Engineer*.

Car Department

Harry Saunders has been promoted to car foreman of the Canadian National, with headquarters at Readville, succeeding A. Ludon, deceased.

J. A. Roberts has been appointed special inspector of the car department of the Chesapeake & Ohio, reporting to Paul Maddox, superintendent car department.

Shop and Enginehouse

E. C. Hanneman has been promoted to general foreman of the Atchison, Topeka & Santa Fe, with headquarters at Shopton, Iowa, succeeding J. P. Morris.

A. M. Semon, machine shop foreman of the Atchison, Topeka & Santa Fe at Chanute, Kan., has been promoted to assistant roundhouse foreman, with headquarters at Arkansas City, Kan.

A. B. Erickson, formerly gang foreman of the Chicago & Alton at Bloomington, Ill., has been appointed general foreman of the Missouri Pacific, with headquarters at Hoisington, Kan.

J. S. Ford, road foreman of engines of the Chicago, Burlington & Quincy, with headquarters at Aurora, Ill., has been promoted to assistant master mechanic of the Galesburg division, with headquarters at Galesburg, Ill., a newly created position.

P. A. Meyer, general foreman maintenance of equipment department of the Panhandle division of the Pennsylvania at Scully, Pa., has been appointed general foreman of the scrap dock and reclamation plant, Eastern division, with headquarters at Conway, Pa.

Purchasing and Stores

E. L. Cates has been appointed acting division storekeeper of the Minnesota division of the Northern Pacific, succeeding R. G. Becker.

J. C. Neph has been appointed assistant district storekeeper of the Eastern district of the Southern Pacific, with headquarters at El Paso, Tex.

John W. Cockrill has been appointed division storekeeper of the Illinois Central, with headquarters at Clinton, Ill., succeeding R. E. Downing, resigned.

A. L. Tucker, assistant general storekeeper of the Chicago & North Western, with headquarters at Chicago, has retired on pension after 45 years of service with the North Western.

R. G. Becker, division storekeeper of the Minnesota division of the Northern Pacific, with headquarters at Staples, Minn., has been transferred to the St. Paul division, with headquarters at St. Paul, Minn., succeeding W. L. Peabody, who has been assigned to reclamation work at Brainerd, Minn.

Railway Mechanical Engineer

Vol. 99 February, 1925 No. 2

Order your indexes

Indexes for the twelve issues of the *Railway Mechanical Engineer* published during 1924 are now ready for distribution. These are sent only to those of our subscribers who place orders for them with our circulation department, as it has been found that many of our readers have no use for them. If you wish to have a copy to include with your bound volume, or for use in referring back to the unbound copies, your order should be placed at once.

Safety appliance violations

One of the most prolific sources of violations of the United States Safety Appliance Laws is at interchange points. One road delivers cars to another with defective safety appliances and the receiving road moves them to its yard, thus making two distinct violations of the law, one by each carrier. This situation should not exist, as the law is well established that the delivering road cannot legally offer in interchange cars with defective safety appliance equipment. The law permits only such movement by the carrier on whose line the equipment becomes defective as is necessary for the repair of the defective appliance, and then only when such movement is necessary for purposes of repair. The movement to an interchange track cannot be justified as a movement for the purpose of repair. The receiving carrier cannot legally move the car, even for the purpose of repair, as it did not become defective on its line of road. The remedy for this situation lies in adequate inspection and proper repairs prior to assembling the cars for interchange movement, thereby eliminating the necessity of refusing such equipment on the part of the receiving carrier as well as the extra handling involved to make the repairs after the cars have been offered for interchange.

Fuel economy at power plants

Elsewhere in this issue is an article entitled "Fuel economy at Southern Pacific power plants," which deserves the careful study of every mechanical department officer responsible for the efficient operation of railway power plants. Many power plants need improvements which would involve considerable capital expenditures. It is also true that hardly any power plants are so efficiently operated that further economies cannot be made by the careful attention to certain minor defects capable of correction at small expense. The article referred to describes a comprehensive plan for improving the efficiency of operation of 94 stationary boiler plants located at various points on the Texas Lines of the Southern Pacific. The total cost of the oil consumed at these plants in 1923 was over $600,000, so the possibilities of saving were correspondingly great. When the work of making the improvements is completed it is anticipated that at least $125,000 will be saved annually, with an expenditure for minor improvements not exceeding $25,000.

The article is especially valuable because it shows in detail the improvements made, their cost, and the savings effected at one of the 94 terminals, namely, the passenger locomotive terminal at Houston, Texas. In this particular case the saving was $15,000 a year, or 38 per cent of the total 1923 fuel cost at that point. Some of the improvements made at Houston include such small but important items as the installation of oil-measuring meters, removal of dead-end steam pipes, insulation of boiler drums and steam pipes, repairs to dampers, installation of soot blowers, etc.

It has been said that the subject of the economical operation of stationary boiler plants is one which the railroads in general have neglected. Whether that is true or not, the experience of the Southern Pacific seems to indicate that it will pay to make a careful check at every railway power plant and ascertain if the proper attention is being given to economical operation.

Uniform location for conductor's valve

Among the subjects discussed at a recent meeting of the Manhattan Air Brake Club was "what should be the proper location of the conductor's or emergency brake valve." The interior design of many of the modern types of passenger equipment do not permit a cord from the conductor's valve to be run through the car. Some roads have abolished the cord in order to remove the temptation of an excited passenger to pull it. Thus, in case of an emergency necessitating the use of the conductor's valve, the trainman must go to the valve itself, which is usually located at one end of the car. Some of the cars recently built have a conductor's valve at each end, but this practice has not been extended to all types of equipment now being built, the design of which prohibits the use of a conductor's valve cord.

The importance of having the conductor's valve in a location of easy access to the members of the train crew should not have to be explained to any one familiar with passenger train operation. The function of the conductor's valve is in many respects the same as that of a fire alarm box in a factory or large office building. In a great many states the installation of such devices is demanded by a law, which usually provides for periodic inspection and demands that the floor space around the fire alarm box be kept clear of obstruction and easy of access at all times. This idea might also be used to good advantage in the selection of a location for the conduc-

tor's valve. Like a fire alarm box, the conductor's valve is seldom used but when it is used, it is usually badly needed.

The question of a standard location for the conductor's valve for all passenger equipment not equipped with a cord, should also be given consideration. Few trainmen take the trouble to ascertain the location of the conductor's valve in all of the cars in a train before starting out on a run and even if this were done, they would probably not remember if an emergency should arise. Perhaps if the valve was placed in a standard location for all passenger equipment considerable confusion might be avoided at an inopportune time.

The members of the Manhattan Air Brake Club have submitted this question for the consideration of other air brake clubs throughout the country, and it is hoped that consideration will be given to this important subject by the proper committee of the Air Brake Association. A number of accidents have occurred in recent years through the misuse and nonuse of the conductor's valve and there is no reason why they could not be prevented to a large extent by seeing that this valve is properly located.

Make use of the test plant

Elsewhere in this issue will be found a description of a locomotive which represents one of the most important pioneer efforts in locomotive design and proportions which has ever taken place. The principal purpose of the design is to make available the possible increase in thermal efficiency offered by the use of high steam pressure. In adapting the locomotive to the development and use of steam at 350 lb. boiler pressure, two outstanding departures have been made from the usual type of locomotive construction. One of these lies in the boiler in which a large amount of stayed heating surface in the firebox has been replaced with water tubes. Indeed both the construction and the proportions of this boiler are so different from anything heretofore employed in American practice that it would be difficult to predict just what results it will produce, either as to maintenance or steam production performance. The other innovation is the reintroduction of cross-compound cylinders, which disappeared from American practice about twenty years ago.

The real test of a locomotive is its performance in actual road service. This, and this alone, can determine the practicability of the mechanical design both from the operating and maintenance standpoint. After this has been determined, however, assuming that the verdict is favorable to the fundamentals of the new design, much more is necessary before a sound engineering basis will be available on which to make the most effective use of the principles back of the new design. In this case, for instance, it has been estimated partly on theoretical considerations and partly on the basis of experience with other types, that the special features of the new locomotive will effect a combined fuel economy of about 39 per cent in fuel consumption per horsepower-hour as compared with locomotives of straightforward conventional design and proportions.

It is tremendously important for the future development of the steam locomotive in America that accurate data be made available on which may be determined the extent to which these estimates are justified, and this data should be determined in such detail that its analysis will give a clear idea of the relative value of the different factors which go to make up the overall result. Such data can best be made available by operating the locomotive on a testing plant and, unless the preliminary road service trials prove the locomotive to be a complete failure, it will be unfortunate indeed for American railroads if complete test plant results for this locomotive are not ultimately made available.

More specialized men needed

One of the things most needed to increase the efficiency and general effectiveness of railroad mechanical departments is a larger staff of better paid, more highly specialized men in charge of the various branches of maintenance of equipment work. It is not the intention in this editorial to discuss the question of how many men a shop foreman or gang leader can efficiently supervise, although this question is a timely one and of great importance. It is of still greater importance, however, to the railroads, that adequate general supervision be provided for this department, to which is assigned the tremendous task of maintaining the cars and locomotives in this country in condition for safe and economical operation.

Without attempting to make an impression with large total figures, some idea of the magnitude of the work may be gained from the statement that on quite a number of individual railroads in the United States the labor payroll in the mechanical department for 1925 will exceed 20 million dollars, and the expenditures for material 80 per cent of this sum in addition. Statements have been made comparing the efficiency of the conduct of modern industrial enterprises and the railroads to the disadvantage of the latter. If railroad mechanical departments are not as efficient as they might be—and where is the railroad officer who would say they are—may not the trouble be lack of adequate, specialized, general supervision? What business involving the expenditure of 36 million dollars annually for labor and material would expect to conduct its affairs without a board of directors, president, series of vice-presidents, general manager, district managers and other general officers, not only exceeding in number the staff of the average superintendent of motive power but receiving vastly higher salaries?

In the opinion of the *Railway Mechanical Engineer* the average mechanical department executive in the general office is loaded down with duties in excess of his capacity to handle them efficiently and his difficulties are accentuated by the fact that the railroad is an institution primarily of length, with shops, terminals and power plants located at various points from one end of the system to the other. In other words, the officer must spread himself over a great deal of territory, spending much time in travel which the ordinary business executive can utilize by getting further into the details of his business. In view of this condition it would be reasonable to suppose that the railroads should have more, rather than less, general supervision than that found necessary in other industries.

Many instances could be cited to show the load under which mechanical department officers are expected to labor and yet produce approximately 100 per cent results. The general superintendent of motive power of one of the large midwest railroads is known to spend practically all his waking hours, usually not less than 17 out of each 24 hours, traveling, studying problems and making decisions either directly or indirectly connected with the conduct of the vast property over which he has general supervision. With little or no vacation, this man labors year in and year out and it is a continual source of surprise to his staff and acquaintances that he does not break down under the nervous strain of attempting to perform all the duties which in his opinion require the personal

attention of the officer in charge of the mechanical department.

Another case might be mentioned in which the general machine tool expert of a big railroad system is also responsible for the general efficiency of operations in all the shops. In this capacity he is installing a bonus system at one shop on the road. In addition, he sometimes instructs the apprentices, and, while it seems hardly credible, it is also reported on good authority that when an epidemic of rod failures, stoker failures, or what not, occurs, this combination machine tool expert, production engineer and apprentice instructor is sent out to investigate and report on the trouble.

The case cited may be extreme, but it certainly indicates in no uncertain way how short-handed some mechanical departments are in the general office. Let us have more specialized men, better trained and better paid, to exercise general supervision over the various important branches of mechanical department work.

Machine tools improve in design

During the past year the *Railway Mechanical Engineer* has published in its New Devices section 192 descriptions of various types of machine tools which could be used in railway shops. To one who has followed these descriptions, the progressiveness of the machine tool manufacturers in developing equipment to meet the large variety of conditions encountered in the railway shop is evident from the numerous designs of new and improved machine tools and auxiliary devices that are continually being introduced. A review of the recent developments of modern equipment shows a number of well defined trends, a knowledge of which may well prove of interest and value to those whose duties require them to make the final selection in the purchase of new tools.

The selection of a tool is first based on the primary requirements for which the tool is intended. These may be either representative production, accurate production, simplicity of design, or adaptation to a wide range of work. The efficiency of a given machine and its durability under service conditions are points that have a most decided influence upon the design and general arrangement. Consideration must also be given to the preservation of the original accuracy of alinement between important machine tool members by reducing wear and by adequate means of compensating for unavoidable wear. To obtain this result in a machine tool involves not only the design of adequate bearing surface for the use of special bearings, but effective lubrication and protection against dust or gritty material that might injure the bearing surface.

One of the outstanding characteristics in recent machine tool design has been the care given to the proper location of levers relative to the operator's normal working position. Considerable progress has also been made in reducing the number of controls as well as in simplifying their arrangement. The designers' object in focusing their attention upon these features has been to increase the output of the operator through the convenience of the control mechanism and to safeguard both the operator and the machine itself. The methods of transmitting power in machine tools either for driving the cutters or the work, or for feed movements, have been subject to constant improvement. One of the principal improvements in this respect is the use of helical gears for connecting parallel shafts. This method of gearing provides smooth transmission free from injurious vibrations. The use of special steels and heat treated gears is also becoming quite general, the hardened gears in some cases being ground to eliminate even the slightest distortions caused by heat treatment. Again, considerable attention has been given to the methods of controlling speeds and feeds. They are being simplified considerably so that operators can readily determine how to make changes, thus being encouraged to alter speeds or feeds whenever advantageous from the viewpoint of production.

Almost without exception in every machine of major importance which was described in the pages of this magazine last year the motor drive was an integral part of the machine. Improved methods of mounting the motors have been devised, in order to minimize vibrations and to make the motor an integral part of the general design. Where suitable interior space is available the motors have been installed inside the base or frame of the machines. The object of this is to protect it from dust and dirt and conserve valuable floor space. The use of variable speed transmissions of the geared type has been eliminated in certain machines by arranging the motors to give speed variations which can be used for securing different changes of speed when required. Independent motors are also being used for the movement of different parts of some machines. For example, a recent design of a heavy duty vertical boring mill includes a separate motor for power rapid traversing the saddles and tool spindles, and a planer recently put on the market has a separate motor for moving the cross rail and side head.

The hydraulic form of transmission has replaced the mechanical transmission on certain machine tools and the present trend is toward a wider application of the hydraulic type. This form of transmission is utilized with the idea of obtaining an unusually smooth action and flexibility of control that is beyond the range of mechanical transmission. This type of transmission has been utilized more particularly for grinding machines. Some applications have also been made on woodworking machinery.

In the class of service for which the average railway machine tool is used, the vibration set up in it should be reduced to the minimum. There are many methods used by the builders to eliminate vibration. One of the methods employed in accomplishing this result is the use of massive members that are much stronger and heavier than are required for strength alone. The manufacturers also have paid particular attention to torsional vibration. A car wheel boring mill was recently designed with special attention paid to the elimination of vibration. The housings are bolted, dowelled and tongued to the extension and tied together on top of a heavy box arch.

More attention is being paid to the lubrication of machine tool bearings owing to the higher speeds and bearing pressures incidental to the high duty operation required of the tools. Lubrication is accomplished in some cases by a pump and a centralized special tank with circulation to the moving parts and back to the pump. In others the splash system or an oil-tight case for submerged lubrication is used. The automatic control of the flow of cooling compounds or oils, to facilitate reloading and inspection of work, is another feature that is becoming common to certain designs of machine tools.

The review given here is necessarily incomplete. But it is evident that the machine tool manufacturers are constantly introducing designs which, in many instances, represent a vast amount of research and experiment. The railroads ultimately benefit by this research when they buy new machine tools which, if properly used, increase their production and materially reduce the cost of the maintenance of cars and locomotives.

New Books

Recent Progress in Engineering Production. *By C. M. Linley, consulting engineer. 340 pages, illustrated. 7 in. by 9½ in. Price 42 s. Published by Ernest Benn Limited, 8 Boverie street, E. C. 4, London, England.*

The cost of production is the most serious problem confronting industry today. The main direction in which economy of operation can be sought is obviously in the employment of the most up-to-date time and labor saving machines and appliances. This book contains 51 well illustrated chapters dealing with all kinds of machines and appliances used in the industrial field. It covers the products of machine tool builders of the United States and England and describes the machines built in both countries which the author believes to be best suited for the particular class of work which he may be describing. The book will serve as a reference work to those in the industrial field whose duties require them to select machines for various classes of work.

Aside from that part of the text dealing particularly with machine tools and their uses, the author has described in a general way the equipment and practices common to case hardening and heat control, metal cutting by means of machine controlled oxygen jets and has included chapters on pattern making, and the use of aluminum alloys with a brief description of extrusion processes. As a whole this book constitutes a broad treatment of modern industrial plant equipment and practices.

Arc Welding and Cutting Manual. *A 127-page, 7¾ in. by 10½ in. illustrated manual. Published by the General Electric Company, Schenectady, N. Y.*

The purpose of this manual is to acquaint the uninformed in a general way with some of the applications of arc welding, and to provide a simple and logical method by which one may acquire a certain familiarity with the manipulation of the electric welding arc and its characteristics. The volume is well illustrated with photographs, diagrams and charts, explanatory of the text. It is divided into three parts, the first devoted to general information on arc welding, the second to a training course for operators and the third giving a number of applications of arc welding.

The general information deals with polarity and the source of welding current for the arc. The characteristics of a good arc are pointed out. Considerable attention is given to electrodes and accessories. The training course for operators is a timely subject and is developed in the text in such a clear manner that it can be readily used as a framework to organize a training course for operators by those who are desirous of obtaining skilled workmen. The welding of cast iron, manganese steel, structural steel, steel and iron alloys and non-ferrous metals is taken up from all practical angles. The manual should prove valuable in practically all industries and trades.

Handbook of Wooden Car Repairs. *By E. W. Hartough, formerly general car foreman, Missouri-Kansas-Texas, Pere Marquette, 219 pages 4½ in. by 9½ in., illustrated. Price* $2.50. *Published by the Simmons-Boardman Publishing Company, 30 Church street.*

The author describes the construction of and the repairs made to wooden cars, gondolas, box and stock cars, refrigerators and cabooses. Sections of the book are devoted to freight car roofs and car doors for all classes of house cars, both wooden and steel.

Part I deals with wooden flat cars and gondolas. General descriptions of these cars are given, particular attention being paid to sills and attachments, car floors and timbers liable to failure. The most economical methods of making repairs are then discussed. Part I concludes with an interesting explanation of brake gear. It takes up the methods of calculating the pull exerted by levers and total braking pressure. The fundamental brake gear is described. Attention is called to the results obtained by making wrong lever combinations.

The wooden box cars are taken up next with considerable attention to the methods of repairing the car body. This is followed by a discussion of stock and refrigerator cars and cabooses. An interesting explanation is given about insulating materials for the car body. The defects developed in insulation and in car construction are pointed out with suggestions as to how to make proper repairs. The standard types of ventilators and the ventilated and heated refrigerator cars receive considerable attention. Part 5 explains the various types of freight car roofs in use today. Their defects and remedies are clearly explained. The book concludes with a discussion of the construction, defects and method of making repairs to freight car doors.

Car Truck and Draft Gear Maintenance. *By E. W. Hartough, formerly general car foreman, Missouri-Kansas-Texas and Pere Marquette Railway. 158 pages, 4½ in. by 7½ in., illustrated. Price* $2.00. *Published by the Simmons-Boardman Publishing Company, 30 Church street, New York.*

The work of the railroad carman is so diversified that the writing of an average size book on the entire subject of car repairs would result in many important details receiving but scant attention, or being omitted entirely. This volume deals only with the construction and maintenance of car trucks and draft gears. For the sake of easy reference, five distinct separations have been made. Sections I and II cover arch-bar truck repairs, and Section III is devoted to the subject of cast steel and pressed steel side trucks. Sections IV and V go into draft gear repairs.

The first part of the sections dealing with car trucks goes into a detailed description of the general construction and operation of a freight car truck. Mention is also made of the causes and the methods of failure of the component parts. This is followed by the more important subject of repairs, including a description of the methods and the apparatus actually employed in car repair yards to repair the damaged parts of a truck in an efficient manner. Each part of the truck is considered in detail, beginning with general operations, such as jacking and the removal of bolts and nuts, and proceeding to repairs of a more easy nature, such as those that deal with the component parts of the truck side. The section on car trucks closes with a general description of trucks with cast steel or pressed steel side-frames, rigid bolster trucks and others constructed with the purpose of evolving a truck that will possess a maximum number of advantages with a minimum number of defects. Particular attention is given to the features which provide special advantages in assembling or that secure more efficient operation.

Sections IV and V pertaining to draft gears open with a detailed description of the construction and operation of the A.R.A. standard *D* type coupler. This is naturally followed by a discussion of the various types of draft arms in use and the methods of repairing them. Spring gears are considered first including a description of the construction, operation of parts liable to failure and methods of repair of the more common spring gears in

present day use. The concluding chapters deal with the numerous types of friction draft gears and methods for repairing them.

PULVERIZED FUEL, COLLOIDAL FUEL, FUEL ECONOMY, AND SMOKELESS COMBUSTION. *By Leonard C. Harvey. 466 pages, illustrated, 7½ in. by* 10 *in. Price* $18.00. *Published by the Macmillan Company, New York.*

This book presents to the reader the results of a thorough and intensive study of the various applications of pulverized fuel. A large part is devoted to the describing of successful systems for handling and burning this type of fuel in power plants as well as in the metallurgical and railway industries. The author has given the underlying principles and has shown the advantages and disadvantages that are liable to be incurred in the use of pulverized coal. In this, he has presented numerous extracts from the writings of engineers and scientists of many nationalities and has also shown the results of practical work performed by experts.

The book has 17 chapters, the first six of which are devoted to a contrast of past and present day practices, a discussion of the combustion of pulverized fuel, fuel conservation, the difficulties to be encountered in handling pulverized fuel and the various systems of washing and conveying. The remaining chapters are devoted to the application of pulverized fuel to various industries. Chapter 15 gives a discussion of the firing of locomotive boilers with pulverized fuel. This chapter gives an account of the most recent applications on various railroads both in this country and abroad. It also contains the results of comparative tests run with pulverized and lump coal and gives an interesting account of the various difficulties that were encountered and eventually overcome. The remaining portion of this chapter is devoted to descriptions of the various types of equipment. The last chapter contains an appendix which includes tables and data on combustion and firing efficiency, air mixtures and water vapor, etc. There is also a list of pulverized fuel installations in various parts of the world and a bibliography of recent articles and publications on this subject. The text of the book is well illustrated with drawings and photographs.

What Our Readers Think

Reclaiming files

CEBU, P. I.

TO THE EDITOR:

In the November, 1924, issue of the *Railway Mechanical Engineer,* James Sheridan of the Copper River & Northwestern, raised a question concerning the reclamation and recutting of files. I have had some experience in the reclamation of files with acid solutions and with the sand blast machine. There are various formulas for acid solutions.

Formula No. 1—Boil the files in a strong soda solution to clean off all grease, oil or gum, then dip for a few minutes in a bath of one part nitric acid and two parts water. The length of time is less on a fine file, as experience may suggest.

Formula No. 2—Wash the file in a warm potash solution to remove the grease and dirt, then wash in warm water and dry by heat. Put 1½ pints of warm water in a wooden vessel and place the files in it; add 3 oz. of finely powdered blue vitriol and 3 oz. of boric acid. Mix well and turn the files so that every one comes in contact with the mixture. Add 10½ oz. of sulphuric acid and ½ oz. of cider vinegar. Remove the files after a short time, dry thoroughly and rub them with olive oil, then wrap in porous paper. Coarse files should be kept in the mixture for a considerably greater length of time than is necessary for the fine ones.

The above formulas are for files that are not wearing out, but only such files as have been used on soft metals, such as brass, copper and white metals. The teeth become filled up with the metals. It is believed that the most economical process for the reclamation of files is the sand blast machine.

J. T. BOOTES,
Division foreman, Philippine Railway.

Using dividers to set valves

PORTLAND, ME.

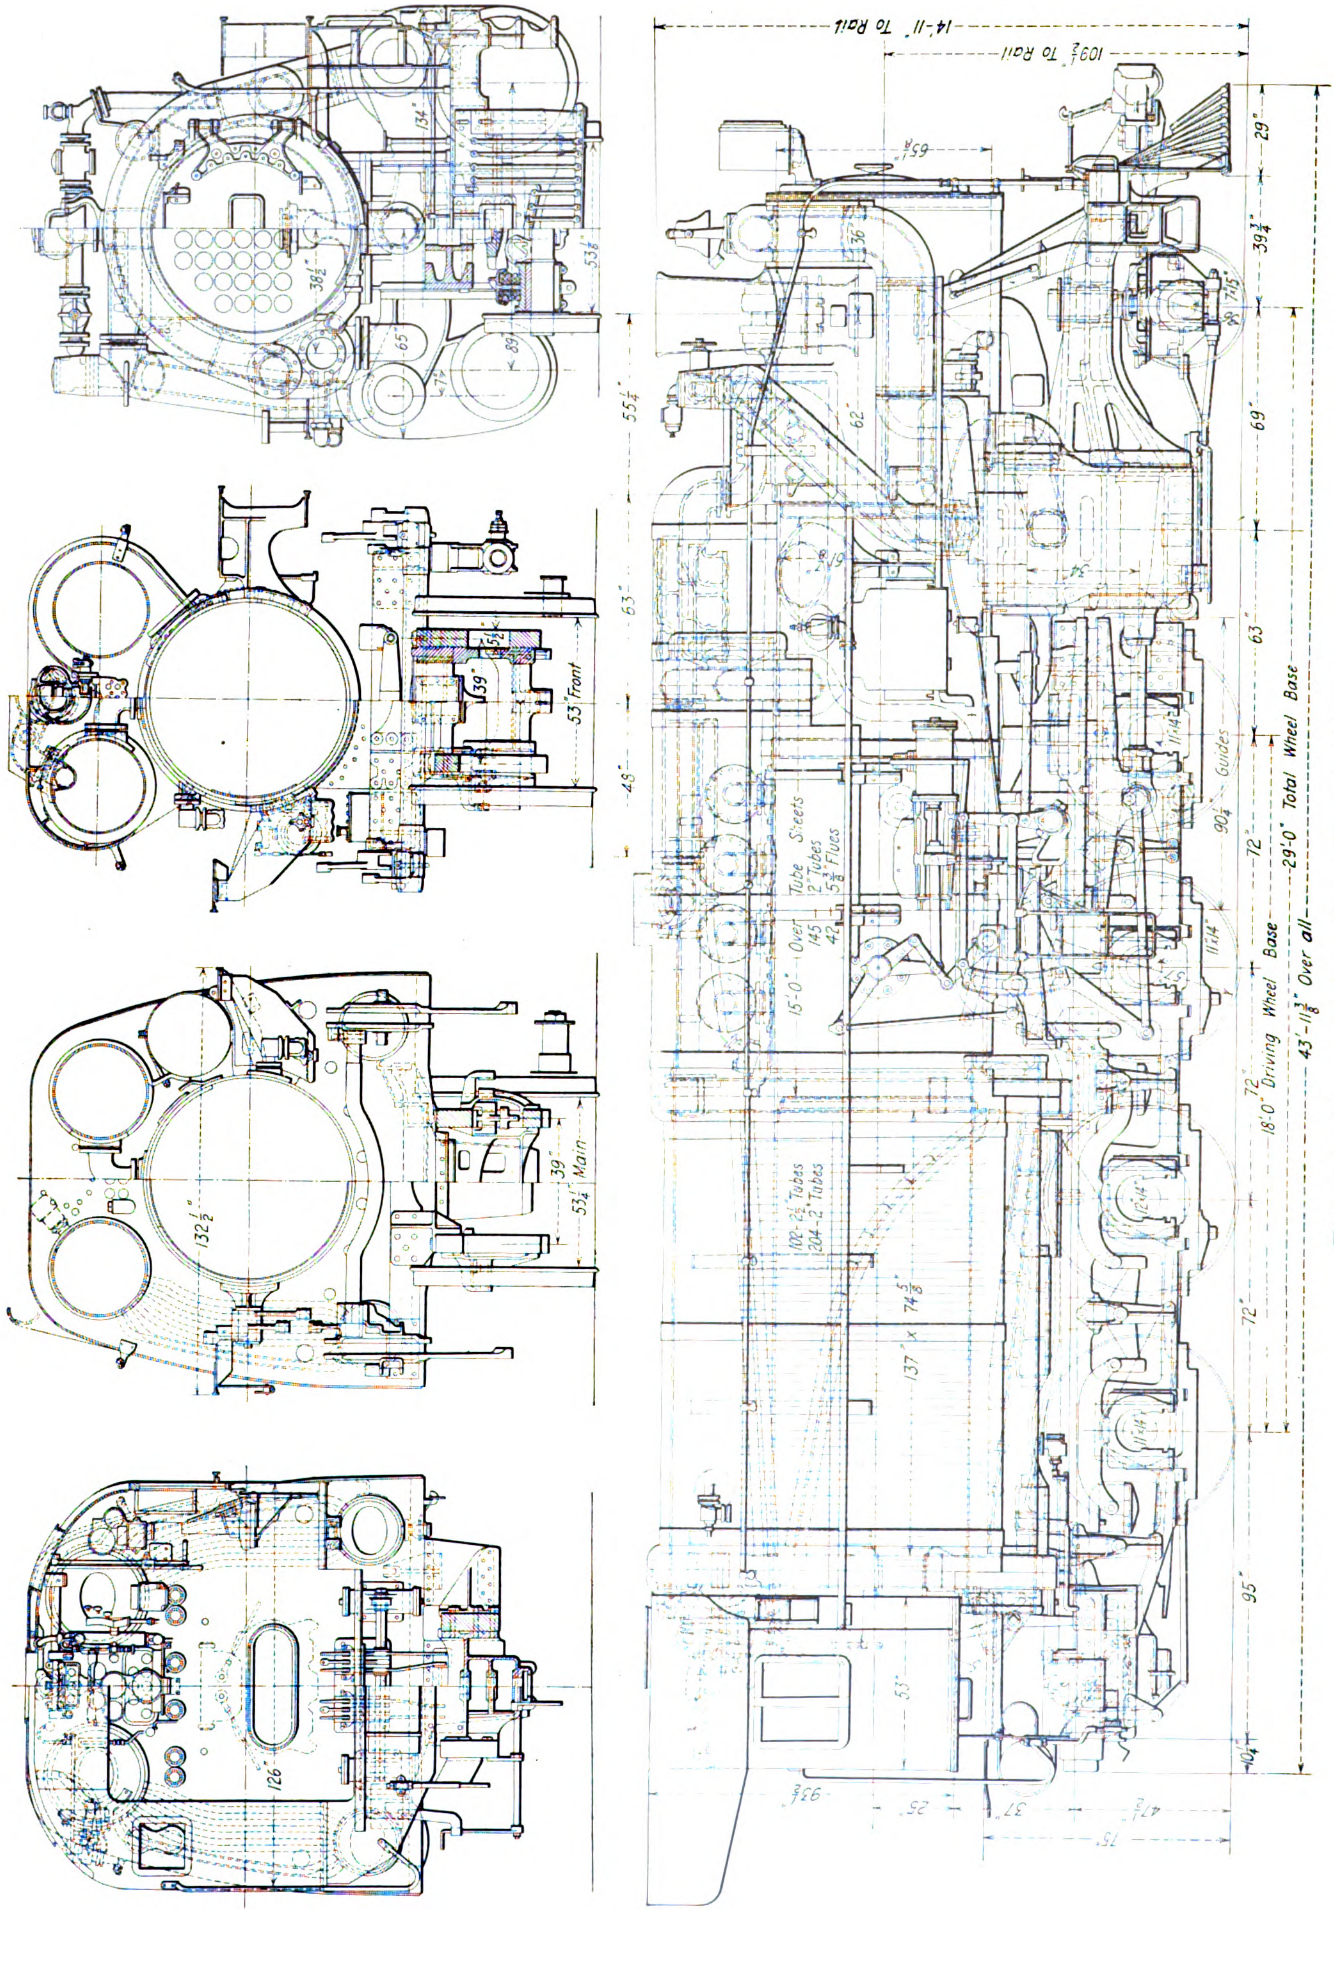
TO THE EDITOR:

I have been reading Mr. Stowell's article on "Helpful Suggestions for Setting Locomotive Valves," which appeared on page 596 in the October issue of the *Railway Mechanical Engineer.* I don't want to criticize his method but I think that the fewer figures used the less liable there are to be mistakes. I have been setting valves for ten years and do most of my work with dividers. I make it a practice of turning wheels backward, with the reverse lever in full gear ahead when getting quarter marks. After marking each dead center I roll the wheels forward and obtain the lead marks. This will give all four centers and lead marks for the head gear. Then get the lead marks for the back gear, in the same manner. The next operation is to set the crank. If it is to be set at right angles to the pin the front lead marks must measure the same distance apart as the back ones. If they do not then this is the point where the dividers are used. Let *a, b, c, d* represent the lead marks $\frac{a. \quad b.}{c. \; F. \; d.}$. Set the dividers *a b* and mark on a line on some convenient smooth surface $\frac{a. \quad b.}{c. \quad d.}$. Then set for *c d* and mark *a d.* If the lead marks are equal they will measure *a c.* Remember that we are in the back gear. Between *c* and *d* mark lightly the center *F.* Now set the dividers one-half of *a c,* and using *F* as the center, move the crank so that *c* or *d* according to the end of the stroke, will come under the other leg of the dividers.

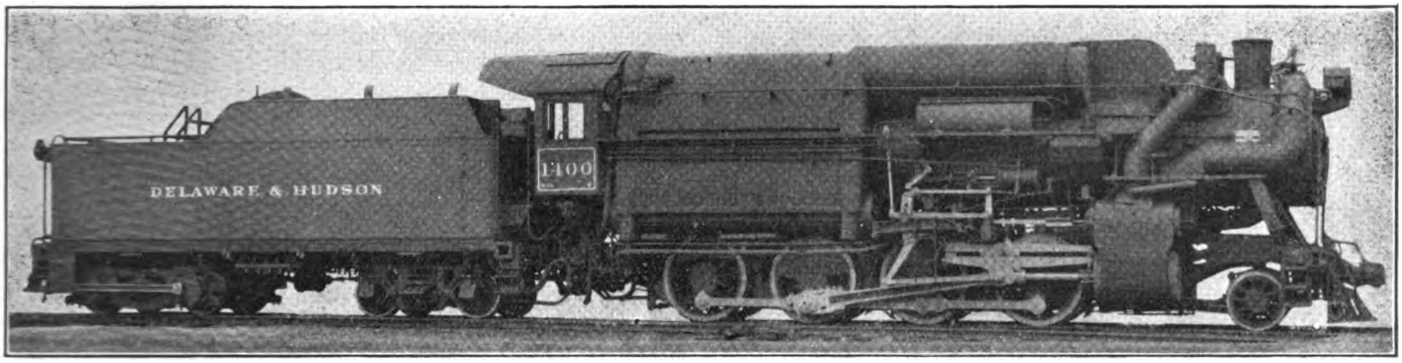
One revolution of the wheel in each gear is usually sufficient to prove the work. If the eccentric needs to be changed, the center foreward gear marks and the reverse gear center marks must come together when correct, so move the eccentric rod according to the motion. If the engine is in direct motion in foreward gear, the reverse gear mark needs to go ahead and it follows that the crosshead must come back. To do this, shorten the eccentric rod one-half of the distance between the centers multiplied by three. (It is understood that the fixed point of the tram is on the crosshead guide and the crosshead moves under it.) After getting the lead marks right, get the port marks and move the valves on the stem by adjusting the nuts to equalize them with the lead marks. By this method the wheel roller can be put under the engine and the setting completed in one day ready for the side rods, providing of course, that there are no new main pins to have key-ways cut in.

I would like to hear from others on this subject.

W. C. SPARROW.



Elevation and cross sections of the "Horatio Allen"



The "Horatio Allen" developes 104,000 lb. maximum tractive force, including the tender booster

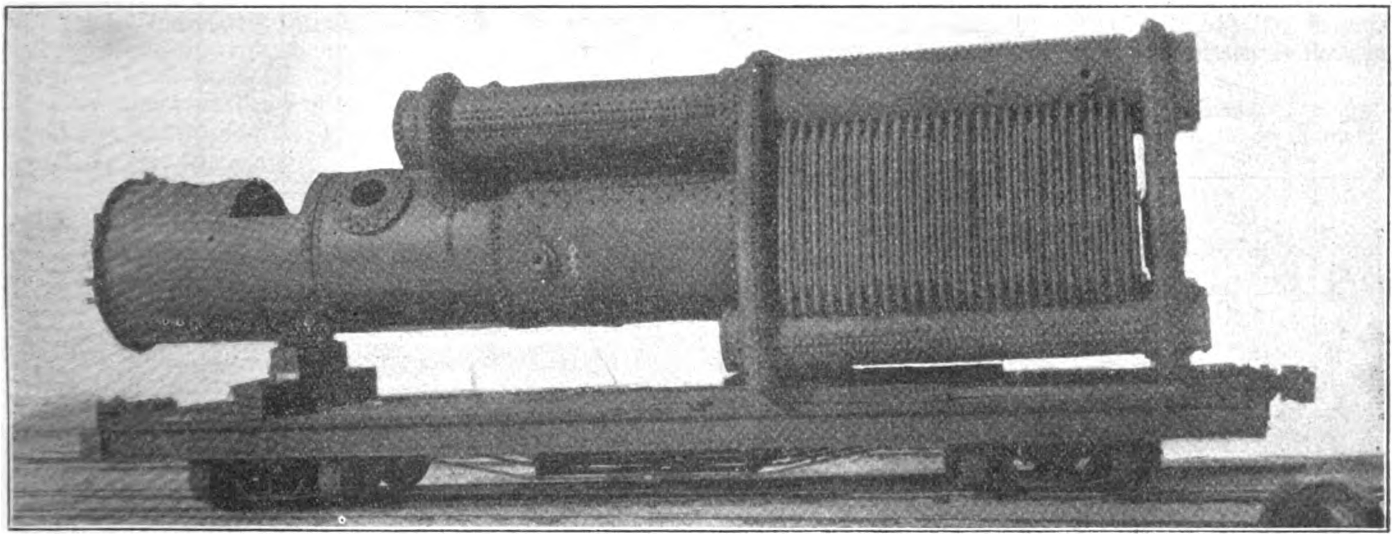
The "Horatio Allen," a high pressure locomotive

Water-tube firebox contains 37 per cent of total heating surface—Cross-compound cylinders

ON December 4, 1924, the Delaware & Hudson, with ceremonies fitting the occasion, christened a new Consolidation type locomotive of unique design, the "Horatio Allen," in honor of the engineer who was responsible for the building of and was the first operator of the "Stroubridge Lion," which went into service on what is now a part of the Delaware & Hudson on August 8, 1829.

The design of the new locomotive was developed by John E. Muhlfeld, consulting engineer for the railroad, and it was built by the American Locomotive Company. Naming it after a pioneer in steam locomotive development is suggestive of its character as, in effect, it represents a pioneer attempt to increase the thermal efficiency of the locomotive by employing the greater expansive range made possible by steam pressures much higher than are now employed in conventional locomotive designs. There are also a number of interesting details of construction in which conventional design has been departed from, aside from those made necessary by high steam pressure.

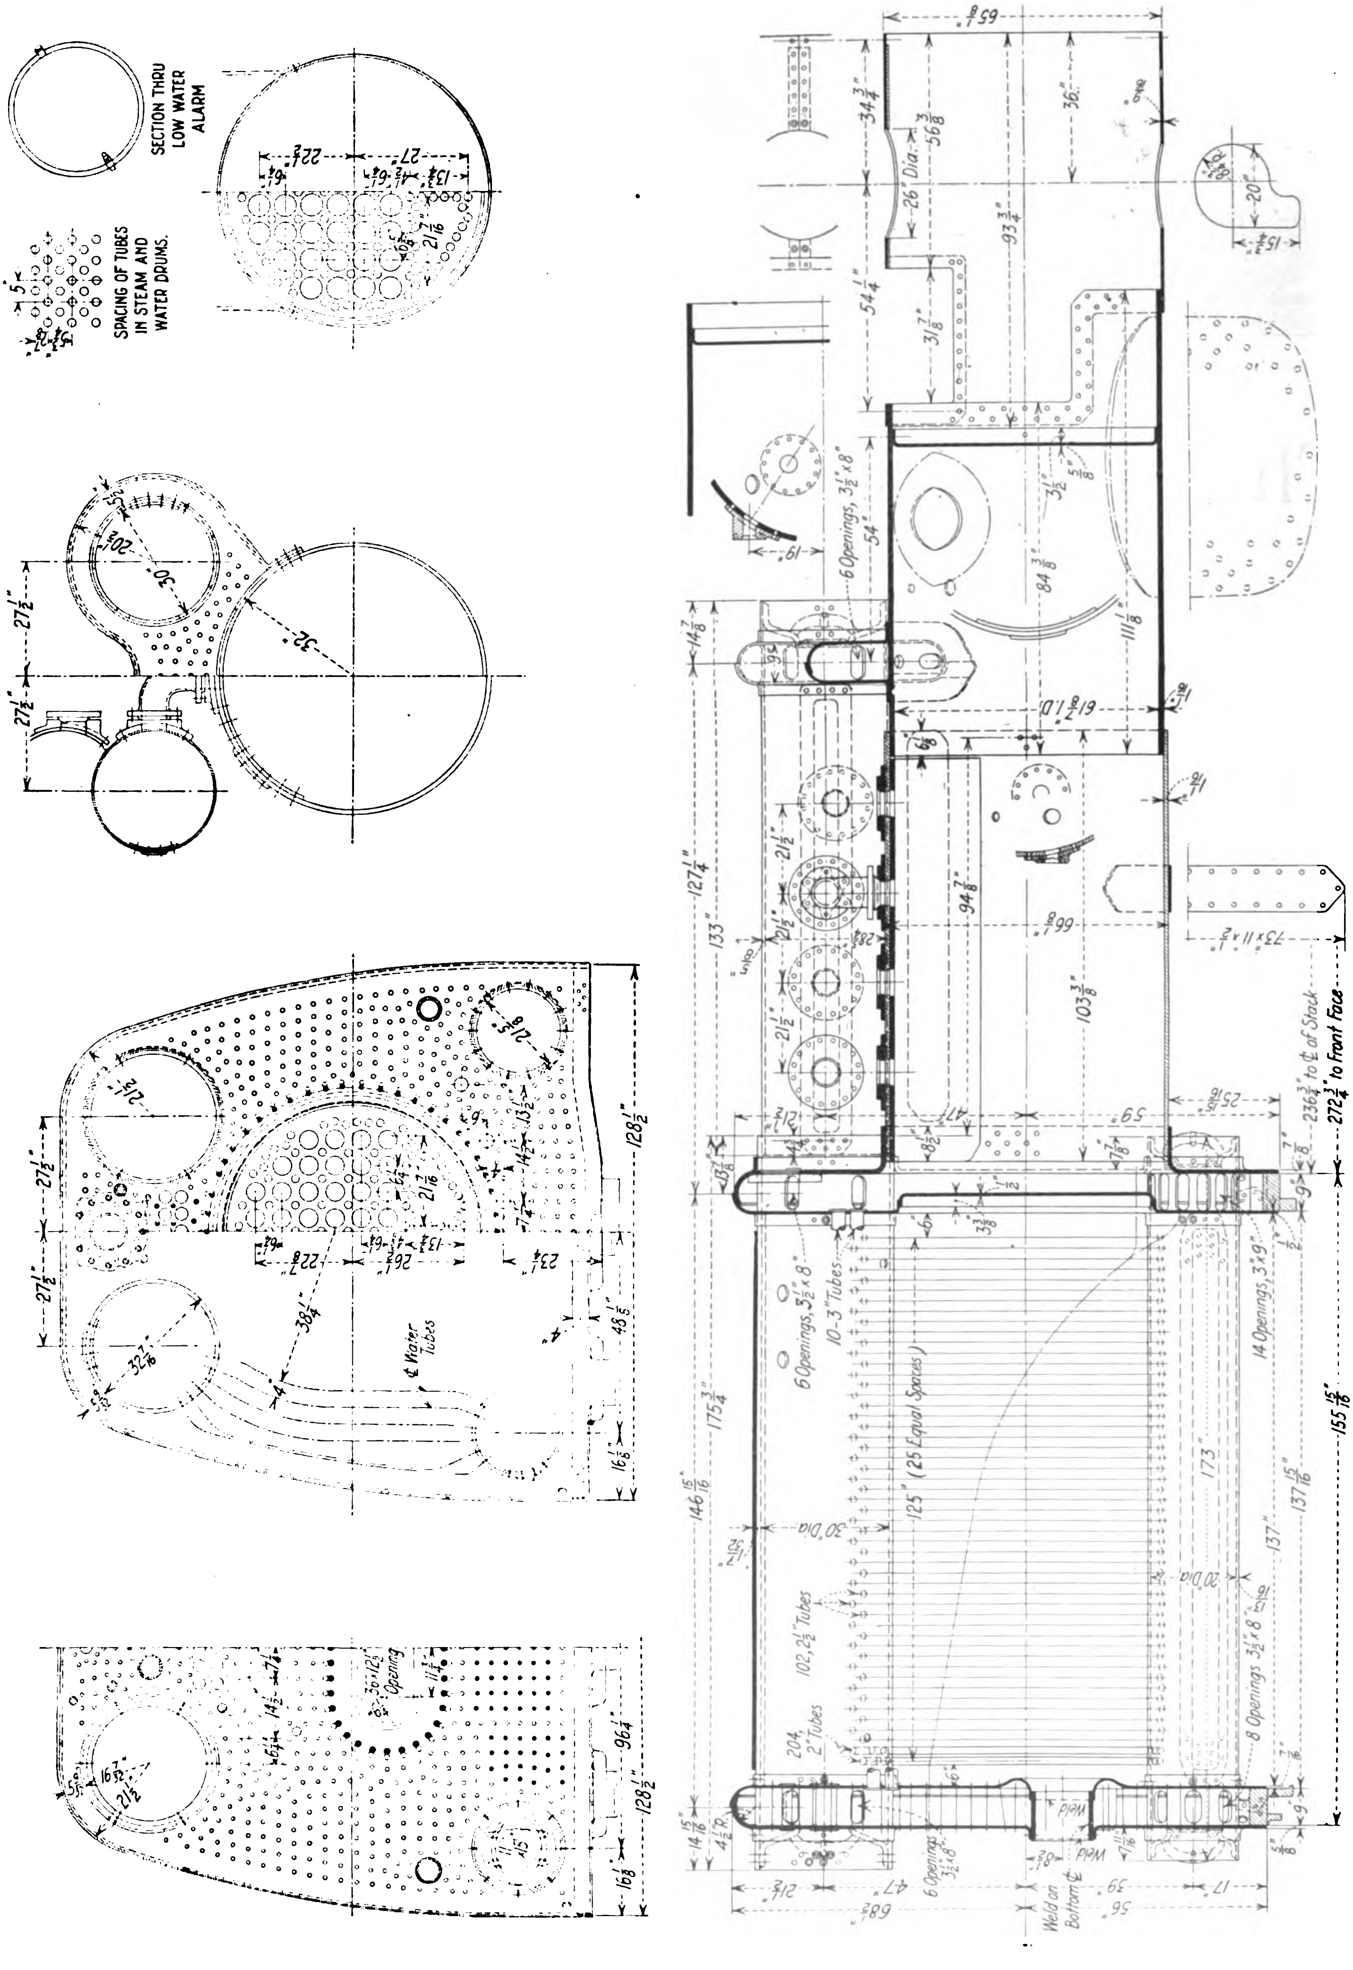
The "Horatio Allen" is of the Consolidation type weighing 297,000 lb. on the drivers, with tractive force ratings of 104,000 lb. simple including the tender booster, 84,300 lb. simple for the engine alone, and 70,300 lb. compound. The locomotive carries 350 lb. boiler pressure and works steam expansively in cross-compound cylinders of 23½-in. and 41-in. diameters, respectively, by 30-in. stroke. The driving wheels are 57 in. in diameter. In actual service the locomotive has developed drawbar pulls of 105,000 lb. at starting simple with the booster cut in; 95,000 lb. in simple gear at 4 miles an hour; 75,000 lb. in compound gear at 5 miles an hour; 65,000 lb. in compound gear at 10 miles an hour, and 53,000 lb. in compound gear at 18 miles an hour.



The complete boiler before the application of the firebox lagging—The man-hole in the front barrel course gives access to the interior in the absence of a dome

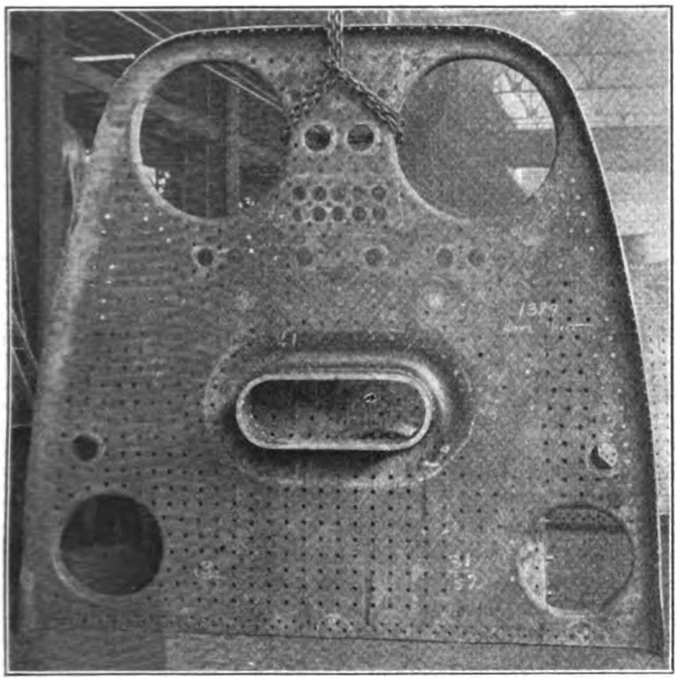
The boiler

The boiler represents a complete departure from customary locomotive design. Its construction is clearly shown in the drawings and photographs. The back head and rear tube sheet connections of the firebox are both of



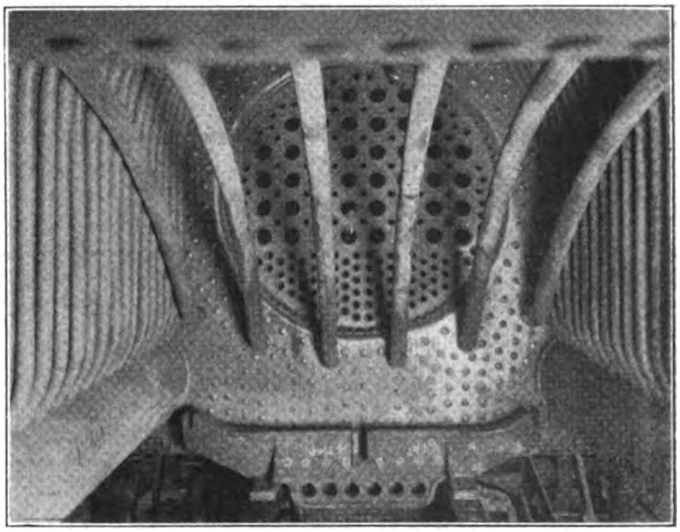
Longitudinal section, cross sections and back head elevation of the boiler

similar construction. They are 9-in, water leg headers composed of parallel stayed sheets, flanged and riveted together around the top and sides and secured to steel foundation castings at the bottom. Circular openings through each of these members near the lower corners receive water drums, 20 in. in inside diameter. These



The inside sheet of the back firebox header

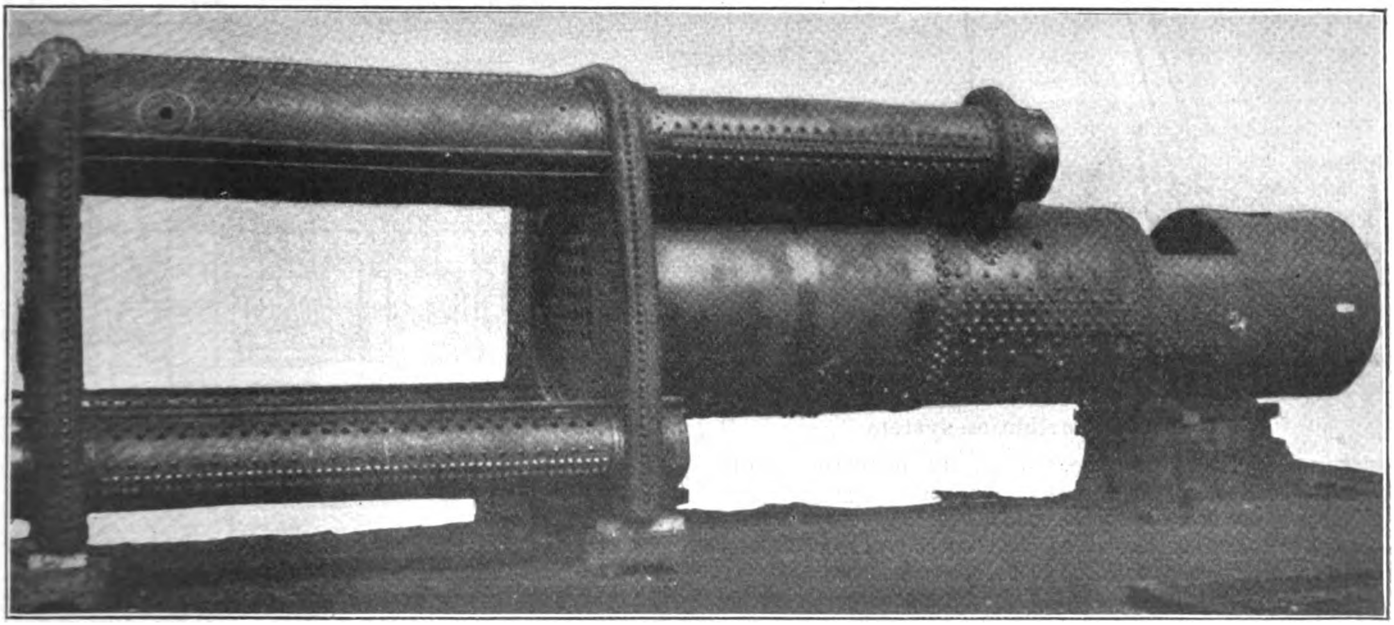
drums pass completely through both of the headers, and ports are cut through their shells in the header water spaces. The 30-in. steam drums at the top are secured to the front and back headers in the same manner. These drums are in two courses, the front course fitting inside boiler barrel. The ends of all four drums are closed with internally projecting heads and hand-hole covers. Referring to the boiler drawing, it will be seen that four pipe connections lead out from the top of the boiler barrel between the forward extensions of the steam drums and connect alternately into the two drums thus adding considerably to the freedom of communication between the boiler barrel which is completely filled with water, and the drums, the upper parts of which constitute the steam



Interior of the firebox before the arch or grates were applied

space of the boiler. The front sheet of the forward firebox header is flanged outward to receive the back course of the two-course boiler barrel, which is 66⅛ in. in outside diameter. The inside sheet of this header is flanged inward to receive the firebox tube sheet.

The heating surfaces at the sides of the firebox are composed of 306 tubes, 102 of which are 2½ in. in diameter

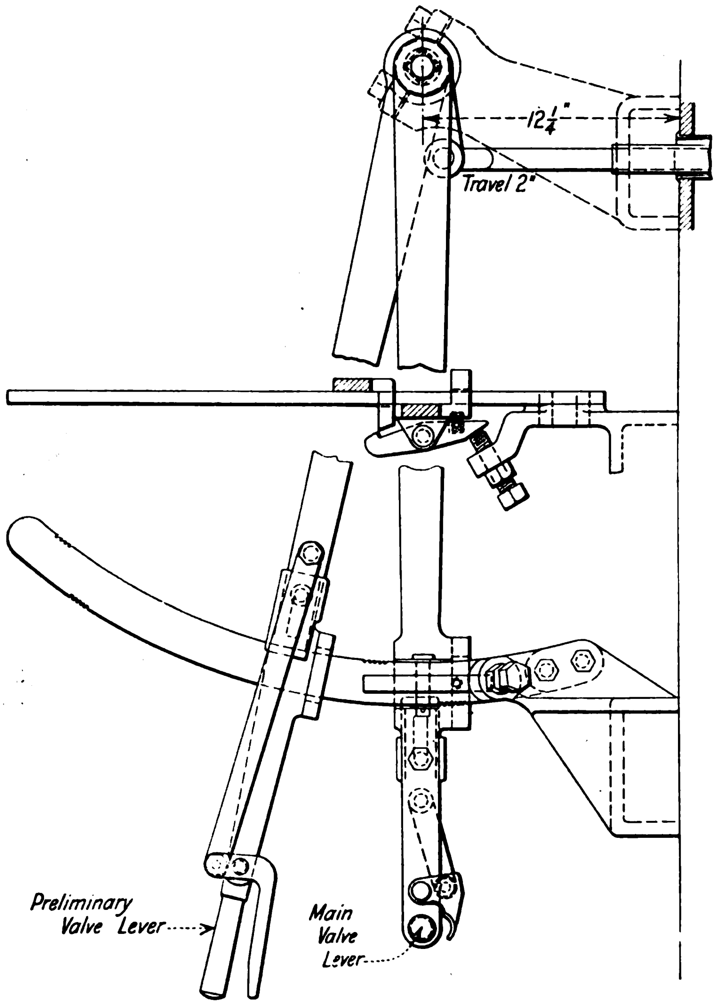


The boiler before the application of the water tubes

the rear course and extending 133 in. forward along the boiler shell. The front ends pass through a stayed saddle secured to the top of the boiler barrel and ports through the drums and through the boiler shell provide for communication through the saddle between the drums and the and 204 of which are 2 in. in diameter. These tubes are expanded into the top and bottom drums. It is thus evident that the amount of stayed surfaces has been considerably reduced and are flat, parallel surfaces, with the exception of the small area of the firedoor flange. The

drum and header type of construction, with the top headers carried forward and securely attached to the boiler barrel also provides an extremely rigid structure.

Additional heating surface is provided in the firebox by ten 3-in. longitudinal water tubes which lie between the upper drums and connect the front and back stayed headers. There are also six 3½-in. arch tubes. The arch in this locomotive is unbroken from the tube sheet to the door sheet, thus completely dividing the unobstructed firebox volume into two parts. This directs the hot gases and flame outward at either side and up through the staggered rows of water tubes, thence inward



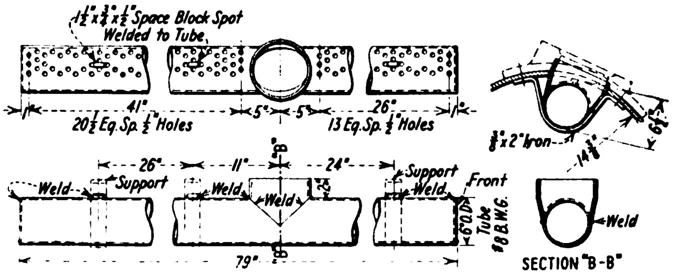
The operating levers for the main and auxiliary throttle valves

to the combustion chamber volume above the arch and into the fire tubes.

The steam distribution system

Steam is taken from the tops of the forward sections of the steam drums. A welded collector pipe of ¼ in. steel, 6 in. in outside diameter and 79 in. long, is suspended from the top of each drum. The upper surface of each of these pipes is perforated with several rows of ½-in. holes, through which the steam enters, thus distributing the gathering of the steam over a large water surface and removing any tendency for a local surge to lift the water. From these pipes the steam passes out of the drum into a yoke header casting between the drums, to the front flange of which is bolted a Sanford-Riley Stoker Company's desaturator. This is of the centrifugal type, the whirling of the steam through a horizontal spiral passage causing the water to be thrown off and collected at the bottom of the casting, from whence it is trapped back into the boiler. The front flange of the desaturator is bolted directly to the throttle casing.

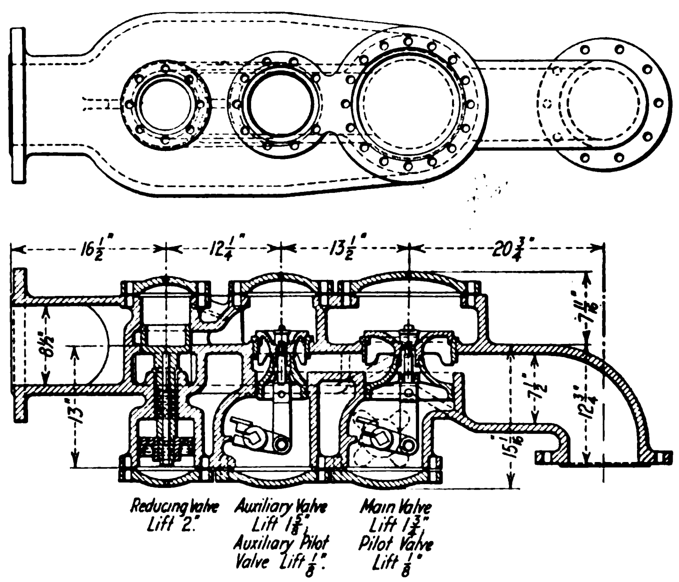
The perforated steam collector has proved so effective in service that very little water is removed by the desaturator and some question has arisen as to whether or not it is actually needed. The overall effect of both the



The steam collector—One of these is located in the top of each steam drum

collector and the desaturator has been found by calorimeter readings to limit the maximum moisture content of the steam to two or three per cent.

The throttle is of unique design, known as the duplex type. There are two throttles, each operated by a separate lever. What is termed the preliminary throttle is used in starting the locomotive. This takes its steam through a reducing valve which limits the pressure to 300 lb. per sq. in. When the locomotive has been started by the use of this throttle, the main throttle may be opened and the two throttle operating levers automatically interlock so that the continued opening of the main throttle picks up and carries with it the auxiliary throttle lever. Closing

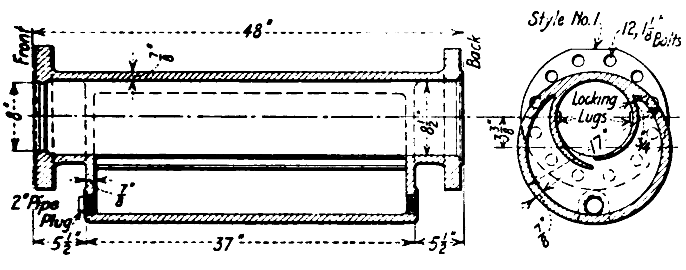


Details of the duplex throttle valve casing

the main throttle unlocks the connection between the two levers so that the preliminary valve lever is free to move independently in starting. The throttle valves are of the Chambers type.

From the throttle the steam flows directly into the superheater header, which is mounted on a cast base over the top of the smokebox. The unit bolts are applied with the nuts at the top of the header, where they are accessible for tightening without opening the smokebox front. This arrangement is clearly shown in one of the drawings. There are 42 superheater units, each of which

consists of a single loop. The unit pipe leading from the saturated steam header is twisted above the return pipe in a spiral and the two pipes are threaded and welded into a cast steel return bend which is located 12 in. from the back flue sheet. The whirling motion imparted to the



The desaturator—The steam passage contains a spiral core

saturated steam is designed to bring such moisture as the steam may contain into intimate contact with the unit surface, thus producing a more effective heat transfer. It also serves to equalize the expansion strains on the return bend joints. Steam from the drifting valve passes through the superheater and thus serves to protect the units from overheating, when the throttle is closed.

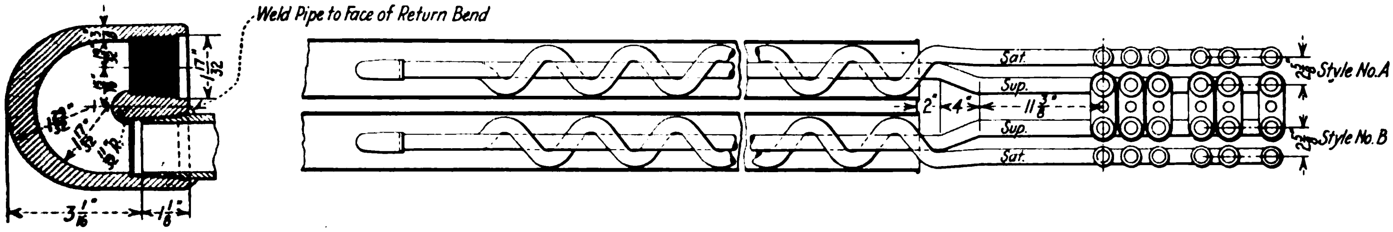
A flange on the right side of the superheater header leads the superheated steam into a branch pipe connection to the high pressure steam chest. In the design of this cylinder, close attention has been given to providing unobstructed flow to and from the valve chamber and special attention has been given to collecting.

The simpling of the cylinders at starting and change to compound operation either automatically at the proper speed or manually at the will of the engineman, is controlled by a Mellin intercepting valve. This valve is inserted in the receiver line and is attached directly to the exhaust cavity opening on the front face of the high pressure cylinder casting. From the intercepting valve casing the receiver pipe is carried forward and over the top of the smokebox in front of the stack, thence back to the valve chest connection of the low pressure cylinder.

The steam distribution is controlled by the Young valve gear, operating a 12-in. piston valve in the high pressure steam chest and a 14-in. double ported piston valve in the low pressure steam chest.

Considerable attention was given to the design of the steam passages to provide ample area free from obstruction. The dry pipe passage up to the throttle is 8½ in. in diameter, except for a flange at the outlet of the desaturator, which is reduced to 8 in. in diameter. From the throttle to the superheater header the passage is 7½ in. in diameter, and this size is retained through to the high pressure cylinder. The passage through the receiver pipe is 10 in. diameter.

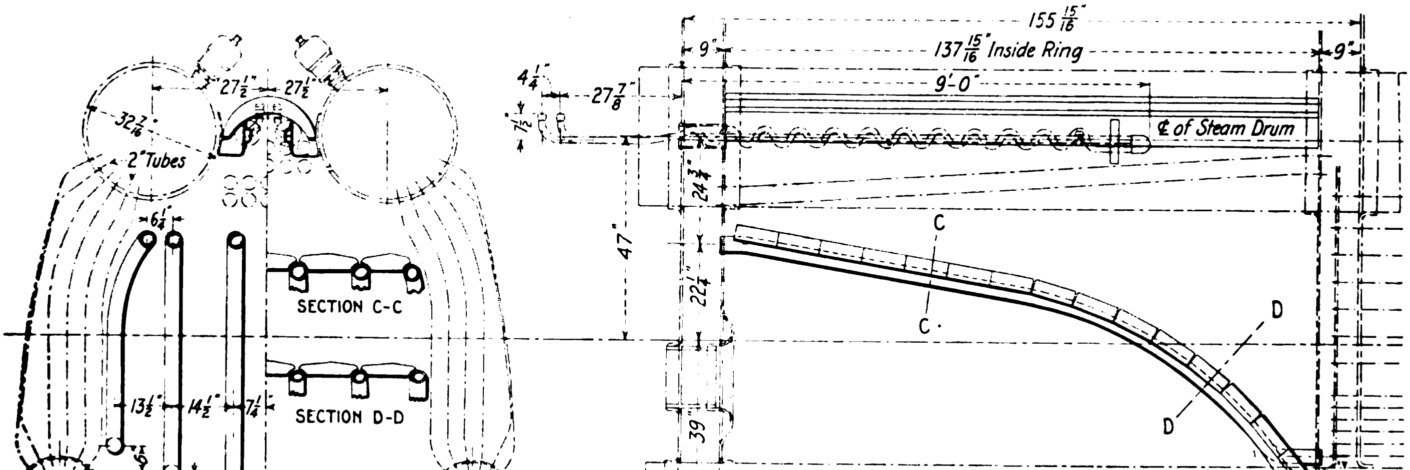
Superheated steam for the tender booster is taken from the high pressure branch pipe where it connects to the main superheater header. Superheated steam for the other auxiliaries is also provided by an auxiliary superheater, the units of which pass into the upper part of the firebox through the tubes in the back header.



How the superheater units are arranged

Frame and cylinder construction

One of the most interesting departures from conventional design is in the frame construction. The main frames terminate just back of the cylinders and the front rails are replaced by a combined saddle, frame and front deck casting of steel. The high-pressure cylinder is secured on the right side and the low-pressure cylinder on the left side. The smokebox saddle fit is made in a separate casting, which is bolted to the top of the main casting.



Details of the firebox arch—The location of the auxiliary superheater units is also shown

This permits the removal of the boiler without disturbing either the smokebox saddle fit or the main frame splice. The details of the main casting are clearly shown in one of the drawings.

The only steam passage cored through the steel saddle casting leads from the exhaust passage of the low-pressure cylinder to the front face of the saddle casting on the center line of the locomotive. From this point an outside exhaust pipe carries the steam forward and up into the exhaust nozzle in the smokebox. The center line of the exhaust nozzle is located 65½ in. forward of the transverse center plane through the cylinders.

Other details

One of the drawings shows the detail construction of the exhaust nozzle. This provides a direct passage for the low pressure exhaust, the diameter of which is 10 in. at the base, reducing to 8¼ in. at the nozzle tip fit. The diameter of the tip at the outset was 5½ in., although this may since have been subjected to adjustment.

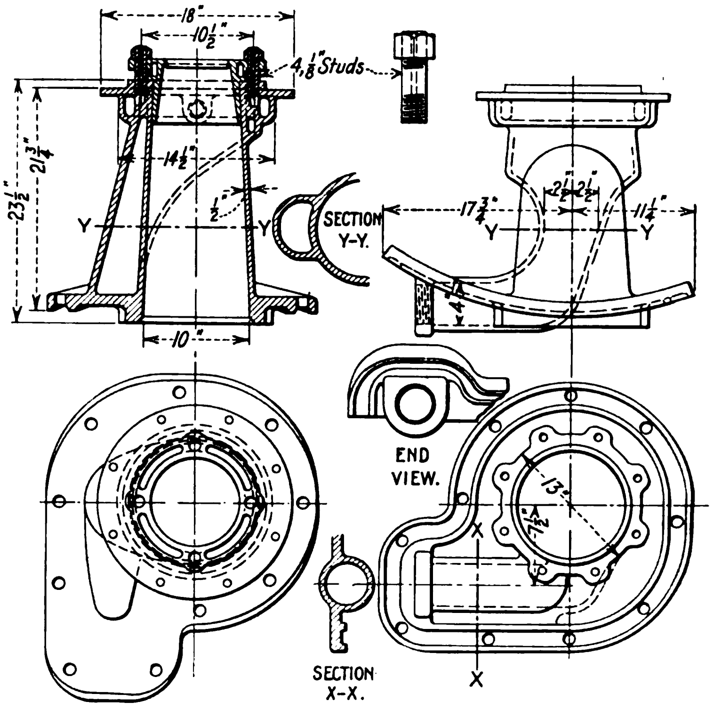
The high-pressure exhaust, when operating simple, is carried from the intercepting valve through a 3½-in. pipe to an opening in the base of the exhaust nozzle casting outside the smokebox. This opening leads to an annular chamber outside the main exhaust passage and discharges through annular openings in the top of the casting. The high-pressure steam connection is a 3½-in. pipe which leads directly into the main steam passage at the top of the steam chest of high-pressure cylinder casting. The location of the intercepting valve in direct connection with the high pressure cylinder not only makes it readily accessible for repair or adjustment, but shortens such pipe connections as are required.

Among the other special features, which may be mentioned in the equipment on this locomotive, is the use of the Owen's system of force feed lubrication, with oil inlets at the bottom of both cylinders as well as in both valve chests. The boiler tubes are fitted with Coleman safe-ends, one of which is illustrated.

The tender, which has a capacity of 9,000 gal. of water and 15¼ tons of coal, is carried on a Franklin tender truck at the front end and an M. & L. tender booster truck.

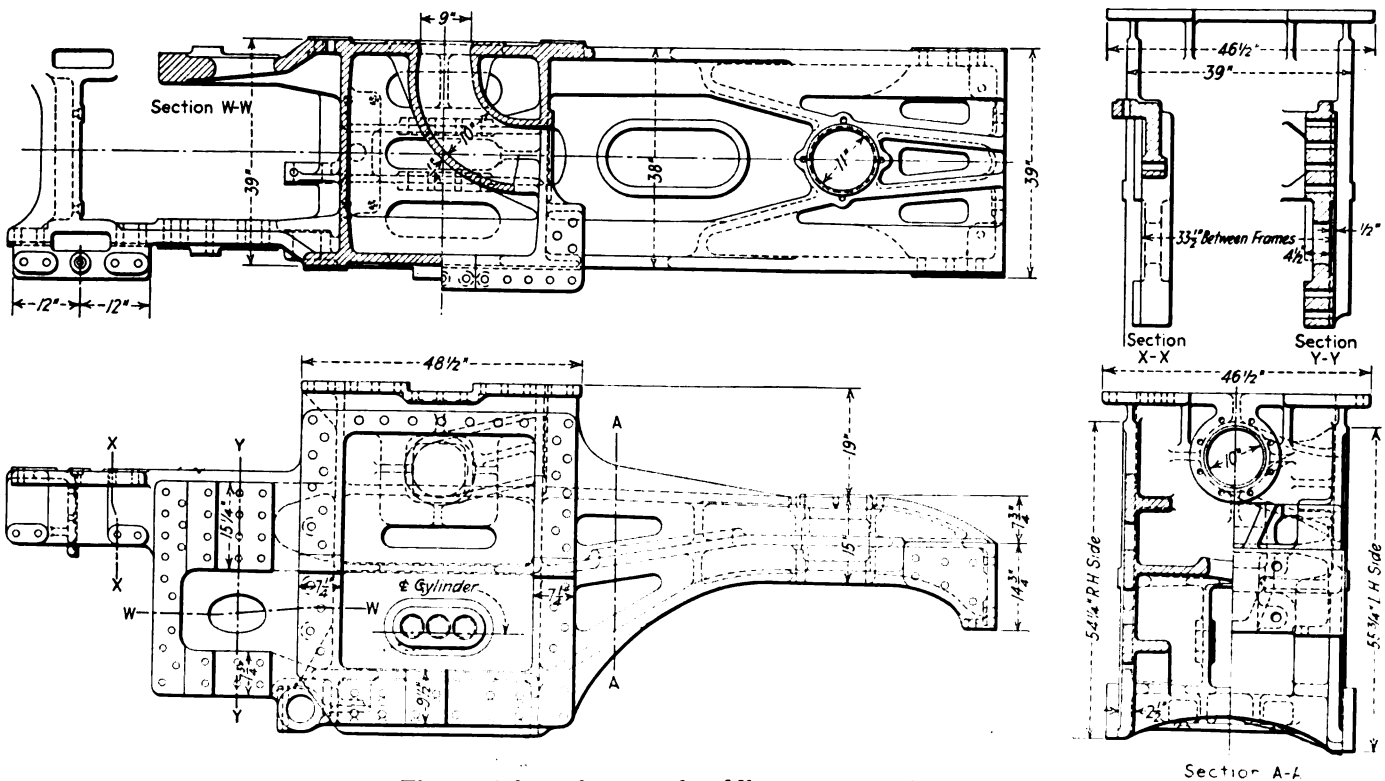
What is expected of the "Horatio Allen"

Probably the outstanding difference in the proportions of the "Horatio Allen" as compared with locomotives of



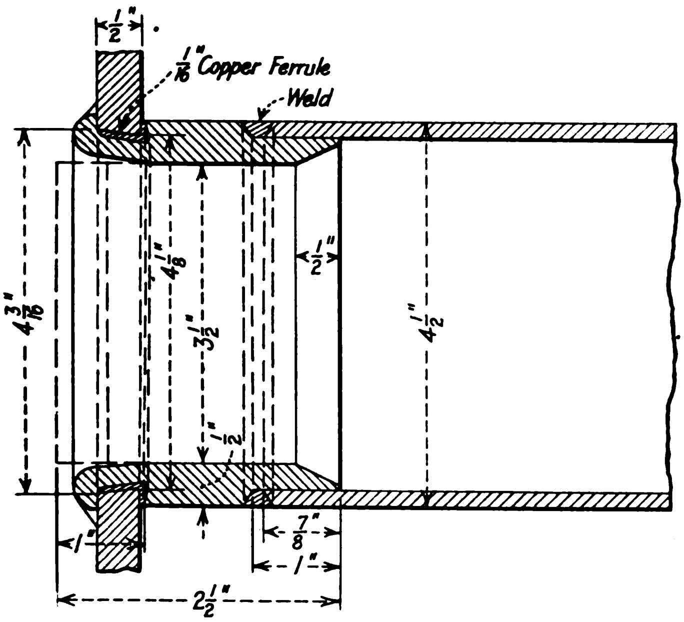
The exhaust nozzle

conventional design will be found in the distribution of the heating surface in the boiler. Out of a total heating surface of 3,200 sq. ft., 1,187 sq. ft., or 37 per cent, is located in the firebox. This is the result of the water-tube



The steel front frame and saddle support casting

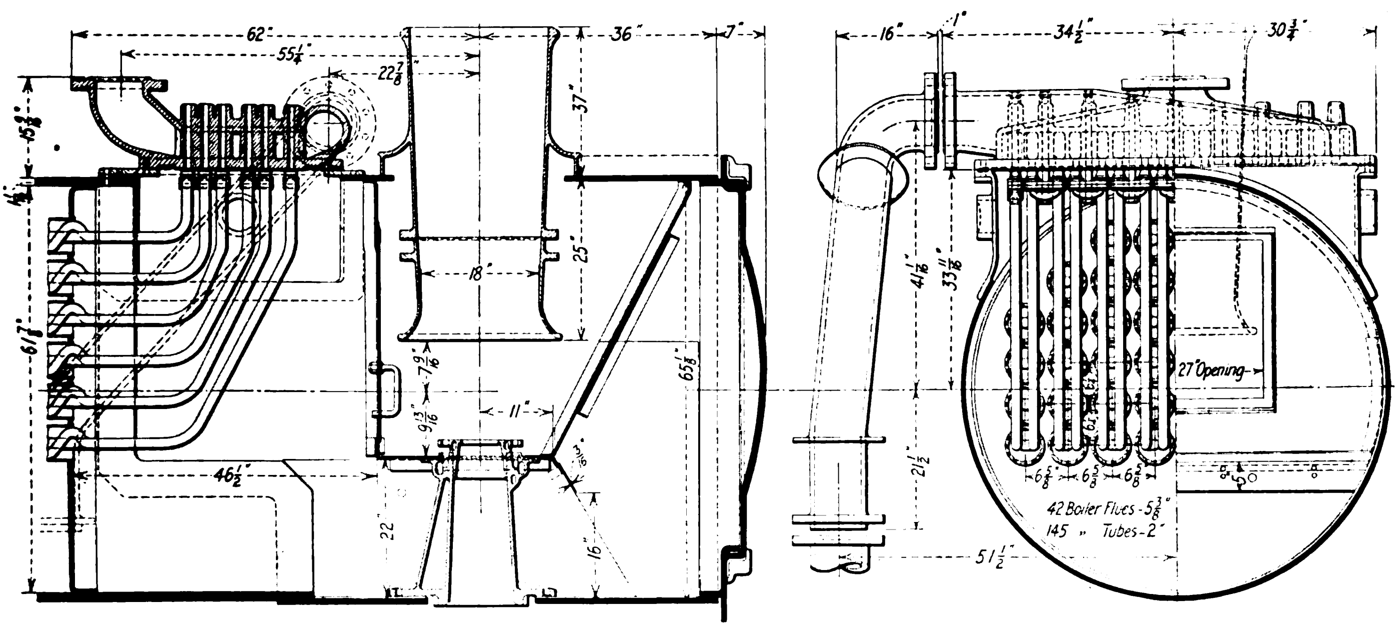
construction. Considering the much greater evaporative value of the firebox heating surface as compared with that of the fire tubes, the capacity of the boiler is much greater than indicated by the total heating surface when compared with the same total amount in a boiler of conventional design, where probably less than 10 per cent of the total would be contained in the firebox. Another factor of interest is the comparatively small amount of superheating surface, the total of which is 579 sq. ft. The purpose in this case, however, was to limit the maximum steam temperature to approximately 600 to 620 deg. F. and this temperature became the controlling factor in the design rather than the amount of superheat. With a boiler pressure of 200 lb. per sq. in., the superheater starts to build up the temperature of the steam from a saturated temperature of 388 deg. F. With the pressure increased to 350 lb., however, the saturated steam temperature is raised to approximately 436 deg. and the amount of heat which can be imparted to the steam within a limit of 620 deg. is correspondingly reduced. Until it is determined what effect will be produced by a combination of high pressures and high temperatures, it was considered safer not to exceed the above maximum temperature.



The Coleman safe end as applied to the superheater flues

The main purpose throughout the design of this locomotive has been to make available the increase in economy and capacity provided by the greater expansion range of pressures considerably higher than those commonly employed. Considering the latent heat of evaporation as a fixed charge which must be distributed over the additional heat applied to build up the pressure to its working point, it is evident that considerable thermal advantage is to be gained by increasing the working pressure and thus decreasing the amount of latent heat which must be charged against each pound of useful pressure. The total heat in one pound weight of steam at 200 lb. pressure, is 1,199 B.t.u., but 1,150 B.t.u. remain in the steam after it has expanded down to atmospheric pressure, a difference of 49 heat units per pound. To raise the steam from 200 to 350 lb. requires a fraction over 7 additional heat units while the expansion range has been increased 75 per cent.

The calculated improvements in economy, which are expected from this design, are 15 per cent less fuel per drawbar horsepower-hour from the increase in pressure; a reduction of 12 per cent in fuel per drawbar horsepower-hour attributable to the boiler, because of the generation of 75 per cent instead of 40 per cent of the steam in the firebox, and the improved circulation in the water-tube type of construction and a reduction of 17 per cent in fuel by compound expansion in the cylinders. This amounts to a combined estimated saving of approximately 39 per cent in the fuel consumption per drawbar horsepower-hour.



The front end arrangement, showing the outside superheater header

The principal dimensions and proportions are as follows:

Table of dimensions, weights and proportions

Builder	American Locomotive Co.
Railroad	Delaware & Hudson
Type of locomotive	2-8-0
Service	Freight

Cylinders, diameter and stroke	23¼ in. by 41 in. by 30 in.
Valve gear, type	Young
Valves, piston type, size	H.P., 12 in.; L.P., 14 in.
Maximum travel	9 in.
Weights in working order:	
On drivers	298,500 lb.
On front truck	49,500 lb.
Total engine	348,000 lb.
Tender	197,800 lb.
Wheel bases:	
Driving	18 ft.
Rigid	18 ft.
Total engine	29 ft.
Total engine and tender	65 ft., 7¾ in.
Wheels, diameter outside tires:	
Driving	57 in.
Front truck	36 in.
Journals, diameter and length:	
Driving, main	12 in. by 14 in.
Driving, others	11 in. by 14 in.
Front truck	7 in. by 15 in.
Boiler:	
Type	Combined water and fire tube
Steam pressure	350 lb.

Superheating	579 sq. ft.
Comb. evaporative and superheating	3,779 sq. ft.
Tender:	
Water capacity	9,000 gals.
Fuel capacity	15¼ tons
General data estimated:	
Rated tractive force, simple	84,300 lb
Rated tractive force, compound	70,300 lb.
Booster	19,700 lb.
Weight proportions:	
Weight on drivers ÷ total weight engine, per cent	86
Weight on drivers ÷ tractive force, simple	3.54
Weight on drivers ÷ tractive force, compound	4.24

Design of the steam locomotive

Discussion of three-cylinder advantages—Vital importance of proper design as a maintenance factor

By J. G. Blunt

Mechanical engineer, American Locomotive Company

As we approach the end of the first hundred years of locomotive service and reflect on the increasing benefits which the reciprocating steam locomotive has given to the transportation problems of today, we are mindful of the seventy-five or more experimental years which preceded it in the making of that historic event. Surely that occasion will, in due time, be celebrated as a reminder of the principles developed during those experimental years, which are the basic ones involved in our locomotive construction today.

In those early years, the problem required a locomotive having the greatest starting power, with means for exerting the maximum tractive force gradually throughout its speed range. The problem today is likewise to produce an individual power unit, possessing this fundamental principle and capable of exerting its full tractive force per unit of weight on each driving axle, while attaining speeds within the limit of safety to human life, the locomotive mechanism and to the right-of-way generally, requiring a minimum of maintenance, with the most economical use of fuel per ton mile hauled.

We have today various means of locomotive power transmission other than the reciprocating steam locomotive, such as electric locomotives using various mechanical and electrical means of transmitting power to the driving wheels, the steam turbine, and various forms of internal combustion engines using gasoline or crude oil which are receiving marked attention, both here and abroad, as sources of locomotive power. Transmitting power from a constant speed motor to the driving wheels, requiring a speed range from nothing to maximum, offers difficult mechanical problems or involves large expenditure in the utilization of electrical transmission.

Various speakers have predicted a decline in the ability and efficiency of the reciprocating steam locomotive to meet the major transportation problems of the future. While these predictions may eventually be confirmed, the fact remains that no locomotive power unit has been produced on a commercially economic basis to cope with the reciprocating steam locomotive in cost of operation per ton mile under average conditions in long distance heavy duty transportation. It, therefore, remains an economic necessity to make the steam locomotive as efficient a power unit as possible until those predictions have reached a degree of commercial utility warranting their general substitution in place of the reciprocating steam locomotive. Many noteworthy efforts have been made, or are now undergoing experimental development, possessing great potential value.

With the foregoing assumption, the problem now is to select that application of the reciprocating principle for the larger steam locomotive units most nearly approaching these commercial requirements and one which will, under varying conditions, deliver the maximum power, speed and economy, at the same time requiring the operation of the fewest number of units to handle the traffic, while transporting the maximum possible trainload over an existing railway line.

The advantages of the three-cylinder type

Thorough investigation has convinced many that the single expansion, three-cylinder application most fully meets these commercial requirements at this time, although future improvements will undoubtedly follow its more or less general use. Efforts, in other ways, are being made and much has been accomplished to utilize higher boiler pressures, devices to provide auxiliary power and great fuel economy, as well as better means for handling the larger power units with greater ease and safety. It readily lends itself to the usual wheel arrangements, with a minimum complication in return for the power produced per locomotive unit having a given driving axle load.

Undoubtedly the most efficient wheel arrangement obtains when connecting the middle cylinder to the crank axle and the outside cylinders to an adjacent axle, thus more evenly distributing the cylinder power throughout the mechanism,

*A paper presented at a meeting of the St. Louis Railway Club, November 14, 1924.

with the least tendency toward slipping or dynamic effect.

In comparing two locomotives with the same wheel arrangement, one having two cylinders and the other three, and assuming equal boiler pressures and driving axle loads, the normal tractive force can be materially improved without increasing the slipping tendency, at the same time increasing the starting power by double the normal tractive force increase. Tests have shown a substantial fuel saving per ton mile hauled, with speed increases, following the better distribution of forces within the mechanism, in combination with the lesser dynamic effects to the rail and roadbed.

In considering locomotives of the sizes required on our trunk lines at this time, no application offers as many practical advantages throughout the speed range as a locomotive equipped with the three-cylinder principle.

It straightens out the tractive force fluctuations for each driving wheel revolution, delivers more tractive force per pound of weight involved and reduces the dynamic effects on the rail. It provides more even power distribution to the mechanical parts, with correspondingly reduced stresses in the locomotive mechanism and right-of-way construction. It eliminates the nosing effects of the inside cylinder entirely, while materially reducing this effect in the outer cylinders by reason of their smaller diameter. It requires less truck lateral resistance, with correspondingly less wear from hub and flange pressure. It enables the steam in the cylinders to be used more expansively through a larger percentage of its running time, while having greater starting ability, accompanied by a substantial fuel saving for tonnage hauled. There is less danger of frame failure on account of the smaller outside cylinders, with less overhanging pressure acting through the rods and axles on the frames. The six exhausts per driving wheel revolution produce a more even draft on the fire, enabling the use of larger exhaust nozzles, with less back pressure in the cylinders, resulting in still greater fuel economy.

Some factors in design

To function best throughout the speed range, a road locomotive should have a leading and a trailing truck to guide it around curves and absorb the lateral vibrations while sliding the driving wheels across the rail when changing the direction of motion from a tangent line through curves, and to absorb the vibration set up by the unbalanced reciprocating forces, as well as those brought about by track irregularities.

The lateral resistance in either truck acts as a long lever arm, extending from the center of one to the center of the other, in absorbing these forces, providing their lateral resistances are operative immediately when moving from their central position and in proportion to the length of wheel base and speed requirements of the locomotive. Under these conditions, the lateral resistance requirement becomes a minimum. With these provisions, hub friction and flange wear are likewise reduced and the frames, frame structure and boiler attachments are subjected to the least detrimental forces.

The spring suspension also has an important bearing on the riding qualities of the locomotive, which becomes increasingly more important in absorbing the rolling tendency as the speed increases. It is fundamental that the load resting thereon should be carried on three independent bearing points, having no connecting equalizations tending to lessen the vertical stability or disturb the even setting of springs and equalizers so linked up. Unmechanical means for correcting or maintaining this stability tend to disturb the individual axle loading.

The relation of design to maintenance

The annual maintenance costs for each freight and passenger locomotive, according to I. C. C. reports for the last four years run around $10,000.* Many causes contribute to these outlays, but I shall discuss them primarily from the viewpoint of the builder.

While operating over irregular track and around curves, the locomotive mechanism is subjected to many complex movements. Where possible of analysis, provision must be made in the design, such that every movement involved is amply provided for in a manner to avoid unknown and incalculable stresses and to relieve bearing surfaces from imperfect surface contact. Failure to provide for them involves excessive wear or fracture and the addition of useless weight. They become, therefore, a fruitful source of increased maintenance. These correct movements must be obtained, however, with a minimum of complication else the cure will be more expensive than the cause. If they are well done, the mechanical efficiency will be increased, along with the mileage, and maintenance costs decreased throughout the life of the locomotive.

Main connecting rods are illustrative of this condition, connected as they are at one end to parts above and oscillating over the spring rigging, while the other is connected to parts below the springs. A degree of universal movement is required in one end relatively to the other, in order that these bearing surfaces may rest uniformly on their respective pins while assuming varying angular positions, which become increasingly more severe as the rod angularity, speed and rolling of the locomotive increase. The angular positions of the rod, together with the maximum angular variations of the axle or pin, unnaturally stress the rods and twist the bearings on their pins, resulting often in heated journals, wasted lubricant, pounding, broken brasses, broken or dislocated rod parts, or failure at the weakest point subject to these unknown stresses. A rolling engine and an uneven track simultaneously centralize unknown stresses in the rods or their connecting parts, the weakest point of which often gives trouble. This involves expensive maintenance which can be corrected only by the use of mechanical construction fully responsive to these movements. Floating bushings have given much relief. Rods constructed as a universal joint offer a naturally correct means for the relief of these abnormal stresses.

Side rod and driving box design

Means to partially relieve coupling rod troubles have been found in the use of floating bushings, while the use of rotative bearings on all but the main connection offers still further relief in providing for the varying angularities of axles, thus eliminating some of the contributing causes for the unknown stresses to which side rods are subjected. These conditions become more pronounced as the size of bearings increases. Surely an automobile or truck would not remain long in service if its power were transmitted in a similar manner.

Driving boxes should undoubtedly be provided with means to prevent the sides from closing in on the journal, due to the reciprocating action of the rods. Supplemental bearings, fitting the axle for a distance below its horizontal center, offer means to minimize the accumulation of longitudinal play in the driving journals, giving substantial relief from the pounding effects in the boxes, which are in turn transmitted to the coupling rods. It may be practical to apply driving box brasses with slight pressure in the box casting if suitably designed, as many are found loose when locomotives come in for repairs. Such an application would relieve the box casting of distortion from the high pressures used when forcing in the journal brasses.

All main journal bearings for engine truck, drivers and trailer, as well as tender, should be provided with means to oil, pack or regrease through non-detachable spring lid covered openings, having means for supplying as free a flow

*See Railway Age for September 9, 1924, page 531.

of clean lubricant to hub surfaces and oil bearing surfaces as possible and well protected from contact with dirt and cinders. Generally speaking, the aim in design should be to require the fewest number of points to lubricate, each of which will supply the need for the greatest length of time and be in the most accessible location. Hub liners securely fastened, easily removable and replacable without dropping wheels may be used to simplify maintenance.

Provision for easy removal and inspection of drawbar pins between engine and tender at engine end, when stoker applications prevent lifting them from above and the booster prevents removing them from below, has been frequently suggested by railway men. Devices using horizontally removable pins have been applied, using double bars equalizing through a circular disc at the tender end. These double bars increase the safety factor between engine and tender and in case one bar or pin fails, the other provides the safety feature while making constant use of both.

The boiler, aside from its pressure stresses and those due to heat expansion, forms the backbone of the locomotive, maintaining the mechanism in alinement. A previous paragraph explains how stresses in the frame fastenings are relieved by absorbing the causes of vibration in the truck resistance mechanism before those stresses reach the frame. The whole frame structure and its attachments to the boiler are thus relieved. If frame attachments to the boiler give trouble, attention should be directed to the truck resistances, because one of the main functions of leading and trailing trucks is to guide the engine and absorb the vibratory actions so destructive at these points.

One of the most destructive forces set up in the locomotive is caused by unrelieved water in the cylinders. Application of effective means to prevent such pressures from exceeding, say 50 lb. above boiler pressure, would assist in preventing the fracture of cylinder heads, forcing the piston or crosshead on the piston rod, carrying the end of the cylinder away or loosening its frame fastenings. Evidently these unrelieved pressures, which at times are destructive, contribute to broken piston rods, connecting rods, axles, frames and other parts subjected thereto, which would largely disappear with the removal or partial removal of the cause. Working steam pressures are the least contributing cause of such trouble.

Center pin bolster bearing trucks, whether of the two-wheel radial or four-wheel center bearing type, should provide for lateral motion devices whose bearing surfaces maintain constant alinement with the axle throughout their range of lateral movement. Otherwise, twisting on the bearing surfaces of these mechanisms, or binding on their bearing surfaces, provide another expensive maintenance cause.

This provision is simply made in the four-wheel center bearing truck by machining the guiding surfaces of the bolster and bolster guide, and in the two-wheel trucks by providing means to maintain the alinement of its top and bottom surfaces relatively to each other throughout their range of lateral movement.

Improved design and construction throughout the locomotive to meet the conditions described, will, in some cases, involve additional first cost, although ingenuity and originality will as often eliminate it. Mindful, however, that destructive causes following incorrect construction are a fruitful source for maintenance expense, some additional outlay at the start would seem well worth while, and I believe the time is coming when the locomotive mechanism will be perfected so as to respond fully to every involved movement capable of analysis. This should always be the objective, for with it go longer individual runs, increased mileage between shoppings, decreased maintenance costs and fewer locomotives to move a given tonnage.

Discussion of locomotive steels*

Heavy modern power requires a better grade of steel—Proper heat treatment essential when repairing alloy steel parts

By Lawford H. Fry

IF the time were not limited it would be interesting to cover the subject fully, following the processes of manufacture from the ore to the locomotive builder's shop. However, we can only touch briefly on the important points. Examination of the various steels entering into locomotive construction shows that they range in composition from one per cent carbon of the springs to less than two-tenths of one per cent of carbon in boiler and structural steels, with several alloy steels included in the forging grades. Recent developments make this group the most interesting to steel treaters.

In order to present the subject logically, let us first analyze the structure of a locomotive. Take as an example the heavy Decapod freight locomotive of the Pennsylvania System. Examination shows that it is made up of three structural units—

(A) The boiler.
(B) The chassis, made up of frames, axles, wheels and springs.
(C) The engines which rotate the wheels.

Let us further dissect these units to ascertain what steels enter into their composition—

(A) The boiler, though large and important, is comparatively simple so far as steel is concerned. The sheets of the barrel and of the inside firebox are of low carbon low tensile steel, the flues and superheater pipes are of similar material, though in some cases charcoal iron flues are used.

(B) The chassis contains a more varied collection of steels; the principal parts classified by the carbon content of the steels used are as follows:
  (a) Carbon about 1.0 per cent, springs.
  (b) Carbon about .75 per cent, tires and rolled steel wheels.
  (c) Carbon about .50 per cent, forgings, such as rods, axles, crank pins, etc.
  (d) Carbon about .25 per cent, castings, such as frames, crossties, driving wheel centers, etc.

(C) The engine adds little to the preceding list of steels, as outside of the cast iron cylinders with which we are not concerned, they are built of forgings and castings similar in composition to those in the chassis.

We are now in a position to group the various steels together and to consider them more in detail. In order to give background to this consideration I offer for comparison one of the first Pennsylvania Consolidation locomotives. The Consolidation locomotive thirty years ago was, as is the Decapod locomotive today, the heaviest standard freight locomotive on the Pennsylvania System. The old Consolidation engine weighed in working order about 126,000 lb., while the modern Decapod locomotive weighs about 386,000 lb. The weight has tripled in thirty years. This great increase in size has brought new problems to the locomotive designer, to the steel

*A paper presented to the New York Chapter of the American Society for Steel Treating, December 17, 1924.

maker and to the steel treater. Formerly it was sufficient for a draftsman to write *steel* on his drawing of a forging, and no one would raise any question as to specification or heat treatment. Today the designer must choose between a variety of steels and many heat treatments, and his choice must be determined not only by the properties of the steel as it appears in the finished part, but also by the behavior of the steel during the life of the locomotive, by the treatment it must receive during repairs, and by the facilities for such treatment which are available in the railroad repair shops. We shall see this in greater detail in considering the various steels.

Boiler steels

The boiler of the Decapod locomotive weighs without flues about 58,000 lb., and about half as much again with flues and superheater. The largest plate measures 269 in. by 90 in. by 1⅛ in. and weighs 8,550 lb. In the boiler of thirty years ago the largest plate measured 191 in. by 83 in. by 7/16 in. and weighed 1,970 lb. The increase is 60 per cent in area and nearly 200 per cent in weight. So far as material is concerned there has been little change. Boiler plate, then as now, was bought to a specification requiring a tensile strength of 55,000 to 65,000 lb. per sq. in. with approximate ductility requirements. Bend tests are required and nick-and-break tests for homogeneity are now made on firebox plates and on others requiring special flanging. The quality appears to be stabilized and no developments are anticipated in the near future.

Steel castings

The frames are the largest single castings, weighing about 22,000 lb. each and measuring nearly 45 ft. in length. The driving wheel centers account for about another 30,000 lb. and the crossties, frame braces, foot plates, etc., about as much again, say, in round figures, 50 tons of steel castings. This represents a branch of the steel industry which has practically come into existence in the last thirty years and is still developing. Thirty years ago locomotive frames were of wrought iron, driving wheel centers of cast iron and crossties were built up from shapes. The majority of steel castings now used in locomotive work are furnished to a minimum tensile strength of 70,000 lb. per sq. in., but conditions have by no means crystallized. Special designs and special steels are being tried out. There has been a tendency to combine more and more parts into a single casting. Starting with the trailing truck frame and tender truck and tender frames cast in one piece, unification has developed to the point of making a single casting to replace the two locomotive frames and their crossties. This bold experiment is still in the making, but it represents a continuation of development along lines which have already proven satisfactory.

Springs

There has been little development in thirty years, except in size. At present, attention is being given to the question of improvement in springs. To carry out such improvements exact data as to the service being given by locomotive springs are required. If this is accumulated by the railroads and better springs are demanded, steel makers and steel treaters will respond. The large majority of locomotive springs are made of a plain carbon steel having about one per cent of carbon and low silicon and manganese. The steel is quenched from the fitting temperature and removed from the oil which is still so warm that a separate draw is not required. Some railroads are using a steel with from .25 to .50 per cent silicon and a few of the more progressive roads are looking to the use of modern accurate methods of heat treatment.

Tires and rolled steel wheels

The use of rolled steel wheels for engine trucks is a growth of the last twenty years. The steel is of the same general composition as is used for tires with carbon from .60 to .85 per cent. For tires the carbon runs from .55 to .70 per cent for passenger, .60 to .80 per cent for freight, and .70 to .85 per cent for switching service. These are the steels which have been used with practically no change for the last thirty years. Further, there has been no change in tire dimensions. This is the one steel part of a locomotive which shows no change in dimensions or material. Nor is any to be expected. There is little indication of any change being made in the grade of steel used, and there is no possibility of increasing the tire section. This is fixed by well established clearances and rail designs. While locomotive weights have increased three times and the wheel loads two and one half times the tires carrying these loads have remained unchanged. As a consequence, if the tires are to carry the increased loads satisfactorily, great vigilance must be used in maintenance. Shimming should be avoided wherever possible, and when unavoidable new steel of known and uniform thickness should be used. Shims should be applied in as few pieces as possible without overlaps and without gaps. Tires should not be removed from wheel centers for turning. The heavy modern wheel loads cause a certain amount of distortion of tire and wheel center so that the removal of a tire and reapplication in a different position leave part of the tire unsupported. Further distortion follows naturally, and failure may result.

Forgings

As has already been pointed out, we find here a greater variety of steels and of heat treatments than in any of the other steel parts. Let us first dispose of the smaller forgings such as valve motion parts. As it is desirable to have lighter moving parts, some railroads have taken advantage of specially made and treated steels. Good results can be obtained thus, but such parts must not be heated in repairing. Eccentric rods which may require heating for setting to length in construction or repair should be of a comparatively low carbon, say not over .40 per cent without alloys.

For the main locomotive forgings such as driving axles, main and side rods, and crank pins, the following steels will be found in current use:

- Plain carbon steel.
  - Carbon about .45 to .50 per cent. Such steel is to be used annealed or quenched and tempered, or even, in the case of parts made in railroad shop, unannealed.
- Chrome nickel steel.
  - Quenched and tempered.
- Chrome vanadium steel.
  - Quenched and tempered.
- Carbon vanadium.
  - Steel normalized.

Of these the quenched and tempered alloy steels with an elastic limit of 65,000 lb. per sq. in. and a tensile strength of 110,000 to 125,000 lb. per sq. in. give the greatest strength per unit of weight. They have the disadvantages of high first cost, difficulty in machining, and the necessity for care in maintenance to avoid heating which would remove the desirable properties given by the original heat treatment.

Standing next in point of strength is the normalized carbon vanadium steel with a yield point of 62,000 lb. per sq. in. and a tensile strength of about 100,000 lb. per sq. in. This steel owes its strength to a manganese content of about .90 per cent, the vanadium serving to ensure ductility on normalizing. The heat treatment usually consists in heating to about 1,600 deg. F. and cooling in air

(normalizing) followed by a reheating to about 1,150 deg. F. This steel compared with the quenched and tempered steels has the advantage of not having been subjected to the severe internal strain of quenching, and also does not lose so much of its strength on being reheated in repairs.

Quenched and tempered carbon steel with an elastic limit of 50,000 to 55,000 lb. per sq. in. and a tensile strength of about 90,000 lb. per sq. in. stands close to carbon vanadium steel in strength. It loses more of its strength on being reheated.

In using the quenched or tempered steels or normalized carbon vanadium steel for round forgings, such as axles or crank pins, it is of great advantage to bore a hole of ample diameter along the longitudinal axis. It is recommended that the diameter of the hole be approximately half the outside diameter of the forging. This has the advantage of reducing the thickness of metal through which heat must penetrate during treatment. In a bored forging, heating and cooling take place in the bore as well as from the outside, and in the case of quenched forgings this is of great importance in reducing the internal strains set up during quenching. Large forgings when bored respond more readily to heat treatment and better physical properties can be obtained. Even apart from this, boring is advantageous in giving greater strength per unit of weight. With two forgings of the same material and of the same weight the bored forging can be made about fifteen per cent stronger than the solid.

Last but not least come the annealed firebox steel forgings. These make up the majority of locomotive forgings. Annealed carbon steel is simple to make and simple to handle, and is to be preferred except under special conditions in which higher tensile strength is necessary. Though the annealed plain carbon steel forgings are the simplest to make, it must be remembered that with these as with all other forgings it is essential to have sound well-made steel to start with if satisfactory results are to be secured. Also correct and accurate control of annealing temperatures is desirable.

Locomotive and motor car orders in 1924

A number of developments of previous years have progressed sufficiently to be incorporated into new power

A TOTAL of 1,413 locomotives were ordered for domestic service in the United States during 1924. This total compared with 1,944 in 1923, and with 2,600 in 1922, and represents an amount of business much below the average. Since 1901 there have been but four years, other than 1924, in which domestic locomotive purchases have failed to exceed even such a small total as 1,500.

The information given in Table I shows that the orders placed by railroads in Canada with Canadian builders totaled 71, comparing with 82 in 1923, and with 68 in 1922. The National Railways of Mexico were heavy purchasers of equipment in United States markets; their buying included 50 locomotives, as well as large numbers of cars. Other export business, outside of the Mexican purchases, totaled 92 locomotives.

Table I—Orders for locomotives since 1915

Year	Domestic	Canadian	Export	Total
1915	1,612	....	850	2,462
1916	2,910	....	2,983	5,893
1917	2,704	....	3,438	6,142
1918	2,593	209	2,086	4,888
1919	214	58	939	1,170
1920	1,998	189	718	2,905
1921	239	35	546	820
1922	2,600	68	131	2,799
1923	1,944	82	116	2,142
1924	1,413	71	142	1,626

The number of locomotives built for domestic service—in contradistinction to new business taken as shown in the totals for orders—was 1,726. This compared with 3,362 in 1923, and, as in the case with orders, was considerably below average.

The Car Service Division reports each month the number of locomotives installed and retired on the Class I roads. For the year 1923 these reports showed that there were installed 4,037 locomotives, and that there were retired 3,672. The latest report from 1924 to date is that for November. In the first eleven months of 1924, installations totaled 1,951—indicating a figure for the year less than half the total for 1923—while retirements for the eleven months totaled 1,844.

In no month during the past year was locomotive buying particularly heavy. The best month of the year was March, in which month orders for 283 locomotives were reported, and the next best was October, in which month orders totaled 135. Orders in June totaled one only, and in August only eight.

The railways handled in October the largest amount of

business, gaged by net ton-miles, that they ever handled in a similar period of time. On December 1 there were on hand 4,904 locomotives stored in serviceable condition, thereby indicating the results of the buying program of 1922, followed by the ambitious repair program of 1923, as well as the results of better locomotive utilization. This may be the explanation of the failure of locomotive purchases in 1924 to be commensurate with the volume of other railway purchases. Possibly the balance will be restored in 1925, and resort had to purchases of new power needed now less to increase merely the total amount of tractive effort, but desired rather because of the possibility of securing more effective motive power units in place of much of the older and less efficient power still remaining in service.

Table III—Types of locomotives ordered in 1924

Type	Railroad	Industrial	Export	Total

Louisville & Nashville	1	334,000	23 x 28 & 32	2-8-2	Frt.
Missouri Pacific	1	302,500	22½ x 28	4-6-2	Pass.
Missouri Pacific	1	334,000	23 x 28 & 32	2-8-2	Frt.
N. Y., N. H. & Hartford	10	245,000	22 x 28	0-8-0	Sw.
Southern Pacific	16	438,000	25 x 28 & 32	4-10-2	———
Wabash	5	351,000	23 x 28 & 32	2-8-2	Frt.

During the year which has just closed, the total capital expenditures authorized by the Class I railroads of the United States amounted to $1,077,297,000. Of this amount $101,233,000, or 9.4 per cent of the total authorized expenditures, was for locomotives. In 1923, 19.75 per cent of the total expenditures were for locomotives.

Types of locomotives ordered

A summary of the more important orders, grouped according to roads and types, placed in 1924, will be found in Table II. This list includes 1,286 locomotives for 34 railroads or 79 per cent of the locomotives ordered by the American, Canadian and Mexican roads. The balance was in small orders from a number of railroads.

Table III shows the types of locomotives which were ordered for the railroads, industrial concerns and for export. Similar information for the preceding year will be found on page 77 of the February, 1924, issue of the *Railway Mechanical Engineer*.

It will be observed that of the 1,436 locomotives ordered by the railroads in 1924, 316 or 21 per cent were for switching service. The preponderance of the orders were for the 0-8-0 type, for which there were 295. The largest orders for switch engines were those placed by the New York Central and the Pennsylvania for 50 each of the 0-8-0 type. An interesting phase of last year's purchasing was the comparatively few orders placed for the 0-6-0 type.

Locomotives with two-wheel leading and three, four or five pairs of drivers, totaled 685 or 47.7 per cent of the railroad orders. In this group, 582, or 40.5 per cent, were of the 2-8-2 type. Roads which placed orders for at least 25 locomotives of the 2-8-2 type were the Atchison, Topeka & Santa Fe; Canadian National; Chesapeake & Ohio; Cleveland, Cincinnati, Chicago & St. Louis; Illinois Central; Louisville & Nashville; Missouri Pacific; National Railways of Mexico; New York Central; Seaboard Air Line; Southern and the Wabash. Of the 61 orders for the 2-8-0 type 25 were for the Philadelphia & Reading and 25 were for the National Railways of Mexico. It will be recalled that the Philadelphia & Reading ordered 25 of the same type in 1923. Orders for the 2-10-2 include 15 for the Atchison, Topeka & Santa Fe and 10 for the Los Angeles & Salt Lake.

There were 34 Mallet locomotives ordered in 1924 or 19 less than the number ordered in 1923. The largest order placed for this type in 1924 was 20 for the U. P.

A total of 405 locomotives of the type usually employed in express and passenger service were ordered last year; this was 20.8 per cent of the total of all orders. Of these, 167 were of the 4-6-2 type, 113 were of the 4-8-2 type and 69 were of the 4-6-0 type. The largest order for the 4-6-2 type was for 50 placed by the Pennsylvania, which also ordered 50 of the 4-6-0 type. Orders for 20 of the 4-6-2 type were placed by the Atlantic Coast Line and the Missouri Pacific.

Table V—Principal orders for 2-8-2 locomotives in 1924

Road	No.	Weight, lb.	Cylinders, in
Chesapeake & Ohio	50	358,000	28 x 30
Atchison, Topeka & Santa Fe	26	343,200	27 x 32

New York Central	50	219,000	25 x 28
Louisville & Nashville	8	217,000	25 x 28
Cleveland, Cincinnati, Chic. & St. Louis	20	216,500	25 x 28
New York, Chicago & St. Louis	10	216,500	25 x 28
Florida East Coast	11	215,000	25 x 28
Southern	30	214,000	25 x 28
Grand Trunk (in U. S.)	15	211,000	22 x 28

* 3 cylinder.

The 4-10-2 type, of which 16 were ordered by the Southern Pacific, is the first of this wheel arrangement. They are of the three-cylinder design, having a tractive force of 76,900 lb., not including the booster, and a weight of 306,000 lb. on the drivers.

Three-cylinder locomotive and high-pressure 2-8-0 of the D. & H. are the outstanding developments

Without doubt, the three-cylinder simple locomotive is the outstanding development for the past year. Table IV shows a total of 43 three-cylinder locomotives ordered in 1924. These locomotives are distributed among nine roads, 16 of the 4-10-2 type being ordered by the Southern Pacific and 10 of the 0-8-0 type by the New Haven.

The most striking motive power development which has

culminated within the past year is the Muhlfeld high-pressure, cross-compound 2-8-0 type locomotive of the Delaware & Hudson. This locomotive carries a working boiler pressure of 350 lb. and is rated at over 80,000 lb. tractive force, simple, and over 100,000 lb. with the tender booster in operation. The most apparent limitation of this locomotive is the unusually heavy load carried on the drivers which averages approximately 74,600 lb. per pair of drivers.

Tendencies as to size

An idea of the size of locomotives required to meet present-day operating conditions may be obtained by referring to Tables V to VIII inclusive, in which important orders for the leading types ordered in 1924 are grouped according to weight. Similar information for the 2-8-2, 2-10-2, 4-6-2 and 4-8-2 types of locomotives ordered in 1923 will be found on pages 77 and 78 of the February, 1924, issue of the *Railway Mechanical Engineer.*

Table VII—Principal orders for 4-6-2 locomotives in 1924

Road	No.	Weight, lb.	Cylinders, in.
Atchison, Topeka & Santa Fe	10	312,000	25 x 28
Pennsylvania	50	308,890	27 x 28
Chicago, Rock Island & Pacific	1	305,000	22½ x 28*
Missouri Pacific	1	302,500	22½ x 28*
Southern	15	299,000	27 x 28
Atlantic Coast Line	20	280,610	25 x 28
Louisville & Nashville	6	277,000	25 x 28
Philadelphia & Reading	10	273,600	25 x 28

* 3 cylinder.

Table VIII—Principal orders for 4-8-2 locomotives in 1924

Road	No.	Weight, lb.	Cylinders, in.
Illinois Central	25	362,500	28 x 28
Atchison, Topeka & Santa Fe	6	361,600	28 x 28
Los Angeles & Salt Lake	5	340,000	29 x 28
Canadian National	15	339,950	26 x 30
Florida East Coast	32	308,000	26 x 28

Of the 2-8-2 type, see Table IV, 12 of those listed are of the three-cylinder design. These locomotives stand fifth from the top of the list with weights of 334,000 lb. Both the Missouri Pacific and the Louisville & Nashville three-cylinder locomotives have the same size cylinders, 23 in. by 28 in. and 32 in. The 30 locomotives ordered by the Chesapeake & Ohio are exceptionally heavy. They weigh 350,000 lb. and have 20 in. by 30 in. cylinders. These locomotives are slightly heavier than those of the same type ordered in 1923 by the Delaware, Lackawanna & Western, which weighed 356,500 lb. and had 28 in. by 32 in. cylinders.

The order of 10 three-cylinder locomotives of the 0-8-0 type by the New York, New Haven & Hartford, shown in Table VI, is the only order for three-cylinder locomotives designed for switching service. These locomotives weigh 245,000 lb. and have 22 in. by 28 in. cylinders. The largest orders of the 0-8-0 type were the 50 ordered by the New York Central and an order for the same number placed by the Pennsylvania.

Table VII includes eight railroads and 113 of the 167 locomotives of the 4-6-2 type ordered in 1924. It will be noted that two 4-6-2 type locomotives of three-cylinder design ordered by the Missouri Pacific and the Chicago, Rock Island & Pacific have been included in this list. Table VIII includes five railroads and 93 of the 113 locomotives of the 4-8-2 type ordered. The Canadian National also ordered 6 locomotives weighing 339,000 lb. each, which are not included in this table. Of the 4-6-2 type locomotives, 72, or 43 per cent, weighed 300,000 lb. or over. Of the 4-8-2 type locomotives, 55, or 48.6 per cent, weighed over 350,000 lb. and none weighed less than 308,000 lb.

Comments on designs

Considerable may be learned from the tabulations as to the general type and size of locomotives that are being purchased. The eight-wheel type seems to be the most popular for switching service. The large number of orders placed for the 2-8-2 show that this type is still the general standard for freight traffic with a tendency for heavier models. The ordering of 10 three-cylinder locomotives of the 0-8-0 type by the New York, New Haven & Hartford is perhaps, with the exception of the "Horatio Ollen" ordered by the Delaware & Hudson, the most striking feature in the year's developments.

The popularity of the Mallet for heavy freight service

Table IX—Important motor equipment orders in 1924

Road	No.	Type	Length	Horsepower	Seating capacity	Weight	Builder
American R. R. of Porto Rico	3	Coach	57 ft. 0 in.	...	46	33,141	Wason Mfg. Co.

	1	Frt. trailer	25 ft. 0 in.	...	..	12,500	Edwards.

appears to be on the decrease. In 1922 the orders for articulated locomotives amounted to 116. In 1923 the total number ordered by the railroads fell to 53 and only 34 articulated locomotives were ordered in 1924, of which 20 were ordered by the Union Pacific.

The Pacific, or 4-6-2 type, is evidently considered to be the best suited for ordinary passenger traffic if the large number ordered in 1924 may be taken as an indication. Seventy-three of the 167 locomotives of this type ordered weighed over 300,000 lb. The popularity of the Mountain, or 4-8-2 type, appears also to be in the ascendency, the orders placed in 1924 totaling 113. This type of locomotive has evidently found its place not only where long and heavy passenger trains have to be hauled in territory where grades are an important factor, but also for hauling fast freight.

Among the year's developments in this country that are also worthy of special mention are the oil-electric locomotives and the tendency towards locomotive tenders of large capacity. A recent order for fifty 15,000-gal. tenders for the New York Central is an example of the latter trend in equipment design.

The General Electric Company and the Ingersoll-Rand Company have built jointly an oil-electric switching locomotive which embodies the combination of a six-cylinder solid injection type oil engine and a direct current generator driving four motors without intervening accelerating resistances. This has resulted in a remarkably flexible and economical form of motive power, which if experience proves its practicability when adapted to units of greater hauling capacity, should materially aid in the efforts being made to utilize the oil engine with its low operating cost for the propulsion of railway locomotives.

Use of motor cars for handling light traffic increasing

The domestic orders placed in 1924 for rail motor cars amounted to 120. These cars are estimated to have a total value of $2,250,000. A total of 10 rail motor cars, including the two Diesel-electric equipments ordered from the Westinghouse Electric Company by the Canadian National, and two trailers were ordered by various Canadian roads. Among the important motor equipment orders shown in Table IX are the orders for 21 motor cars placed by the New York, New Haven & Hartford and for nine placed by the Erie. It will be noted from the list of types shown in Table X, that there is considerable variation in weight and horsepower not only between the cars built by different manufacturers but by the same manufacturer as well. The lengths of the various types of motor cars run from as low as 32 ft. to as high as the 70-ft. cars built by the General Electric Company for the Jonesboro, Lake City & Easton.

The tendency in design continues toward the development of cars with a larger power reserve. This is a natural trend because it is not economical to require a gasoline engine to run continuously at high points on the horsepower curve, for an overloaded engine requires frequent repairs which result in high maintenance costs. Among the various auxiliaries on rail motor cars, the lighting arrangement has given the most trouble. Storage batteries for lighting purposes have not given entirely satisfactory results and independent lighting equipment is coming into use. The possibility of the application of axle lighting equipment to rail motor cars has received some consideration, but this is still a problem for the future.

The present tendency is toward lightening of the superstructure and increasing the ruggedness of the trucks. The past year has seen an effort to conserve floor space by placing the power units under the floor of the car. This seems to be a step in the right direction as floor space is an important factor in cars of this type, in which the weight limitations are necessarily severely restricted.

Table X—Types of motor equipment ordered in 1924

Builder	No.	Type	Horse Power	Weight	Length	Seating Capacity
J. G. Brill Co.	24	motor	70	29,000	43 ft. 6 in.	38

Fuel economy at power plants on the S. P.

THE Southern Pacific has for many years made strenuous efforts to reduce its fuel consumption in train service with the result that it is in the first rank among railroads of this country with respect to its fuel record. In the latter part of 1923 attention was also called to the possibility of savings in fuel at stationary boiler plants with the result that a fuel committee was formed on the Texas Lines, consisting of the superintendent of motive power, the chief engineer and the engineer of fuel and water service. A competent assistant engineer was employed and a systematic plan devised for the thorough and periodical inspection of all boiler plants; with recommendations for changes in installations, which were studied and passed on by the fuel committee at monthly meetings, and the systematic instruction of boiler plant employees in the operation of the plants.

On the Texas and Louisiana Lines of the Southern Pacific there are 94 stationary boiler plants of various sizes and uses, varying from large plants at shops and terminals to small plants at water and oil stations, etc. All of these plants burn crude oil as fuel and the total cost of the oil consumed in 1923 was over $600,000.

How the H. & T. C. power plant was improved

The H. & T. C. power plant, before recent improvements were made, consisted of one 120-hp. Heine water tube boiler and two 160-hp. Erie City horizontal water-tube boilers, all set singly, their uptakes being connected into a breeching leading to one brick stack 100 ft. high. These boilers supplied steam to operate two 12-in. by 8½-in. by 12-in. duplex Union Steam Pump Company's pumps, used for washing and filling engines, two 12-in. by 10-in. by 12-in. duplex Worthington water pumps for pumping water from sump to stand pipe, one Knowles 14-in. by 7¼-in. by 12-in. Underwriter's fire pump, two 7½-in. by 5-in. by 6-in. duplex Worthington boiler feed pumps, one 500-cu. ft. duplex steam-driven air compressor, one 18-in. by 24-in. simple steam engine for driving machine shop tools and five oil pumps.

During the summer, after a majority of the improvements had been completed and the fuel consumption had been reduced about 40 per cent, it was found that the load could be carried by one boiler. One boiler supplied all steam necessary until the sleet storm on December 19. This operation of one boiler resulted in further fuel savings by firing one boiler at full load in place of two boilers at less than rating and by eliminating large radiation losses from the second boiler. It also provided a large margin of reserve.

Comparative requirements for steam

The requirements for steam during 1923 and 1924 were approximately the same. The same principal equipment was in service such as compressors, engines, water and oil pumps. During 1924, there was put into operation a hot water washing and filling system which replaced one small pump using cold water with two larger pumps for handling hot water. There was also installed an auxiliary oil tank for the power plant with two small oil pumps for pumping oil direct to the burners. The oil pump which formerly pumped oil to the burners through about 800 ft. of two-inch line at a pressure of 240 lb. per sq. in. now pumps oil through a three-inch line to the auxiliary tank.

The following is an itemized statement of the improvements made and the cost of each:

Installation of 2-in. line to waste-reclaiming plant to use exhaust in place of live steam	$90
Connections from hot water washing and filling tank to boiler feed pumps	150
Installation of 6 Hammel oil burners and air chamber on oil line to reduce steam for atomization and improve combustion	340
Hose, boiler tube cleaner and Navy boiler compound	140
Use of hollow staybolt steel plugs and plastic cement to prevent entrance of cold air to furnace	50
Installation of oil meters	100
Removal of 250 ft. of dead-end steam pipes	25
Insulation of steam pipes in boiler room	150
Insulation of ends of boiler drums	150
Installation of lubricated blow-off valves to prevent leaks and reduce repairs and maintenance of previous valves	45
Connections to utilize exhaust in place of live steam to heat oil for burners	20
Installation of steam traps to prevent waste of steam	110
Installation of 400-hp. feedwater heater	1,238
Repairs to dampers to make them adjustable	25
Installation of steam soot blowers to facilitate effective removal of soot from tubes	50
	$2,683

In view of the fact that the H. & T. C. handles only passenger engines and that all demands upon the power plant vary with the engines handled, the number of engines washed each month represents the most accurate index of output of the plant. This demand upon the plant consists of steam for firing up engines, power in the machine shop, air and oil and water supply. The demand increases in winter due to the necessity for heating a few buildings and for heating oil. The following is a record of all engines which were washed or had their water changed, this being the only official and accurate record available. This work necessitates washing, filling, pumping and heating oil, pumping water and a due percentage of other mechanical operations.

Engines washed or having water changed at H. & T. C. terminal

Month	1924	1923
January	554	462
February	550	435
March	587	486
April	553	492
May	572	527
June	594	527
July	663	570
August	605	566
September	499	545
October	486	569
November	451	560
December	542	561
Totals	6,656	6,300

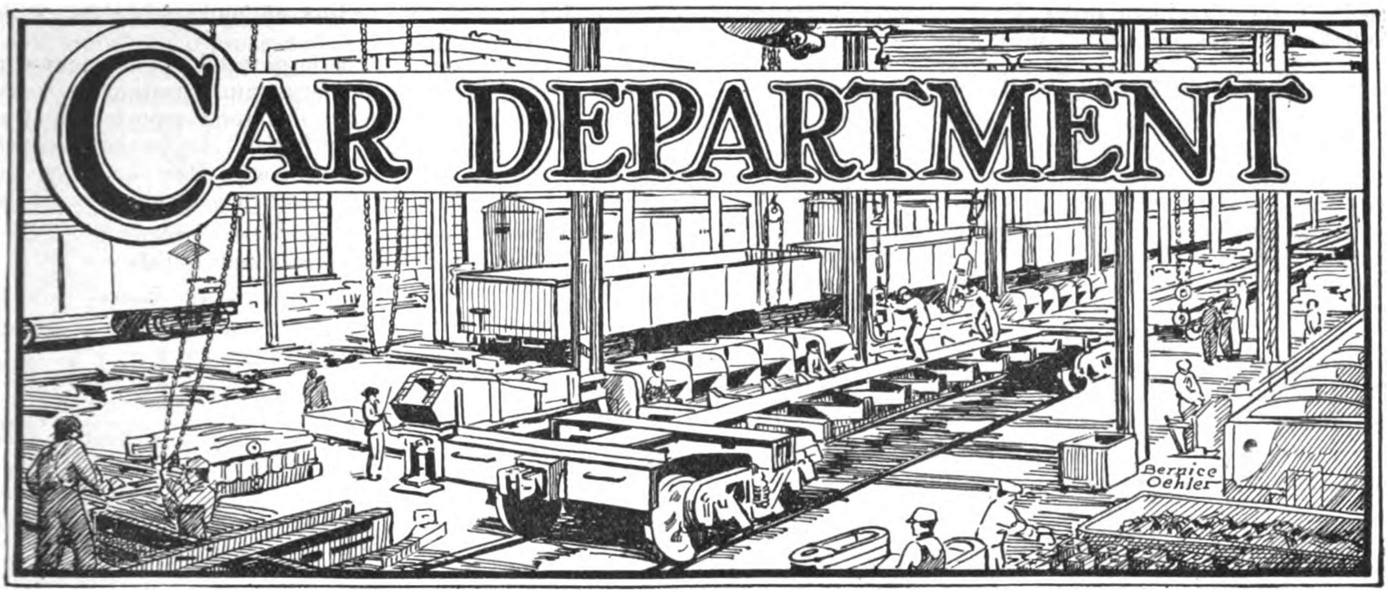
Quantity of fuel by months—1924 price per gallon

Month	Gal. of oil 1924	Gal. of oil 1923	Average price per gal. 1924
January	112,500	88,827	$0.03545
February	92,816	73,640	0.03496
March	90,903	100,948	0.03467
April	83,511	101,800	0.03451
May	78,294	93,425	0.03352
June	65,685	88,177	0.03418
July	62,698	95,391	0.03401
August	59,567	107,820	0.03439
September	59,480	97,633	0.03398
October	63,312	91,710	0.03276
November	56,367	107,610	0.03231
December	77,474	112,963	....
Totals	902,607	1,159,944	$0.37474
Average			$0.03407

In order to determine the savings made at this plant, three methods may be used. First, the difference in the total oil burned in the two years, 257,337 gal. at the average price of oil, $.034 per gal., is $8,749 a year.

A second method would be to compare the last six months of each year. This more nearly reflects the rate of savings, as most of the important improvements were completed during the first half of 1924. This difference is 613,127—378,898, or 234,229 gal., which at $0.034 a gal. equals $7,964 in the six months. This is equivalent to $1,327 a month or $15,924 a year.

A third method would be to base the savings on the fuel record for December of the two years, as in each case it was obtained from an oil meter and is accurate. December, 1924, included several unusual days of ice and sleet and might not indicate the full savings. On this basis the reduction in fuel is 35,489 gal., which at $0.034 a gal. is equal to $1,206 a month or $14,472 a year. These improvements were made under the direction of H. M. Lull, chief engineer, Southern Pacific, Texas Lines.



Car orders placed during 1924

Last year shows a marked increase in equipment orders placed by railroads in the United States

ORDERS for both freight and passenger equipment placed in 1924 by the railroads were of an exceptional volume. Freight cars ordered for service in the United States totaled 143,728. This compared with the 94,471 in 1923 and 180,154 in 1922. Except for 1922 the 1924 total was the largest for any year since 1916. Passenger cars ordered for service on the railways of the United States totaled 2,554, which compared with the orders for 2,214 cars in 1923 and 2,382 cars in 1922; it was the largest number ordered in any year since 1913.

Freight car orders

The Canadian orders for cars placed with Canadian builders totaled only 1,867, as compared with 8,685 in 1923.

The National Railways of Mexico ordered 1,740 cars from builders in the United States; other export business amounted to 2,277 cars.

Table I—Orders for freight cars since 1915

Year	Domestic	Canadian	Export	Total
1915	109,792	......	18,222	128,014
1916	170,054	......	35,314	205,368
1917	79,367	......	53,191	132,558
1918	114,113	9,657	53,547	177,317
1919	22,062	3,837	3,994	29,893
1920	84,207	12,406	9 056	105,669
1921	23,346	30	4,982	28,358
1922	180,154	746	1,072	181,972
1923	94,471	8,685	396	105,552
1924	143,728	1,867	4,017	149,612

Freight car production in 1924 totaled 113,761 cars, as compared with 175,748 cars in 1923. Up to April 30, 1924, orders had been placed for about 70,000 cars. There were, however, practically no orders placed during the following four months. Freight car purchases reported in May, June and July together totaled only 1,355 cars, and those reported in August but 4,751 cars. Improved conditions in September, and since, have changed the situation with the result that, unlike 1923, as much business was placed by the railroads for this class of equipment in the second half of the year as in the first half.

The year 1924 was characterized by some unusually large orders. The New York Central Lines purchased over 20,000 cars. The Pennsylvania purchased one lot of 12,000 in the spring, and another of 10,000 in September, all A.R.A. standard cars and totaling in value $46,500,000. The Illinois Central purchased 6,200 freight cars, and its total purchases of equipment aggregated $25,000,000. Other large purchases included the Norfolk & Western, 11,000; the Louisville & Nashville, 5,700; the Southern Railway, 8,948; the Chesapeake & Ohio, over 10,000; the Missouri Pacific, not including its subsidiary, the American Refrigerator Transit Company, over 4,000; the Reading, 4,050; the Atchison, Topeka & Santa Fe, 7,200, etc.

Table II—Freight cars built in 1924

	United States	Canada	Total
Domestic	113,761	1,721	115,482
Foreign	1,141	....	1,141
	114 902	1,721	116,623

	United States			Canadian			
	Domestic	Foreign	Total	Domestic	Foreign	Total	Grand Total

The types of freight cars ordered for service in the United States, Canada and Mexico are shown in Table III. None of the cars ordered were of unusual capacity,

such as the Virginian order for 1,025 gondola cars of 240,000 lb. capacity, placed in 1923.

Comments on freight car design

The question of outstanding interest in the field of freight car design is the ultimate status of the proposed A.R.A. standard designs for single and double-sheathed box cars. These designs, which are the result of the work of a committee representing more than two-thirds majority of the members of the Mechanical Division required to secure their adoption, were first presented at the 1923 meeting of the division. Since that time they have been through many vicissitudes of letter ballots, reconsiderations and slight modifications and the double-sheathed steel design is now back in the hands of the Mechanical Division for further consideration because of

considerable objection to the inside dimensions on the part of the members of the general committee of the Mechanical Division. Until the future status of these designs is completely settled, there will probably be no marked innovations in the design of the types of equipment to which they apply and on this settlement probably depends the future activity of the Mechanical Division with respect to other types of cars.

But notwithstanding the long uncertainty as to their fate, these designs and the recently adopted standard construction details of the Mechanical Division are having a real influence on car construction. While few railroads have specified complete adherence to them, they are serving as the basis or point of departure in the design of much of the box car equipment built or building in

Table IV—Orders for passenger cars since 1916

	Domestic	Canadian	Export	Total
1916	2,302	...	109	2,411

1924. The A.R.A. standard center sill sections are gaining adherents and are being employed in new construction to a considerable extent in spite of an unfavorable price differential charged for these sections by the mills, as compared with standard structural material. This handicap, however, can hardly be considered as permanent and, as the demand increases the tonnage of these sections, they will undoubtedly be obtainable at current structural steel prices.

Passenger car orders

The production of passenger train cars for domestic service in the United States totaled 2,150, as compared with 1,507 in 1923. The 1924 production was the largest reported since 1914, in which year 3,310 cars were built. Railways in Canada placed orders for 100 passenger cars with builders in Canada, this amount comparing with 263 in 1923.

One of the reasons for the large total of passenger car purchases in 1924 was the large authorizations of cars for the Pullman Company. The total reported by the company as having been authorized to be constructed for Pullman Company service was 506, inclusive of parlor, sleeping, library and even a few dining cars. This

1924	2,150	63	2,213	167	....	167	2,380

number was considerably above the amount ordinarily authorized by that company and presumably results from the attention that is being given to high grade passenger service throughout the country. The railroads, of course, were large buyers and several very sizable orders were reported, including notably one lot of 215 suburban cars for the Illinois Central, in addition to 66 through line cars. Another large buyer was the New York Central Lines, which together placed orders for no less than 394 cars.

During the war period and immediate post-war passenger car purchases were small. In 1918, for example, there were orders for only 9 cars; in 1919, for only 292,

Table VI—Types of passenger equipment ordered for use in the United States and Canada

Type	1922	1923	1924

	2,465	2,469	2,654

and in 1921 for but 246. For the past three years the railways have had opportunity to catch up on the deferred requirements. They have particularly made marked progress with reference to replacing wooden with steel equipment.

Information relative to the types of passenger cars ordered in 1922, 1923 and 1924 will be found in Table VI, which includes all the cars ordered for service in the United States and Canada.

Interior arrangements and finish are principal developments in passenger car design

In considering the developments of 1924, little can be said with respect to the structural design of passenger cars. The principal developments have had to do with interior arrangement and with more originality of expression in the esthetic side of interior finish.

The most pronounced innovation during the year was probably the adoption of an unsymmetrical seating arrangement in cars used for suburban service, which

provides for two persons per seat on one side of the aisle and three persons per seat on the other side of the aisle. The maximum seating capacity is thus increased by approximately one-fourth in a class of service where seating capacity is at a premium during comparatively short periods of time. This arrangement is used notably on the New York, New Haven & Hartford in the east and on the Missouri Pacific in the west.

The Pullman Company during the past year has developed a distinctive treatment of the interior decorations of its parlor cars for use on certain preferred lines which not only adds variety to the general character of interior appearance, but represents in itself a most pleasing and harmonious effect. Apparently the reaction from the elaborately carved and over-decorated type of interior finish commonly incorporated in all cars 40 years ago has run its course and the period of monotonous severity of interior treatment is ended.

To increase output of coach repairs

Use of straight line methods proposed in two alternate shop designs

By Lawrence Richardson
Whiting Corporation, Chicago

The gratifying results obtained from the application of straight line principles to freight car repair shops warrant their consideration for passenger car and locomotive shops. In one case the increase in production per man hour on freight car work was 48 per cent. To secure this increase large additional facilities would be warranted but actually the necessary changes in old shops are small and new shops can be constructed on a straight line basis at little, if any, additional cost.

Straight line passenger car repair shop layouts are shown in diagrammatic plan in Figs. 1 and 2. The main thought has been to bring out the basic principles rather than to try to show the details of an actual layout. Available property invariably sets up limitations that call for a special study of each case. This fact is recognized in the two layouts shown, one being for a long narrow area and the other for a property more nearly a square. The principles in both layouts are the same.

While a uniform run of work and production is necessary in straight line freight car shops, it is not as essential in passenger car shops. Repetition with increasing speed results in the first case while reduction in the movement of material is the basic idea in the passenger car layout. A study of the time actually spent working and that spent moving or getting material shows that these are about equal. Reduction of the percentage of unproductive time is the main idea worked out in the layouts shown. A limited specialization is also possible.

The basis of the layouts is an inbound track where the operations are performed in their usual sequence, and an outbound track where the operations are performed in the reverse sequence. The individual shops are laid out between the inbound and outbound tracks so as to permit direct straight line movement of the material from one track to the other. The distance between these tracks is made a minimum, consistent with the amount of space required for the repairs. This in turn reduces the movements to a minimum. All the worn parts start moving from the inbound track through the repair operations to the outbound track where they accumulate as repaired parts, movement being in one direction only. If any operator does not hold the required pace and keep up to the schedule, the work will pile up back of him. The effect of this is to speed him up in an effort to hold his own. Sometimes he hardly realizes that he is being forced—at other times, he is anxious to avoid the remarks of his fellow-workmen. In either case, it is not necessary for the foreman to drive the man. It thus automatically helps to eliminate the chief source of friction in a shop.

Under the old system, a pile of material did not indicate much. Under straight line production, it immediately points to delay and trouble. In this way a foreman can easily see where his attention is needed. Instead of running around a large part of the time, he can devote the bulk of his efforts to strengthening his organization and perfecting methods. In discussing straight line production with a foreman in a manufacturing car shop, he made the statement that about all he had to do was to blow the whistle every hour. If any particular stage did not shift, he could locate it at once. His main effort was bent on breaking in new men and checking the condition of tools.

The value of shop schedules seems to be an agreed fact. However, there is a tendency among men accustomed to other methods to forget them. Straight line production demands a close adherence to schedule, thus assuring the benefit to be gained from this method of operating shops.

The localization of stripping and fitting is advantageous. Since all of the stripping is done at one point, the bulk of the dirt is kept from the shop proper. This makes it much easier to keep the premises clean. Inspection is also centralized. In doing the bulk of the fitting on the outbound track, it is possible to have specialized gangs do this work. An increase in production of 50 per cent in such cases is not unusual. Benches and special machines can be located adjacent to such points, so that the men can get the full benefit of them. It is a case of less walking and more working. This point can be better appreciated by considering a shop 700 ft. long. A walk to one end and back means one-quarter of a mile. This is not unusual. Pedometer tests on workmen have shown surprising distances covered in the course of a day's work.

Inasmuch as the finishing work is done on one outbound track, it is possible to make all the necessary final inspections without traveling through the shop. This results in better and more efficient supervision. As the inspectors have a permanent location, it is possible for them also to assume supervisory duties, thereby reducing the overhead charges. Some roads prefer to have the re-trucking and final inspection made outside in order to get the benefit of full daylight. In this case, the outbound track would be just outside the shop instead of just inside as shown.

The individual shops are arranged in the sequence in which the work is to be done, the first operation being the

removal of batteries. Therefore, the battery shop is the first shop on the inbound track. In view of the tendency to separate the battery shop from the rest of the repair shops, on account of the fumes and other features, it has been shown in a separate building. The worn batteries are received at one end of the shop, moved through the shop as they are repaired and dispatched through the opposite end in good condition. At this point they meet the outbound car in its last position where they are replaced just before the car is turned out for service. In many cases, the battery shop also takes care of batteries shipped in from road points. Such shipments can be readily handled in the layout shown without interference with the current repair work.

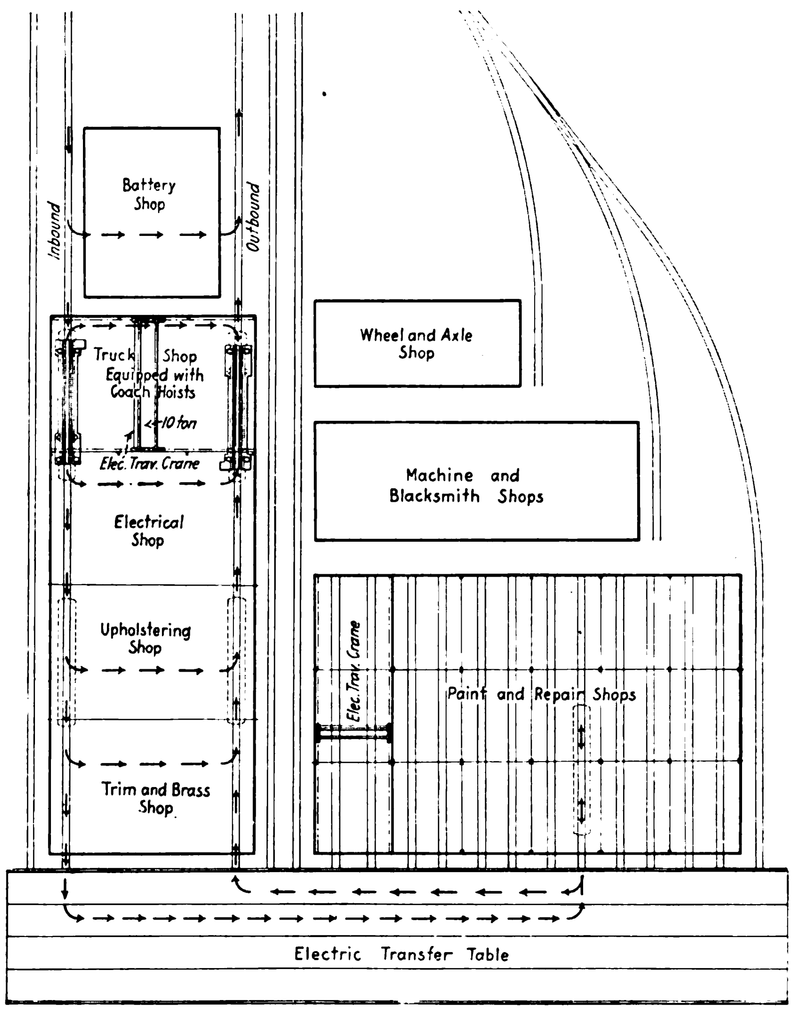

Fig. 1—Straight line passenger car shop layout for an approximately square area

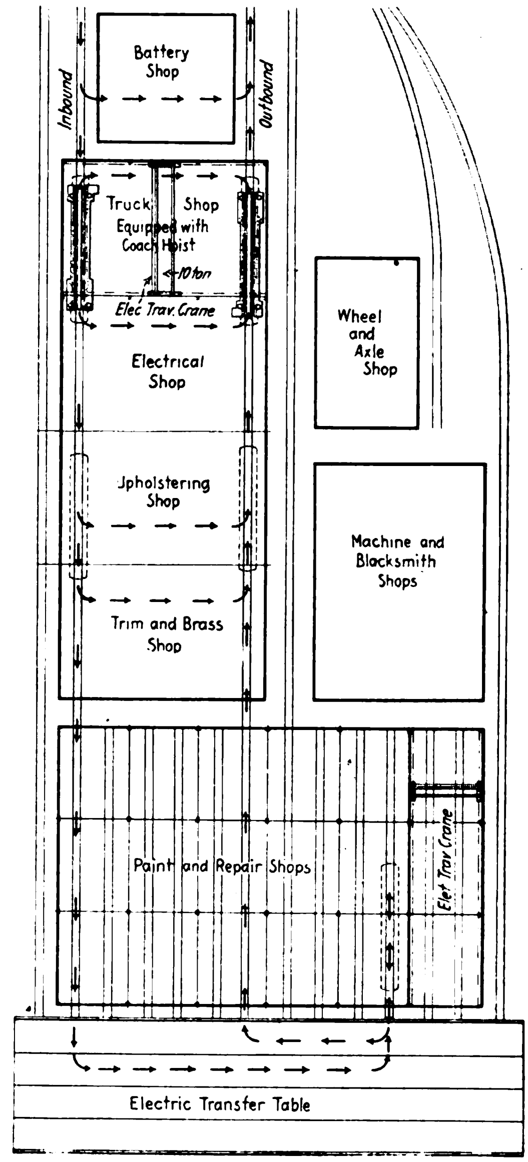

Fig. 2—Straight line passenger car shop layout for a long, narrow area

Design and location of truck and wheel shops

While the location of the truck shop is more or less optional, it has been shown in this location in order to make it adjacent to the wheel shop. In view of the fact that the wheel shop does as much work for outside points as it does for the repair shop, it has been located so that carloads of wheels received from outlying points may be moved in or out without interfering with the general shop operations. To handle the truck work properly, this shop should be provided with crane service. It is possible to give this crane enough capacity to untruck the cars although the more economical way would be to provide a lower capacity crane capable of handling a truck. The cars could then be untrucked by the use of portable coach hoists, or jacks, the crane being used for removing the trucks and handling them through the truck shop. Shop trucks are used for the movement of the car body to and from the main shop. The shop trucks released from the outbound cars are moved across the truck shop and placed under the inbound cars. When the shop is running full capacity, as soon as one car is finished, another one to be repaired takes its place. The one turned out releases a track—and a pair of trucks—to the inbound car. This means that no storage of shop trucks is required. Only when a truck is left unoccupied is it necessary to store shop trucks.

The electrical shop is located next, in order to handle the electrical generators from the trucks as well as electrical apparatus from the cars. The movement through the electrical shop conforms to the general principles mentioned in connection with the truck and battery shops.

The upholstering shop is next. The space for this shop may be a second floor above one of the other shops as only light machinery is required and the cushions and chairs are easily handled. If necessary, storage may be provided in mezzanine galleries. The trimmings and brass work are removed at the last position and moved through the trimming and brass shop in accordance with the principles mentioned.

If desired, this last space may be separated from the shop proper and used as a scrubbing room. In this way, an extra move can be saved before placing the car bodies in the general repair shops.

The number of stops on the inbound and outbound tracks may be regulated to suit the production required. If the output is limited, two stops will be found sufficient as indicated by the dotted lines. If the output is increased, it can be taken care of by increasing the

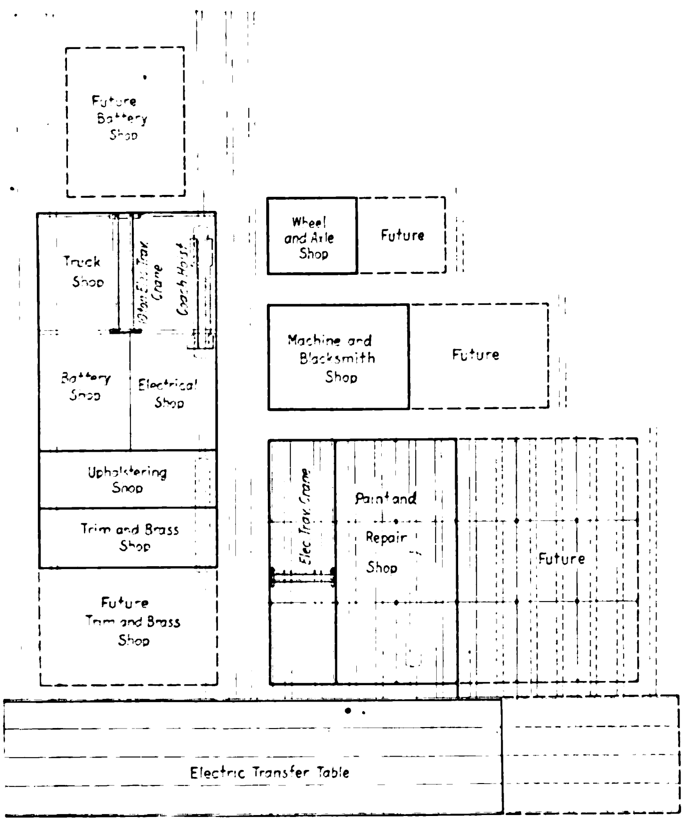

Fig. 3—A small shop layout on the straight line principle with provision for expansion

stops, space having been provided so as to make this number as high as five.

Movement of cars

The movement of the cars from stage to stage may be accomplished in several ways. No one way is best in all cases as conditions vary widely. The weight of the cars has an important bearing. The four methods usually employed are: (1) By a shifter or tractor, (2) by a winch, (3) by hand movers, or (4) by gravity. The last method is to be preferred, when possible to use it, on account of the minimum effort and time required. If the track is given 5 in. drop per hundred feet, the car can be moved readily. With this fall, the car will not start itself. On the other hand, in summer weather, when started, it can be kept moving easily. Sometimes it only requires pushing by hand. Hand car movers are used to give it a start.

After the car is stripped and scrubbed it is removed to the general repair shop by means of a conventional type of **transfer table.** Here it is painted and given repairs in accordance with usual practice. Both operations may be done in one shop or there may be separate repair and paint shops. The largest owners of special and passenger cars have found it satisfactory to do both operations in one shop. This saves several moves. The use of ovens for baking or drying calls for additional moves.

Cars, including wrecks, which need extra heavy repairs, require a considerable amount of heavy lifting. This can best be accomplished by the use of cranes. As the number is usually small, only two tracks have been set apart for this purpose.

The short span gives a low cost crane. This heavy repair shop should be walled off from the other tracks on account of the dust raised as well as the noise.

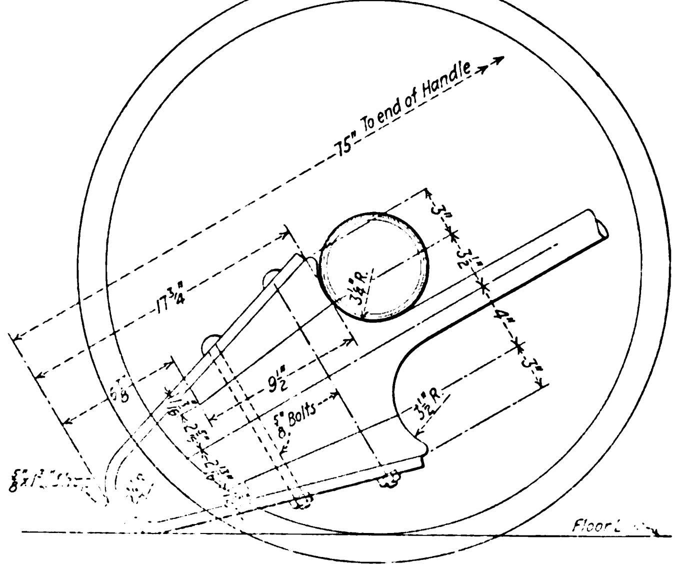
Small shop layout

In cases of roads not having enough equipment to warrant separate inbound and outbound layouts, it is possible to use one track for the purpose at first. Expansion can then be effected by transferring one of the operations to a far track. The development is shown in Fig. 3.

It will be noted that the first cost of the layouts shown is approximately the same as for standard shops. If anything, the first cost should be less as the faster movement requires less space. This makes the economy effected by the increased man-hour productions a net gain.

Wheel stick with renewable blocks

THE simple wheel stick has long served a useful part in practically every car repair yard and shop. In the accompanying drawing is shown one that is in use at the North Billerica Shops of the Boston & Maine, which appears to be a real improvement over the usual type in that the ease of renewal of worn parts has been taken into consideration. Except for the 5/8-in. by 1 3/4-in. strap iron



Method of using wheel stick

around the outside of the head, the whole device is constructed of straight grained hardwood. The strap iron protects against wear where contact is made with the floor or ground and, at the point where the axle rests on the wood, it will be noticed that renewable blocks are provided. Round head bolts hold the parts of the head in place and renewal of parts can be rapidly accomplished.

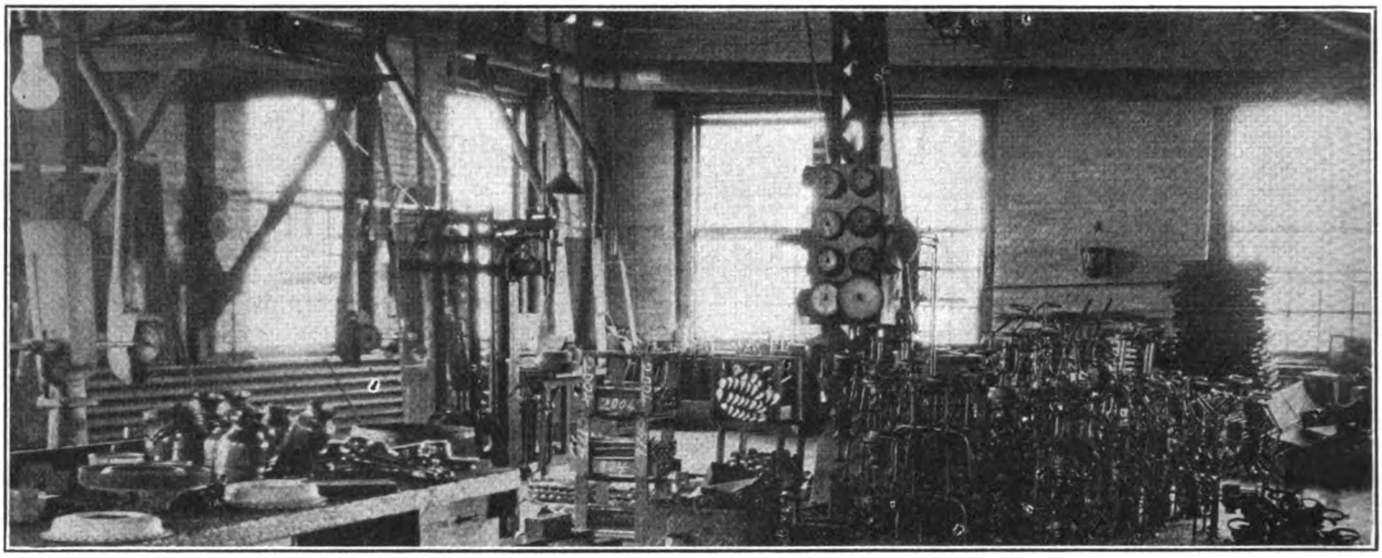
Renovating interior trimmings of passenger cars

A discussion of copper, nickel and silver plating processes used at the Billerica shops of the Boston & Maine

Part II

THERE appeared in the January issue of the *Railway Mechanical Engineer* a complete description of the methods used, at the Billerica shops of the Boston & Maine, of renovating passenger car seats in the upholstering department. On the same floor and connected to this department is the lacquer room in which modern methods are employed in copper, nickel and silver plating.

The brass trimmings of passenger cars, such as baskets, oil and gas lamps, seat arm caps, window fixtures, etc., are removed from the cars by the outside stripping gang. They are brought to the lacquer room where they are taken apart preparatory to cleaning and hung on brass wires ready for renovation.



General view of the lacquer room, showing buffing machines and repair benches

Oxidized or gunmetal finish

The most important factor in any plating process is to have the parts to be plated, thoroughly cleaned. This is generally accomplished in a caustic soda solution bath made up on the basis of 6 oz. of caustic soda (the chemical name is sodium hydroxide) to one gallon of boiling water. The parts to be cleaned are left in this bath from two to three hours, after which they are rinsed in clean hot water.

The parts are now black with a coating of dirt and lacquer which cannot be removed by caustic soda. This black coating is removed by dipping the work in a sulphuric acid bath, which consists of 60 per cent oil of vitriol and 40 per cent nitric acid. It is contained in an earthenware tank surrounded by cold water. The tank is kept filled by adding more acid to it each day until waste matter collects on the side of the tank. This indicates that the mixture is saturated with dirt and should be renewed. Every precaution should be taken to protect the workmen from the poisonous fumes which come from the acid. The parts are dipped in the acid twice and rinsed off in clean hot water. The brass parts now have their original bright appearance.

Method of copper plating

The plating is done in tanks containing 500 gallons of a solution made up according to the still solution formula. The acid or alkaline copper solution may be used. The acid solution is used at this shop. This is made up of the following ingredients:

Water	1	gal.
Copper sulphate	1¾	lb.
Sulphuric acid, 66 per cent	4	oz.
Powdered alum	1	oz.

The alkaline solution is made up from the following formula:

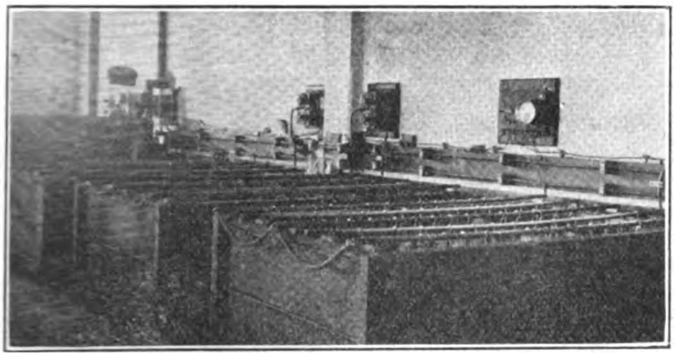
Water	1	gal.
Sodium cyanide	4⅓	oz.
Copper cyanide	4	oz.
Bicarbonate of soda	¼	oz.
Bisulphite of soda	½	oz.

The barrel or mechanical methods of plating are sometimes used. These necessitate increasing the proportions given above to twice the amount. As a rule, for mechanical solutions, the sodium cyanide and conducting salts will have to be increased 25 per cent above the amounts given for the still solutions; even though the proportions of the basic formula have been doubled.

Each tank has 18 copper anode plates which are 99 per cent copper and one per cent zinc and weigh from 12 to 14 lb. apiece. The parts to be plated are hung on the

cathode rod and remain in the tank 30 min., after which they are removed and rinsed in clean water. The electric current used in the plating process is eight volts and from 160 to 200 amperes controlled by suitable meters.

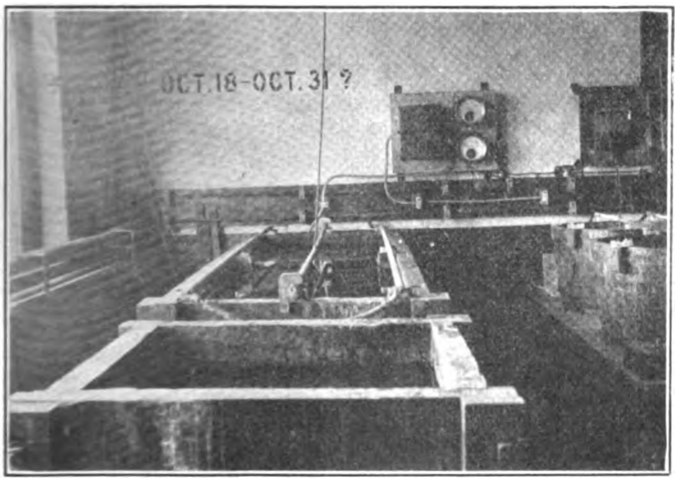
The work is now ready for the liver of sulphur bath. The chemical name for this bath is potassia of sulphurated merck. It is made up in a 150-gal. tub three times a week by mixing 5 lb. of liver of sulphur and a quart of ammonia to the tub. The parts are dipped in and out of this bath to give them the gunmetal finish. They are then rinsed in clean water and dried by compressed air, after



Copper and nickel plating vats

which they are given a scratch brush finish. The finishing process is to dip the parts in the lacquer vat, permit them to drip off and then place them in the drying room, which has a temperature of 180 deg. F., where they remain from 2½ hr. to 3 hr. They are now ready to be assembled and replaced in the cars.

If the natural brass finish is desired, they are taken directly from the sulphuric acid bath and instead of pass-



Silver plating room showing vats and electrical control board

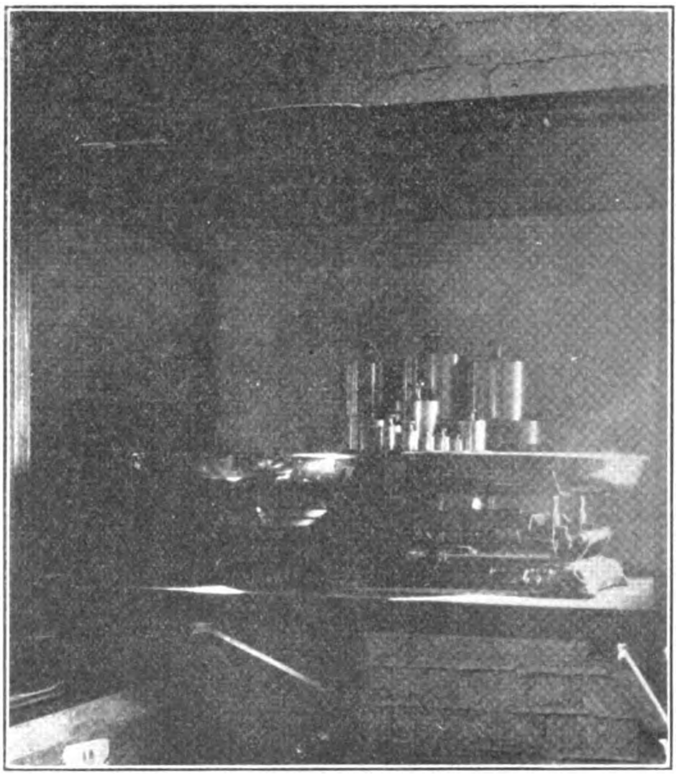
ing through the copper plating tanks, are lacquered and dried.

The requirements of copper plating

When working with solutions which are readily subjected to chemical reactions, the workman in charge must know his work and be constantly on the alert or otherwise he is liable to be responsible for expensive mistakes. It is not uncommon for the solutions to become sluggish so that they will not give uniform results even when several agents are added to increase their activity. This trouble can best be remedied by reducing the solution at least one-third with water and then adding small quantities of sodium cyanide, which will generally bring the solution back to normal again. The solution which has been removed may be heated to 180 or 200 deg. F., and metal cyanide added to increase the metal content. This may then be used as a stock solution for replenishing.

At irregular intervals the copper baths begin to give trouble. The first measure in trying to overcome this is to add common alum in the proportion of one or two ounces to the gallon. If this does not overcome the trouble, the bath needs more metal. Reduce the bath somewhat with water and then add as much sulphate of copper as the bath will absorb over night. This can readily be accomplished by suspending the copper salt in the usual acid dipping baskets made from earthenware or aluminum, upon the negative or work poles.

It is often found that when plating cast iron that the copper deposit peels or is not clear. One or two ounces of bicarbonate of soda or one or two ounces of bisulphite of soda should be added to each gallon of solution. This



Assay scales used to weigh silver bars and parts to be silver-plated

acts as a conducting salt and forms a sulphite in the solution, which is readily soluble in the cyanide. It produces a softer deposit and cleaner anodes.

The electric current must be carefully watched during the plating process. Too much current will blacken the work and not enough will give it a muddy appearance. If the process is pushed, the result will be a batch of spoiled work. On the other hand, if the parts are left in the bath too long, they will blister and peel. In this connection, it is essential that the hydrometer reading of the copper bath be maintained at 18½. When below this figure, 2 oz. of copper carbonate and 12 oz. of potassium cyanide should be added to every gallon of bath solution. If the hydrometer reads too high, reduce the solution by adding water.

Nickel plating cast iron parts

The most essential point when nickel plating cast iron is to have the parts thoroughly cleaned. The object of this

is to prevent blistering and peeling. The work is first polished with fine emery on a felt wheel, which removes all dirt, grease and old nickel. After this, the work is brushed off by a rapidly revolving wire brush. It is then washed off in caustic soda and rinsed in clean water and then scoured by hand with pumice stone and again thoroughly rinsed. The cast iron parts are now ready for copper plating. They are allowed to remain in the copper bath previously described for 40 min. When taken from this bath they are polished on a cotton buffing wheel and again run through the same cleaning process as described above. They are now ready for the nickel bath.

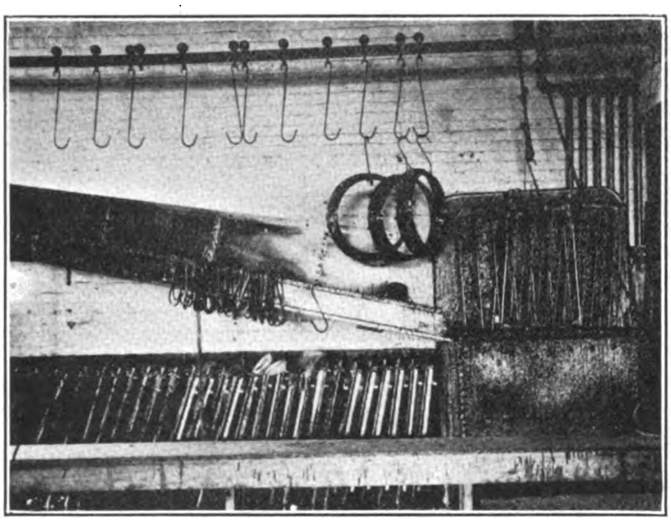
The nickel bath most commonly used for plating cast iron or steel is made up of the following ingredients:

Water	1 gal.
Single nickel salts	10 oz.
Nickel chloride	2 oz.
Boracic acid	2 oz.
Sal ammoniac	1 oz.
Epsom salts	1 oz.

This solution should give a hydrometer test of from 5½ to 7. If it is weak, it should be rebuilt with double nickel salts and water, and if strong, reduced with water. The work is allowed to remain in this bath for three hours after which it is rinsed in clean water and polished on a cotton buffing wheel.

Suggestions for nickel plating

Sometimes a nickel deposit will stain very readily. This denotes that the solution is radically alkaline. Boracic acid is commonly used for acidulating nickel baths, but for many baths, chemically pure sulphuric acid serves the same purpose at a very much cheaper cost. At the end of the day's work, to every hundred gallons of bath add 10 oz. of the acid dissolved in water and stir thoroughly. Hydrofluoric or hydrochloric acid may also be added upon the same ratio with excellent results. In the morning it will

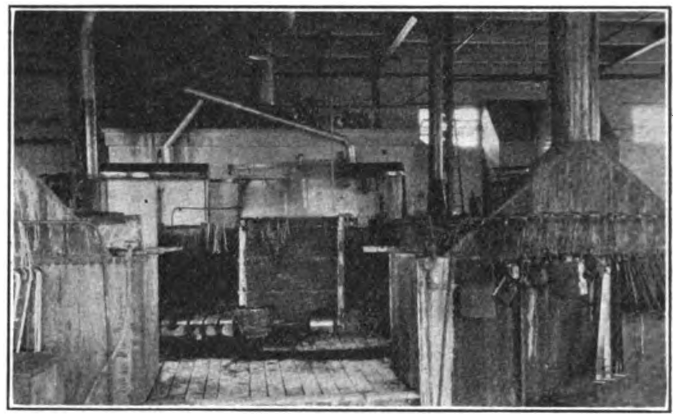


Paint vat in lacquer room, used for painting headlight casings, car gates, etc.

be found that the solution will have cleared and the staining will be overcome.

Stains are sometimes produced on nickel deposits by contaminated rinsing waters, or by drying out in sawdust that has become sour. One of the best aids to drying out nickel or any other deposit and to prevent stains is the old-fashioned plater's compound, called whale oil soap. Two ounces of this material dissolved in each gallon of boiling water will act as a dryer. The water will completely run away from the surface of the articles, thus saving labor and much sawdust.

The pitting of nickel deposits is usually caused by a deficiency of metal in the solution, or too much free acid; either case produces an excess of hydrogen gas upon the articles which appears to burn into the surface of the deposited nickel, producing pitting. The remedy is to add 2 or 3 oz. of nickel sulphate to the gallon if caused by a deficiency of metal. If caused by too much free acid, add carbonate of nickel; this is best added in the plastic form. Plastic carbonate of nickel is produced in the same manner as plastic carbonate of copper from copper sulphate, by adding two pounds of carbonate of soda to each pound of sulphate of nickel dissolved in boiling water. After precipitation, filter carefully and rewash several times with hot water. One-half to one ounce of plastic nickel car-



View showing acid vats and drying room in the rear

bonate per gallon of solution will usually overcome the free acid in a nickel bath. Nickel chloride and also nickel fluoride have been found to be excellent factors in reducing pitting. The chlorine, liberated combines with the hydrogen and is reduced to acid. A half ounce or more should be added per gallon of solution.

The peeling of nickel deposits is not always due to imperfect cleaning, imperfect removal of oxides, free acid, or free alkali in solution, but to a lack of a conducting salt. This can be remedied by the addition of common salt, sal-ammoniac, sulphate of ammonia, epson salts or nickel chloride. When the conductivity of a nickel solution is poor, dark lines will be found covered by the supporting wires or frame. A stronger current applied will not make matters any better. A conducting salt is needed, one or two ounces of which, added to each gallon of solution, will overcome this difficulty. Nickel solutions very seldom need a conducting salt; when once prepared, they do not decompose very readily, remaining quite constant. Some anodes are very hard, especially those cast in chilled moulds, and they do not reduce readily; any disturbance then noted would be due to a lack of metal in the solution, unless the bath had become contaminated with some foreign substance.

When nickel solutions are in a good working condition it is easy to maintain them even when worked constantly during the day. The amount of nickel deposited is not entirely replaced by the anodes even when as much anode surface is exposed to the action of the bath as can be conveniently placed upon the supporting rods.

Equipment for silver plating

Locomotive headlight reflectors are the important items which are silver plated at this shop. Those needing refinishing are collected until a batch of 40 or 50 are ready for renovation. This is done because it is not economical to silver plate a few items at a time. The silver plating is done by the foreman in charge of the department, who is

held responsible for each ounce of silver in his possession, and therefore, keeps a close check on the consumption of the silver and the cost of plating.

The silver plating tubs, scales for weighing the silver anodes, distilling equipment which furnishes distilled water for the Boston & Maine System, and the safe, in which the silver bars are kept are enclosed in a heavy steel wire cage which is always kept locked when not in use. The wooden tub for silver plating will hold 180 gal. of bath and, when not in use, is covered over with a canvas hood to keep out foreign matter. The bath and parts being plated are agitated by means of a rod which is attached to the cathode or rod on which the work is suspended. This rod is rocked back and forth by means of a ¼-hp. motor. The object of this idea is to keep in constant contact with the work, a part of the solution that is saturated with silver deposits so as to obtain a uniform coating of silver on the reflectors.

The following is the formula used when preparing a bath for silver plating:

Water	1 gal.
Sodium cyanide	7 oz.
Silver chloride	4 oz.
Ammonium chloride	½ oz.

This bath is maintained to give a hydrometer reading of 18½. If it becomes weak it is built up by adding sodium cyanide and silver chloride and if too strong is diluted with distilled water. The silver bars which serve as the anodes are carefully weighed before and after using. This determines the amount of silver used. The current used is 160 amp. and from 6 to 8 volts. The general idea of the arrangement of the silver plating room can be obtained from the illustrations accompanying this article.

Silver plating headlight reflectors

Parts to be silver plated are cleaned with greater care than in the processes already described. This is essential, when silver plating, in order to prevent blistering or peeling. The parts are first cleaned in hot caustic soda which removes loose dirt and grease. They are then dried and buffed on a cotton wheel, after which they are stenciled serially on the inside from one up. This is done for weighing purposes in order to determine the amount of silver deposited on each reflector. To prevent the backs of the reflectors from being plated, they are lacquered. They are next given a bright copper finish by polishing on a cotton buffing wheel using Acme white finishing compound. They are again washed off with hot caustic soda, rinsed with hot water, and then cleaned by hand with pumice stone. They are next immersed for five minutes in a mercury bath which provides a base for the silver to adhere to. This bath is made up of cyanide of potassium, a mercury and distilled water. The reflectors are again cleaned with pumice stone and a hand brush and rinsed off in hot water. Each reflector is now carefully weighed and placed on the cathode rod of the silver bath. It remains here about 25 min. during which time approximately .75 ounces of silver is deposited on each reflector. When the plating process is finished the reflectors are allowed to drain off. They are then rinsed in distilled water and dried with compressed air. They are again weighed and then given the final finish by polishing with rouge.

The table shows the cost of silver plating 44 reflectors. Labor and material required for 44 reflectors:

Labor charges

Buffing.—	18 hr. 48 min., @ 66c an hour	$12.41
Plating.—	20 hr. 24 min., @ 73c an hour	14.89
Total	**39 hr. 12 min.**	$27.30

Material charges

Tripoli, 4 lb., @ 12½c a lb	$0.50
Lacquer, 1 qt., @ $1.00 a qt	1.00
Acme white, 3 lb., @ 23c a lb	.69
Rouge, 1 lb., @ 43c a lb	.43
Buffing wheel, 5 sections @ 45c a sec	2.25
Silver, 30.17 oz., @85c an oz	25.64*
Total Material	$30.51
Total Labor	27.30
Total cost of plating 44 reflectors	$57.81
Cost of each reflector	1.31

*Weight of anodes before plating	355.94 oz.
Weight of anodes after plating	325.77 oz.
Amount of silver used	30.17 oz.

Suggestions for silver plating

Care must be taken when preparing a new silver bath not to add too much free cyanide to it as it is much better to have an excess of undissolved silver salts in the bottom of the tank than an excess of cyanide. A new bath is sometimes very erratic. A little water of ammonia added to a new bath helps to age it, and a little ammonia added when the anodes have a tendency to turn dark or black will be found of value. If too much cyanide has been added to the bath at any time, add a little nitrate of silver, one-quarter ounce to a gallon. This will be found better practice than trying to take up the free cyanide with chloride or cyanide of silver.

In freshly prepared silver baths the silver deposit is sometimes dark and granular, and because of the low voltage the anodes do not readily yield up their metal. If small amounts of ammonium chloride or potassium carbonate do not correct the trouble then it is advisable to increase the internal resistance by adding very small portions of a brightening colloid.

Other parts renovated

Various other miscellaneous parts are repaired in this department. Car locks and lamps are repaired and refinished. Headlight casings, car gates and brake levers are painted by the dipping process. These parts are brought to the shop repaired. They are then cleaned in caustic soda thoroughly dried after which they are then dipped in the paint vats, allowed to drip and then placed in the drying room for four hours. One of the illustrations shows the paint vats with headlight casings hanging on hooks suspended from the monorail. This shop can completely renovate the trimmings of four cars each day.

Methods used by the "Milwaukee" for reporting bad order cars and repairs—Problems of personnel

By L. K. Sillcox

General superintendent of motive power, Chicago, Milwaukee & St. Paul, Chicago.

Part II

WORK coming under A. R. A. rules is of such large proportions that the importance of systematizing and organizing the work is very apparent to all concerned. In the past, much of the billing work consisting of transcribing records of various kinds on to the A. R. A. billing card, resulted in mistakes and misinterpretations because the transcribing was usually done by clerks who did not understand the work. At the larger points where many men are engaged and much foreign line work is done, it is possible to reduce the transcribing very materially by using the A. R. A. billing repair card as the original record, having it filled in by the car man or checked at the work and forwarding it to the central billing office for the usual collection. It is necessary to have what is termed the original record, which is to be filed at the point where the work was done and it is considered that this requirement is met by keeping a carbon copy of the A. R. A. billing card at the local points for this purpose.

The method of recording material applied to freight cars differs greatly on the various railroads. Some charge material used from the slips made for drawing material, whereas others charge out the material from records of work done on the car. In the case of foreign car repairs it is possible to use the billing repair card when material is charged out as applied instead of as drawn in case the latter method is used.

The education of inspectors, checkers, repair men, etc., employed in handling foreign line repairs, should be followed closely and traveling inspectors are found to be of very great importance in the proper handling of this work. Periodical bulletins should be issued from time to time showing recent interpretations of rules and also giving answers to all questions submitted to a central office by inspectors.

The practice of following up the bad order car situation is now practically the same throughout the country, the

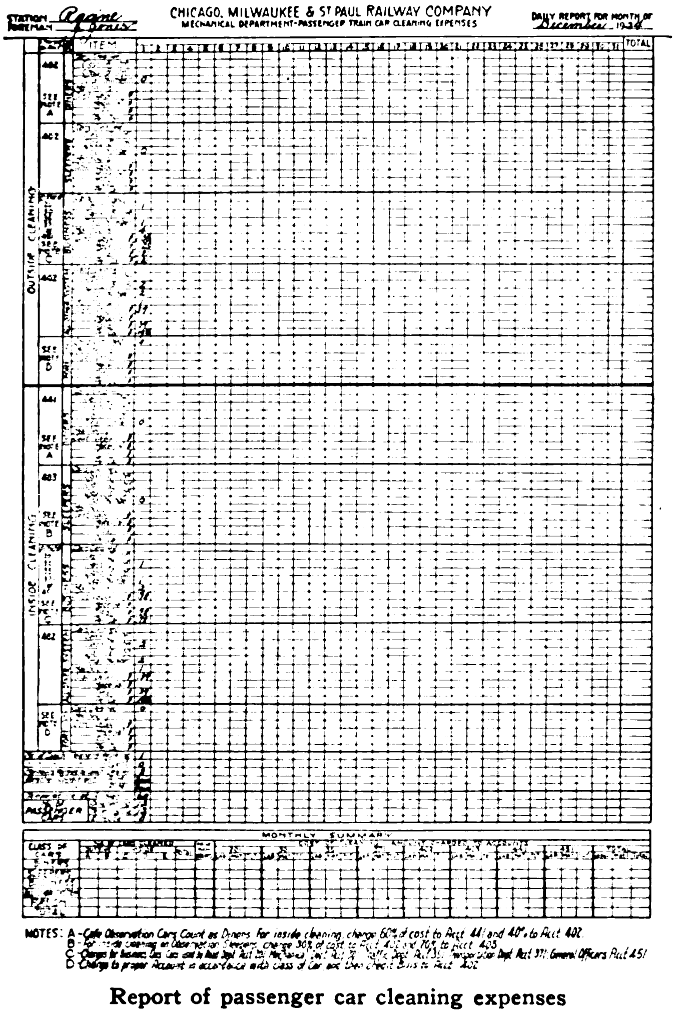
NOTE:—This report should be made out daily, except Sundays and holidays as hereinafter provided for, by foreman of each car repair station and given to Agent who will telegraph all except lower portion to C. G. JUNEAU Master Car Builder, Milwaukee Shops, each evening, and then forward the report by mail, enclosing same in envelope. Form 1518 Cars repaired and number of men working on Sundays and following holidays, New Years, Washington's Birthday, Memorial Day, July 4th, Labor Day, Thanksgiving Day and Christmas, are to be included in the report for the following day.

Signed J. Smith Foreman in Charge

Daily telegraphic report of bad order cars on hand and repaired at 6 P. M.

* The conclusion of an abstract of a paper read at the regular monthly meeting of the Car Foremen's Association of Chicago, held December 8, at the Great Northern Hotel, Chicago. The first part of this paper appeared in the January *Railway Mechanical Engineer*.

difference being only as to the matter of form and application of the data. This involves the question of classification and organization to handle the work and control the bad order situation. For the purpose of simplifying the matter, repair points can be classified, each having a stated output requirement based on the classes of heavy and light repair work handled. On the Chicago, Milwaukee & St. Paul, Class one repair points are those having 100 men or more with facilities to handle heavy and schedule work at a specified maximum output; Class two repair points are those with facilities for doing some heavy work, having no less than 15 repair men engaged in this work; Class three repair points are those having some facilities



Report of passenger car cleaning expenses

and less than 15 men engaged in repair work; Class four repair points are those stations of a lighter nature not included in the above.

Bad order car report

A sample of the daily bad order freight car repair report is illustrated which shows by kinds of cars the repairs made each day and the bad order cars left on hand together with the number of men engaged on car repair work, etc. This is a daily report which is sent to the central office for consolidation. In addition to the daily report a special statement is made once each month showing all bad order cars on hand at the end of the month by individual car numbers, initials, date bad ordered, principal defects and date expected out. The purpose of this form is to determine unnecessary or unusual delays to individual cars and to select those which have been held 30 days or more to see what can be done to overcome such delays. This report is of great value in following up per diem losses and the releasing of cars in time of shortage.

We use the blank back of the daily bad order report for special information and one of the features is a report of personal injuries occurring each day. Personal injuries are followed up closely and recorded in relation to the turnover of labor to see whether it is due to new employees or lack of safety measures, methods of handling work, etc. It is felt that in following up such matters the local foremen are placed in a position where they must naturally assume more responsibility along this line and keep injuries down to a minimum.

We also have shown on the back of this report a statement of material shortage confined to that which is handicapping the work. This shows the requisition number, the date ordered, the follow ups, etc., with a view to assisting the general officers in overcoming the situation.

A car department hand book is issued from time to time designed to embrace practically all of the activities in the handling of car work which come up from day to day and which are more or less standard.

Passenger car cleaning

In the matter of cleaning passenger cars, it is natural to suppose that this is a subject of a minor nature requiring no special records or supervision, but owing to the fact that the Chicago, Milwaukee & St. Paul owns and operates sleeping cars this requires a definite division of the cost as between departments and we have felt it necessary to go into this feature rather closely. The cost of cleaning passenger cars is charged to three different accounts, except business cars, which may go to many different accounts. The outside cleaning of all cars (except business cars) and the inside cleaning of all but sleepers, diners and business cars, is chargeable to account 402. The inside cleaning of sleepers is chargeable to account 403 and the inside cleaning of diners is chargeable to account 441. The cost of cleaning special or officers' cars should be lodged against the superintendence account according to use. This is a rather complicated procedure and as the direct cost of this work is combined with a multitude of other kinds of charges it is not possible to control the expense without dividing these accounts and determining the direct labor and material charges and the amounts allocated in spreading the overhead charges. It is possible to analyze actual individual train operation to control this expense by means of direct labor cost, but this is not always available as the information is based on a variety of data, which is not the same at all times and a mere control of the direct labor feature does not give any idea of the correctness of other allocated charges.

In order to follow up the cleaning cost properly it is necessary to have organization and classification. We are handling it as outlined on the report form illustrated, which is based on inside and outside cleaning and classification of equipment according to the division in the accounts. We have divided the classes of cleaning into the following:

(A) Outside cleaning when car is scrubbed with water and acid and trucks sprayed with distillate oil.
(B) Outside cleaning when car is scrubbed with water only and trucks cleaned with or without oil spray.
(C) Inside cleaning when car is sponged with soap and water and otherwise renovated.
(D) Inside cleaning when car is blown out, swept, dusted and mopped.
(E) Light cleaning of inside en route at intermediate stations.

The classification of cars for making the proper division of the cleaning cost to the appropriate accounts is as follows:

(1) Diners and cafe-observation cars.
(2) Sleeping, tourist, compartment sleepers and observation sleepers.
(3) Business cars.
(4) All other passenger train cars.

The instructions provide that cafe-observation cars

count as diners and that the inside cleaning cost shall be divided so that 60 per cent goes to account 441 and 40 per cent to account 402, this being based on average dimensions. A division of the charges for inside cleaning of observation sleepers provides for 30 per cent against account 402 and 70 per cent against 403. Charges for business cars depend upon the account of superintendence to which the officers' pay is charged. Charges for all other work on ordinary cars go to account 402.

It might appear that this form is too much in detail, but it is as yet an experiment and is lined up something in the same manner as we handle enginehouse expense. It is possible to make an entry of all operations each day in the month and then to use the same form for a monthly summary of the system. The summary at once gives us the total charge against the various accounts for cleaning cars and when the difference between the direct charge and the total charge as made by the accountant is too great, a further analysis is made to determine the reason. This form covers both labor and material, but does not provide for the usual overheads allocated by the accountant, such as store expense, shop expense, power plant distribution, bills, vouchers, etc. This is merely another illustration of intensive supervision of a certain class of work which cannot be fully controlled by other means.

Hiring men

The personnel, comprising labor forces, reflects the intelligence exemplified by the employing officer when selecting new men for the service. In some cases there are periods where he may be restricted from making his judgment effective in the selection of his men, such as we witnessed during the late war when the labor shortage was tremendous and we were compelled, in many instances, to accept men who, under ordinary circumstances, would not meet the requirements. There are other times such as when forces are to be increased immediately for emergency service. This causes the average foreman to overlook the importance of knowing what kind of a man he is hiring. In every instance, where conditions will permit, the objective should be to secure the best available talent. The management must always have this thought in mind when issuing instructions to increase forces. Much can be accomplished, where large numbers of men are employed, by arranging for permanent forces, which results in steady employment to a sufficient number of men to take care of the service adequately. Emergency cases and fluctuations in business can be taken care of by temporary forces, and, if hired as such, it will give the employing officer an opportunity of selecting the best material to be assigned to the regular forces when vacancies occur.

Advancement of men

Proper care having been taken in selecting men for the service, it then becomes important that they receive the right training so as to develop whatever natural qualifications they may have for future advancement. Car foremen who are alert will quickly discover these traits and will endeavor to perfect their development, resulting in highly competent men being available for positions that require special skill or unusual attention on the part of the workmen. Such men should gradually be worked into the organization in the various positions for which their natural qualifications adapt them.

The great need in industry today is to provide employment that has an incentive for the employee voluntarily to do his utmost instead of being merely on the job. In many instances large employers have, at very heavy expense, provided departments to carry out well planned activities of interest to the welfare of their employees and often the results have proved a good investment. These plans are adaptable where the points of employment are confined to comparatively small territory. On railroads, employment is maintained every hour in the day, each day in the year, over thousands of miles, covering in many instances several states, making it practically impossible to follow such a plan, even though it were adapted to the needs. Therefore, of necessity, use should be made of other methods so that the average man will aspire to do his utmost in the interest of the service. To bring this about, it has been suggested that the following outline be striven for: (1) steady employment; (2) clean and sanitary housing conditions; (3) educational facilities; (4) a correct and complete understanding of company objectives.

The proper cultivation of human relations is equally important and mutually desirable in providing an incentive for employees to advance in the service. Every officer should feel that he really exemplifies the spirit in which the management is to be accepted by the rank and file. The foreman, in this connection, by his every act, reflects the policy and desires of the management, and, if they are cordially and humanly applied, it will establish

Monthly report of bad order cars on hand

a mutual understanding that develops conditions which instill in the hearts and minds of the men the desire to succeed.

Too often supervisors, and managements as well, lose sight of these essentials which are so eminently necessary to enlist the undivided support and loyal feeling which results in the men liking their work. Once this is accomplished, the way is cleared to perfect an organization among the men, who can function in units, that will provide successful accomplishment. Capable foremen readily acquire the ability to observe men who have this incentive and who, by their efforts, show distinct evidence of being willing and able to secure greater knowledge of the service and assume the added responsibilities involved in the discharge of the duties in each instance where men are advanced to more important positions. Men of this caliber must always be kept in mind and properly trained so that, eventually, they will be able to understand the fundamentals in connection with handling men, and, when vacancies in supervisory positions occur, they should be filled by those whose service merits such promotion. If properly handled, advancement will generally meet with the approval of the rank and file, and be further evidence that there exists an opportunity for them to do likewise, if they will fit themselves and be ready, at all times, to meet service requirements.

Discipline

The administration of discipline is in itself an act of judgment on the part of the management. No well directed property can function efficiently until the subject of discipline has been thoroughly studied and a definite

policy inaugurated, because discipline can rightfully be construed as constructive criticism. Each property has its individual problems to meet and in applying discipline to employees it should be done with a sense of justice that will be eminently apparent to those involved. Sentiment and personal favors must be entirely eliminated. Honesty, and a willingness to define the facts, should at all times prevail in order to eliminate the greatest evil in the application of discipline, which is discrimination. It is practically impossible to apply constructive discipline in any line of industry where there is a large labor turnover.

Foremen are apt to apply discipline under pressure by removing men from service for causes which when investigated are not substantiated by fact, resulting in their judgment having to be superseded by higher authority, and the employees involved returned to service. Action of this kind often causes the foreman to feel that he has not been properly supported, resulting in his becoming indifferent as to the action necessary in subsequent cases. Care should be exercised to impress each supervisor with the necessity of applying the principles above referred to in each case and profit by the judgment of his superiors because the details differ materially in almost every case where discipline should be applied. On the other hand, when cases are appealed to higher authority, decision must be rendered in support of the foreman where the facts and policy of the management warrant the action taken. Then if leniency is to be applied, the employee involved should so understand and the foreman be informed so that he will appreciate his duty when other or similar cases arise.

If these few facts in connection with discipline are truly observed and applied in harmony with existing conditions, a reduction in labor turnover will be readily evidenced. Close observers realize the tremendous expense, many times avoidable, due to the unnecessary changing of labor forces. If an employee is to be dismissed, it should be apparent that the service is thereby benefited. Very frequently employees are taken out of service and the new men assigned prove inferior, which clearly indicates that it would be an advantage to the railroad to have kept the employee in service, especially if a method could be applied that would eliminate any undesirable characteristics that he may have acquired. In this respect there is an element worthy of consideration. We appreciate, I am sure, that there are men who are objectionable and a detriment, and of course they should in some way be dealt with and definitely removed, care being taken that they do not re-enter the service at some other point without satisfying the management of their intention and desire to function so that their employment will be acceptable and of interest to the service. Discipline resolves itself into a feature of management, which must be comprehended, but never compromised.

Conclusion

In closing, allow me to suggest a few seemingly important items, as a matter of illustration, to indicate the meaning of effective car department service and which embrace:

(A) An organization with fixed ideals of attainment, working together towards the accomplishment of that end and with the right sense and exercise of the importance of individual initiative and responsibility.

(B) The proper contribution towards safe and prompt train performance by obtaining maximum mileage per car per year with a minimum of detention en route due to inspection, physical defects or damage to lading, and at a minimum cost.

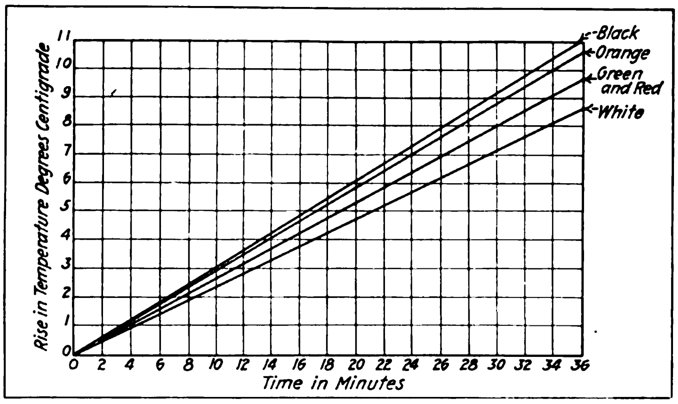
An experiment to reduce refrigeration losses

By Henry A. Gardner
Institute of Paint & Varnish Research Laboratories, Washington, D. C.

During the summer months, surfaces painted in dark colors rapidly absorb the heat rays and become very hot. When white paints are used, the painted surfaces are slow to absorb the heat rays and, consequently, will remain several degrees cooler. An application of this principle might well be made to conserve ice and keep refrigerator cars at a temperature sufficiently low to preserve the perishable foodstuffs for a longer period of time. At the pesent time refrigerator cars are generally painted an orange color which rapidly becomes warm and transfers its heat to the various compartments. The result is a loss of ice and foodstuffs. This is indicated by the results of some of the experiments recently conducted at the Paint and Varnish Research Laboratory at Washington, D. C.

Method of making tests

Experimental carriers were constructed of friction top containers. A double wall effect was obtained by placing a pint container inside of a quart container. The space



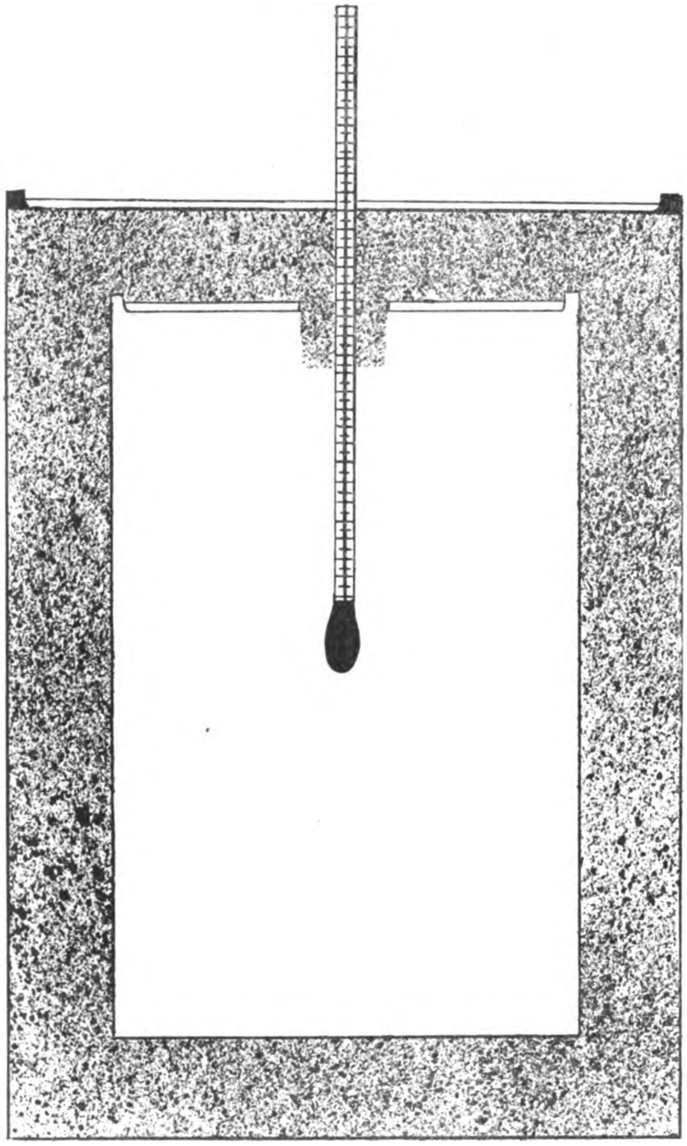
Graphic representation of the rise in temperature of different colors of paint when exposed to the sun

between was filled in with ground cork about 1/16 in. to 1/8 in. in diameter. The exterior surface of the outer container was painted two coats, each with a different color. Several containers were thus prepared and filled at the same time with a low temperature refrigerating fluid. The liquid used in one instance was ice water, and a solution of solid carbon dioxide gas in acetone was used in the other instance, which had a temperature of 40 deg. C. Closely comparable results were obtained with these two liquids. Cracked ice was also experimented with, but it was found difficult to obtain uniform temperatures in each can because of the difficulty of transferring the ice in exactly equal quantities without a loss of temperature.

After placing the liquids in the inner cans, the covers, which were provided with stoppers and thermometers, were adjusted and a layer of cork spread over the upper surface after which the outer containers were sealed at the top. The row of vari-colored containers was placed out of doors in the sun and thermometric readings were made once a minute. At the end of 30 min. the black cans could not be handled because of their high temperature of 140 deg. F. The white cans could be handled

comfortably, indicating a very much lower temperature. Later experiments with white metallic pigment powders indicated that they do not give as efficient results as the white paint, but superior results to most tinted or colored paints.

The rapid transfer of heat apparently took place from the outer can through the layer of cork and air insulating space, and then through the inner can into the liquid. This transfer of heat is very rapid, as is shown by the temperatures recorded at the end of 30 min. It is conceivable that much greater differences might be shown at the end of six or eight hours time on a freight car in



Arrangement of apparatus for determining refrigeration losses

a sunny yard or even in transit. Convection might, however, play an important part in the latter instance. The results obtained with these tests would suggest the use of white or light tints rather than the darker colors on refrigerator cars.

Through the use of test fences out in the open, the value of paint as a preservative has been proved and now through this latest experiment a new use of the right kind of paint to reduce to a minimum refrigeration losses in freight cars has been shown.

Proper application of paint

In line with this research work on the painting of refrigerator cars is the application of the paint. Where it formerly took a man at least a day to apply one coat of paint to a freight car, it now takes but an hour or two provided the principle of atomization or spraying is used. The paint gun, after much experimenting, has been brought from a crude, imperfect tool to a simple, highly effective device. Painting by this mechanical method can be done in a fraction of the time required by hand brushing, the paint is spread more uniformly, and the coating of paint, so important to the refrigeration car, is heavier and more durable.

Decisions of the Arbitration Committee

(The Arbitration Committee of the A.R.A. Mechanical Division is called upon to render decisions on a large number of questions and controversies which are submitted from time to time. As these matters are of interest not only to railroad officers but also to car inspectors and others, the Railway Mechanical Engineer will print abstracts of decisions as rendered.)

Information to be specified in case of replaced springs

The Erie made repairs to C.S.N.O. & P. car No. 122033, which is the property of the Gulf Coast Lines. Among the items of repairs made was included the replacing of one D.C. draft spring on account of being broken. The Gulf Coast Lines returned this repair card to the Erie calling attention to the fact that the repair card did not show that both coils of the draft spring were broken and referred to the interpretation of Rule 8 as authority for request that the charge be reduced to cover the outside coil only. The Erie returned the repair card and refused to reduce the charge as requested, claiming that as the repair card and original record of repairs showed "D. C. Spring" applied on account of being broken, the charge for both coils was correct.

The Arbitration Committee rendered a decision to the effect that: "In order to justify a charge for a double coil spring, it is necessary that the original record of repairs, as well as billing repair card, show that each coil was defective. This information must not be assumed."—*Case No.* 1315, *Gulf Coast Lines vs. Erie.*

Responsibility for car damaged in loading

Buffalo & Susquehanna steel gondola No. 12258 was delivered by the Delaware, Lackawanna & Western to the South Buffalo to fill an order to load pig iron to a point on or via the D., L. & W., the order having been placed by the Rogers-Brown Iron Company with the South Buffalo. In the process of loading this car with pig iron, the body of the car buckled when partly loaded and settled down and the car body was damaged beyond repair. The owner demanded settlement under Rule 113. The South Buffalo contended, on the other hand, that Rule 120 was applicable to the case. The car owner stated that the damage to the car was originally properly reported as a responsibility of the handling line and that the facts in the case did not justify the South Buffalo in changing its report to make the case come under the Rule 120. The owner further stated that if the car had been in the condition claimed by the South Buffalo in its last report, it would not have been accepted loaded by three foreign roads and empty by the same number of roads, including the South Buffalo. It was contended that if the car was not in fit condition for loading it should have been reported, in accordance with Rule 120, by the South Buffalo, before being delivered to the shipper, in order to give the owner an opportunity to inspect the car, and not after

its destruction when an inspection could not possibly reveal the prior condition of the car. The South Buffalo stated that after the failure it was determined that the floor plates were so badly corroded and rusted away, and the center construction in such a weakened condition that the car was no longer fit to carry its marked capacity. It was further stated that this condition was not evident nor would it be on usual junction inspection, nor was it known to the Iron Company. The handling line contended that it must accept the owner's statement marked on the car that it will safely carry a certain load, that failure is the inevitable result of such weakness as developed in this case unless the owner takes the precaution to reduce the loading or to replace the parts which deterioration has rendered unfit for service.

The Arbitration Committee, in a decision rendered February 15, 1924, sustained the contentions of the South Buffalo in that this car was properly subject for disposition under Rule 120.—*Case No. 1317, Buffalo & Susquehanna vs. South Buffalo.*

Narrow gage refrigerator cars for the D. & R. G. W.

TWELVE narrow gage refrigerator cars were built at the Alamosa shops of the Denver & Rio Grande Western in September, 1924, with the object of making them large enough to take a minimum standard gage car load, as most of the produce shipped on the narrow gage has to be transferred to standard gage cars to reach its destination. The trucks on these cars are placed 4 ft. 3 in. from the ends, on account of the numerous sharp curves.

The cars are of wood construction throughout and weigh 34,300 lb. with a capacity of 50,000 lb. The underframe is made up of 5-in. by 9-in. side sills, two 4-in. by 8 3/16-in. inter sills and two 5-in. by 8 3/16-in. center sills. The body bolsters are of cast steel. The walls consist of an inside lining 13/16 in. thick, one layer of 90-lb. paper, ½ in. Flaxlinum, 2 5/16 in. air space, ½ in. Flaxlinum, one layer of 90-lb. paper and 13/16 in. siding. On account of the height of the car, the construction embodies only one belt rail.

The floor is made up of a 13/16-in. sub-floor, a ⅛-in. layer of Unarco waterproofing compound, 2 in. of cork, a ⅛-in. layer of Unarco compound and a 7¾-in. ship lap top flooring.

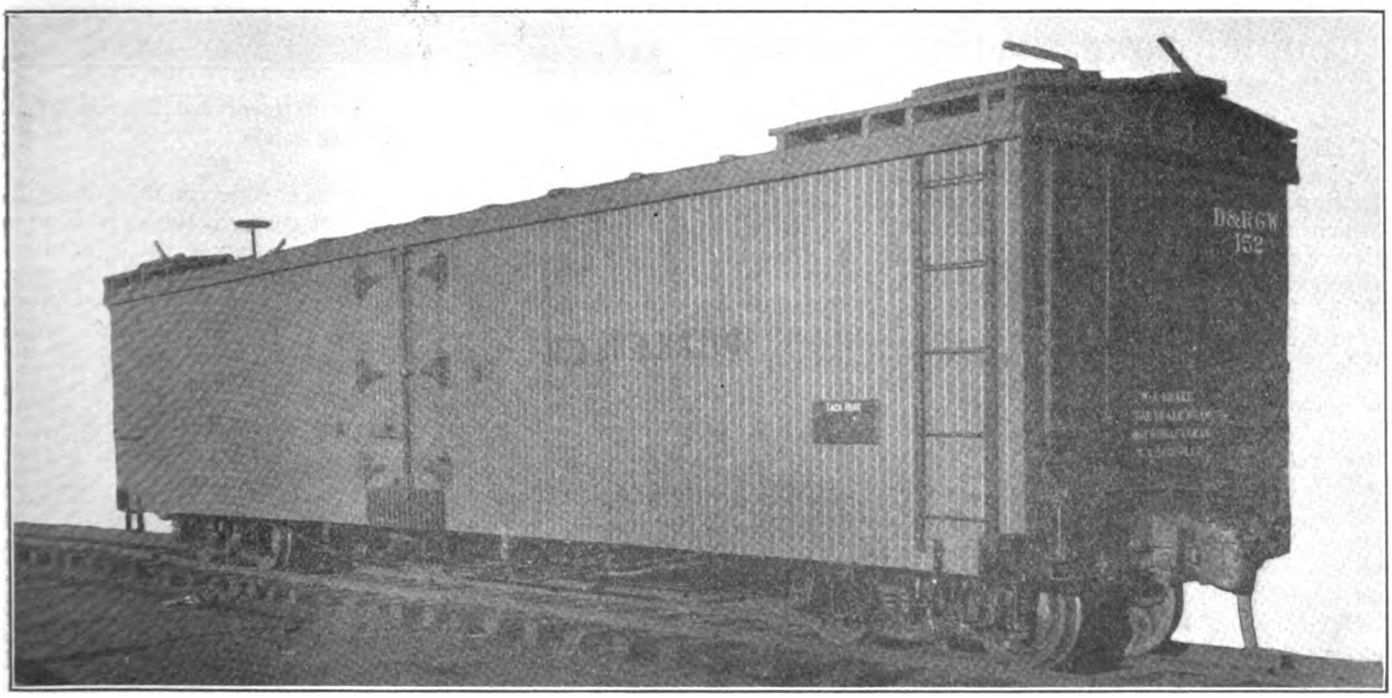
The ceiling is insulated with 1 in. of Flaxlinum laid between the carlines. A Murphy XLA metal roof is used.

The doors are equipped with Ureco self-locking hinges and Miner refrigerator door fixtures. Imperial Type "B" uncoupling rigging and Economy steel ladders are applied.

The dimensions of the car are as follows:

Length between pulling faces of couplers	42 ft. 10½ in.
Length over end sills	40 ft. 0 in.
Width of car, outside	8 ft. ⅝ in.
Inside length between bulkheads	33 ft. 2 in.
Inside width	7 ft. 2¾ in.
Inside height	6 ft. 4 in.

The bulkheads are stationary and insulated with 1 in. Flaxlinum. Tyler bunker netting is used in the ice bunkers. The bulkheads, bunkers, hatch covers, plugs and platforms follow the design of the U. S. standard cars.



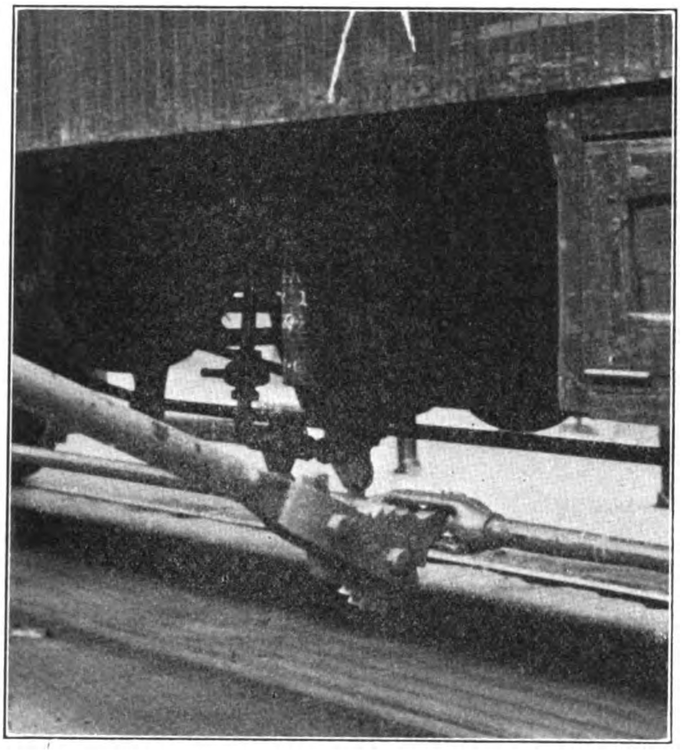
Narrow gage refrigerator car which will take minimum standard gage car load

Ratchet wrench for passenger car truss rods

IN the process of tightening up passenger car truss rods it is not unusual to find that battery boxes, air reservoirs and other equipment interferes with the free use of the ordinary pin bar used for this work. There is in use at the Billerica shops of the Boston & Maine a ratchet wrench which can be readily used where the space is limited.

With a wrench of this kind the buckle can be turned completely around with only a 6-in. space to turn the wrench. The stub end of the wrench is inserted in the buckle and is prevented from slipping out by a cotter key placed in a hole at the end of the stub. The ratchet may be set at a different angle as the buckle is turned around.

There can be slipped over the purposely short, 1-in. diameter lever end of the wrench a long piece of pipe by which a greater leverage may be obtained. This appliance can



Truss rod ratchet wrench adaptable for use in a limited space

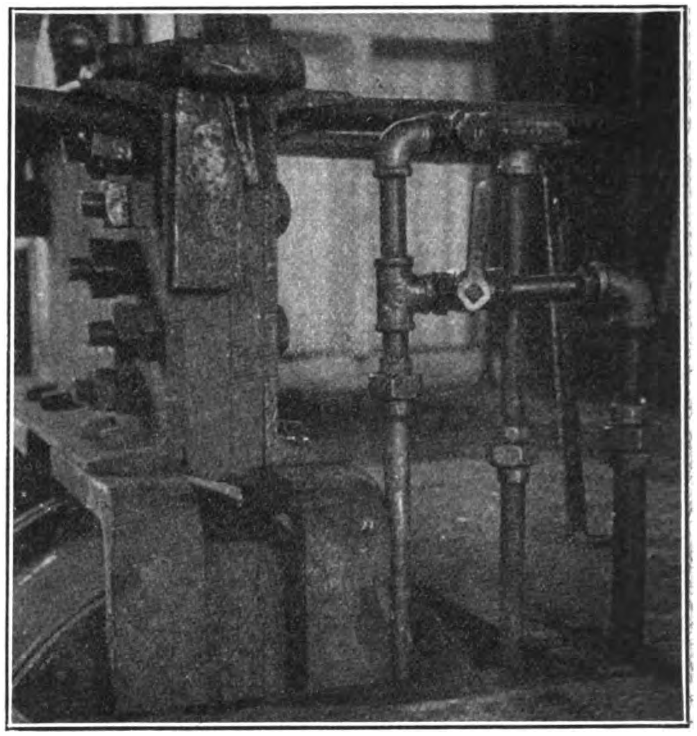
be readily made by any blacksmith and, with a small amount of machine work, there is produced a tool which will prove very valuable in tight places.

Coupler yoke riveting machine

By G. Charles Hoey

THE machine shown in the drawing was devised by a car foreman in order to facilitate the work of getting cars away from the rip track, a problem which he had had considerable difficulty in solving. The device consists essentially of an anvil block *A*, a lever *B*, a supporting frame *C*, two supporting brackets *D* and a 16-in. by 12-in. driver brake cylinder. The supporting frame *C* is constructed from two 12-in. structural channels 28⅜ in. long. The two supporting brackets *D*, are formed from 1¼-in. by 3-in. bar iron. A connecting yoke *E* is welded to the driver brake cylinder push rod. Filler blocks *F*, of varying thicknesses may be inserted in front of the anvil block *A* to suit the different size coupler yokes. The supporting arms *G* are made of 1¼-in. round bar iron, and are riveted to the flanges of the frame channels.

In applying the coupler yoke to the head, the coupler butt is placed in position in the yoke on the supporting arms *G*. The heated rivet is then slipped into place and the coupler and yoke is moved over until the rivet head is in position in front of the filler block *F*. Air is then admitted to the operating cylinder and as the air cylinder



View showing the piping arrangement and location of the operating valves

piston moves forward, the back roller in the connecting rod jaw moves along the inner curve of the lever *B* which is pivoted on the pin *H*. This action of the lever drives down the protruding end of the heated rivet and the recess in the upper end of the lever *B* forms the head of the rivet. Upon releasing the air from the cylinder the spring forces the piston back into position.

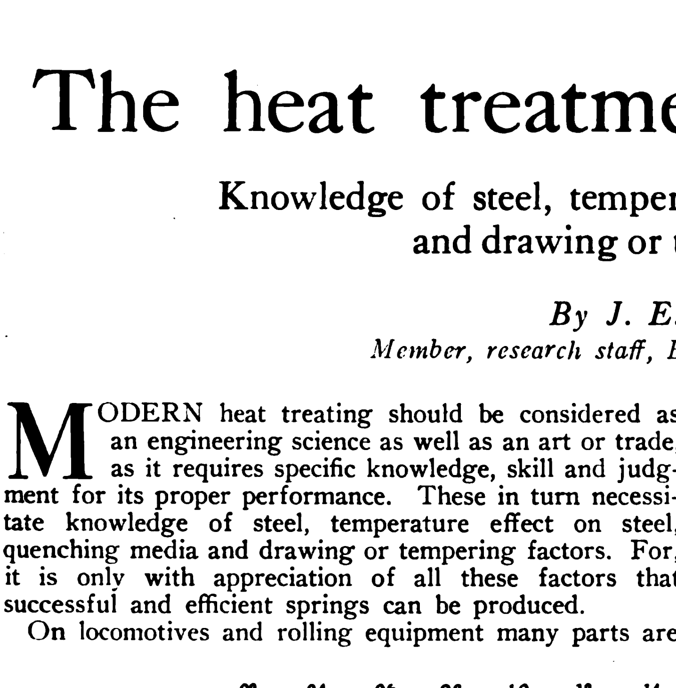
The heat treatment of spring steel

Knowledge of steel, temperature effect, quenching media and drawing or tempering essential

By J. E. Burns, Jr.
Member, research staff, E. F. Houghton & Company

MODERN heat treating should be considered as an engineering science as well as an art or trade, as it requires specific knowledge, skill and judgment for its proper performance. These in turn necessitate knowledge of steel, temperature effect on steel, quenching media and drawing or tempering factors. For, it is only with appreciation of all these factors that successful and efficient springs can be produced.

On locomotives and rolling equipment many parts are used, all having a more or less severe duty to perform and requiring steels possessing various degrees of strength, toughness, resilience, endurance, shock resisting and wearing or abrasive qualities. These various combinations of static and dynamic strength are obtained by adjusting and correlating both the chemical composition and heat treatment of the steel. Certain chemical components intensify the static, others the dynamic qualities.



Graphic presentation of the per cent elongation and tensile strength of steel with various carbon contents

Springs are subjected in service to repeated stresses. These repeated stresses upon steel cause a gradual disturbance of the structure and its component particles, which greatly weakens the material and is called fatigue. These stresses causing such fatigue can be broadly classed as repeated static and acceleration stresses, and it is necessary that a knowledge of the capacity of the steel best able to resist such action should be used and should serve as a basis for its selection.

A steel of the following constituents best meets these requirements (commercial alloys will not be discussed here as their use is not general in railroad work):

Carbon	.90 to 1.05 per cent
Manganese	.25 to 0.50 per cent
Phosphorus	.04 per cent max.
Sulphur	.05 per cent max.
Silicon	.04 per cent max.

Structure of steel

Carbon steel is an alloy, but should not be confused with the term commercial alloys that are now available. Its principal and essential chemical constituents are carbon and iron. With these are usually certain impurities such as phosphorus, sulphur, silicon and manganese.

Of the elements or constituents which go to make up ordinary carbon steels, the impurities manganese, phosphorus, sulphur and silicon approximate one per cent. The carbon will vary from a few hundredths of one per cent to about two per cent and the balance will be iron.

Steel is not a single substance like copper or gold, but is made up of mineral grains, corresponding to the quartz, mica and feldspar of granite. In steels which have cooled slowly from a high temperature, we have ferrite (iron), cementite (carbon) and pearlite (carbon and iron). And just as the relative amounts of quartz, mica and feldspar may vary in the rocks of granite so will the relative proportion of ferrite, cementite and pearlite vary in different steels according to their specific chemical composition.

In steel cooled from high temperatures the carbon is always combined with a definite amount of iron, forming a carbide of iron. This compound consists of 6.6 per

cent carbon and 93.4 per cent iron, and is microscopically known as Cementite. The balance is iron and known as Ferrite.

Cooling at a moderate rate from a red heat, this cementite will form a mechanical mixture with a definite amount of ferrite, the result of which will approximate .9 per cent of carbon and is called Pearlite. Pearlite is regarded as a separate and distinct constituent of steel, as it forms distinct grains, when present in any appreciable quantity, and always contains this definite amount of carbon.

From this it will be seen that a steel containing .9 per cent carbon will consist entirely of pearlite. Such steels are known as eutectoid steels and that ratio of carbon as the eutectoid ratio. In other words, this is the same character of steel as used in the manufacture of both elliptic and coil type springs.

Ferrite is soft, ductile and relatively weak. It has a tensile strength of approximately 40,000 to 50,000 lb. per sq. in., and has no hardening power, as applicable to industry. It is magnetic and has a high electric conductivity.

Pearlite has a tensile strength of approximately 125,000 to 130,000 lb. per sq. in. with elongation of about 10 per cent in 2 in.

The properties of cementite are very little known with the exception of its great hardness and brittleness; it probably does not have a tensile strength over 5,000 lb. per sq. in.

Static strength

We may now sum up these facts in their relation to the static strength of slowly cooled steels as follows:

Free ferrite has a maximum tensile strength with maximum ductility.

Pearlite a maximum tensile strength with low ductility.

Free cementite confers added hardness and brittleness, with a consequent lowering of the tensile strength.

Thus, it is apparent by increasing the amount of Pearlite in steel we increase the static strength but with a corresponding decrease in ductility.

Heat treatment

Heat treatment in general consists of regulating or changing the structure of steel by various methods of heating and cooling. The nature of steel is complex, and its structure may be modified or completely changed by various degrees of temperature, all of which take place in steel in its solid form. These changes take place at temperatures known as *critical ranges.*

They are denoted by the letter A followed by the letter c signifying heating or the letter r signifying cooling. These signs Ac or Ar are further modified by the numerals 1, 2 or 3, indicating the particular point referred to. Thus, Ac 1 would mean the first critical range passed upon heating.

In considering this diagram let us devote our attention to the steel in question, spring steel, .90 to 1.00 per cent carbon, in its normal condition resulting from slow cooling, or in the annealed state, in that it consists of .90 per cent carbon consisting entirely of Pearlite.

Let us first consider the influence of temperature on the constituent Pearlite while passing through the Ac 1-2-3 range. Practically no change in this constituent occurs during heating until a temperature corresponding to the critical range is reached, which in this case is approximately 1,340 deg. to 1,400 deg. F. (727 deg. to 760 deg. C.).

In passing through this critical range there is a complete change in the nature and structure of the Pearlite. It is converted into a new constituent with new characteristics. This is technically known under the term solid solution, microscopically called Austenite. This new constituent, save that it is a solid and not a liquid, has all the properties of a liquid solution. Its original components are merged into a single entity, giving a complete indefiniteness of composition with entirely new characteristics. When quenched in oil at a temperature of 1,340 deg. F. and not over 1,400 deg. F., it passes through a transition and is known microscopically as Martensite. In spring steel Austenite as such cannot be retained by the ordinary methods of oil quenching but changes into Martensite.

Spring steel when slowly cooled from above this critical range of 1,340 deg. F. passes out of solution as Austenite and takes the original Pearlite structure. This is important to note as this fact which is little appreciated is the cause for many spring failures which will be explained in a discussion of quenching media.

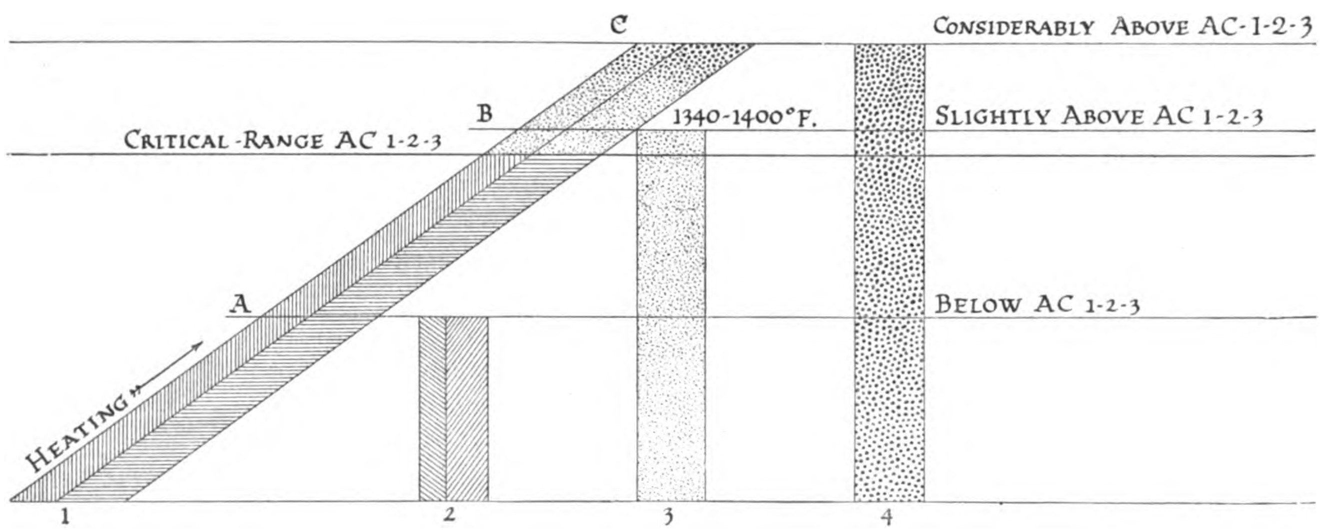


Diagram representing the structural changes which take place in Pearlitic spring steel as it is progressively heated through and beyond the critical range

Refinement and grain size beyond Ac 1-2-3

At slightly above the critical point in .90 to 1.00 per cent steel (spring steel) the original Pearlite grains are changed to Austenite as previously explained and

will possess that maximum refinement which the formation of Austenite can impart. As the temperature is progressively raised above the critical 1,340 deg. to 1,400 deg. F., a gradual coarsening of the Austenite grains occurs with attending weakness in the oil quenched spring.

A very clear understanding of these principles must be had as it is a lack of understanding of these facts that is the cause of many spring failures.

Hardening

The operation of hardening spring steel involves two specific operations of change in temperature, heating and cooling. The function of heating is first to obtain the best refinement, and secondly to obtain the formation of Austenite. The steel must then be held in this condition by very rapid cooling in oil. Associated with both the heating and quenching there must be as great a degree of uniformity as is possible. This is important to note.

Spring steel when properly hardened should show no trace of the original Pearlite structure, coarse grain size, or any other peculiarities of untreated steel. If such is present in the hardened steel it goes to prove the operation was not properly carried out. If the structure of the Austenite has not been suitably developed by the

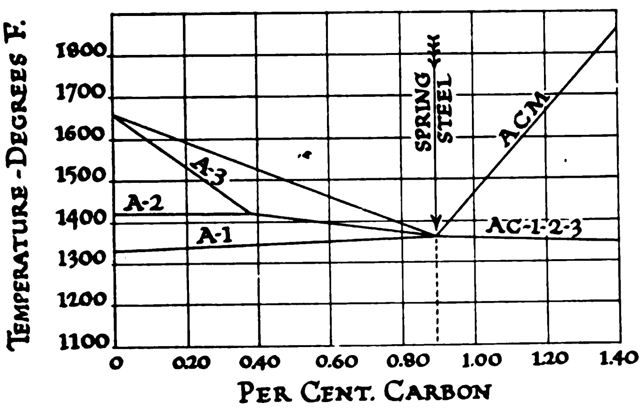

Diagram showing various critical ranges of steel.

heating operation, it will not be altered for the better by subsequent quenching. The most any quenching media can do is to retain the characteristics which the heating operation develops.

Column 1 in the above diagram represents a normal .90 to 1.00 per cent carbon pearlitic spring steel and the structural changes taking place in that steel as it is progressively heated through and beyond the critical range Ac 1-2-3, and we will assume that the structure and microscopic constituents obtained by heating to various temperatures, such as *A* to *C*, may be retained by use of a proper quenching medium as illustrated by columns 2 to 4.

By heating to temperature *A*, under the critical range Ac 1-2-3, 1,340 deg. to 1,400 deg. F., no change will be produced in the original steel, which consists of Pearlite. The quenching likewise will produce no change, as shown in column 2. Heating to slightly over the critical Ac 1-2-3, 1,340 deg. to 1,400 deg. F. will change the Pearlite to solid solution Austenite if held a sufficient time to effect complete diffusion. This will entirely refine the steel, giving it the finest grain size possible.

Quenching column 3 will retain the condition in the form of Martensite, developing the maximum hardness possible. Heating to temperature *C* considerably over that of the upper critical range will tend to increase the grain size, and quenching column 4 will retain this condition and consequently developing a brittle steel.

Heating for hardening of spring steel should be slow, uniform and thorough and to the lowest temperature which will give the desired result. This is due to the setting up of stress which follows rapid cooling. Overheating has been the cause of over 80 per cent of the spring failures checked by the writer on complaints of bad steel. Both theory and practice support the old rule that "The lowest heat which will give the desired results is the best."

Quenching media

The primary consideration of an oil bath for quenching spring steel is the rapidity with which the heat is removed. This property of transference or conductivity is most important. Its ability to arrest Austenite in its Martensitic form is its outstanding attribute.

Animal and vegetable oils will harden satisfactorily when fresh, or when first used. Upon continued use the quenching speed lessens. Any liquid which will not ignite will harden partially. Originally the animal and vegetable oils were employed exclusively for quenching, upon the theory that these two groups of oils possess a much higher flash and fire than mineral oils, but as the temperature of the steel was always at least 1,000 deg. F. higher than the ignition point of any oil, it was afterwards discovered that the ignition or flash point was of no consequence, provided sufficient volume and circulating facilities were used.

It is a well established fact that all animal and vegetable oils oxidize when continually subjected to high temperatures, developing a change in viscosity and a corresponding change in the quenching speed. This change in quenching speed causes unsatisfactory hardening, as the Austenite developed in heating from 1,340 to 1,400 deg. F. is not arrested in the desirable form of Martensite. It shows a semi-Mratensitic Pearlitic structure. This structure does not develop the physical properties necessary to long spring life.

Petroleum oils are peculiar in the fact that they are composed of an innumerable number of hydro-carbons of different boiling points. These hydro-carbons distill out gaseous vapors in the order of their respective boiling points, causing a constant change in viscosity upon continued use. This change in viscosity brings about a similar condition as noted with respect to animal and vegetable oils, and should be avoided for the same reasons in spring work.

Investigation into other quenching media indicates that oils distilled from Degras (wool grease) approach nearest the ideal. These products have all the desirable characteristics, with but few of the undesirable. The quenching speed is more rapid and uniform over a greater range of temperature, the viscosity is constant, the oils do not distill, and while of a hydro-carbon nature, they will saponify under pressure. The use of such a product, with the steel and temperature factors correct, insures the desired development of the microscopic constituent Martensite in the hardening operation.

The impression exists that flash and fire points are essential characteristics of desirable quenching media. Investigation into this subject reveals the fact that, as no oxygen gets into the oil below the surface, and that so long as the oil on the surface which is exposed to the air, does not reach the temperature of its fire test, there can be no ignition, no matter how much heat is introduced into the oil under the surface. For such reasons, flash and fire values are not of importance.

Tempering and drawing

The prevalent practice in the past has been to perform the drawing or tempering operation by the flash back

method which has been productive of very unsatisfactory results. Absolute uniformity of the drawing temperature should be applied in the drawing back operation which cannot be accomplished by the flash back method or by drawing in furnace atmosphere at comparatively low temperature.

The most successful method of performing this operation is the use of a salt bath. A high temperature thermometer placed in the molten salt will indicate the desired temperature for the spring to be drawn. The springs can then be emerged into the bath and when the bath attains the predetermined temperature they can then be withdrawn with the assurance that the application of temperature has been absolutely uniform throughout. The result is a complete spring with the highest physical properties possible to develop in consideration of the character of steel used in its manufacture.

When a piece of spring steel is heated to slightly above its critical point—Ac 1-2-3, 1,340 deg. to 1,400 deg. F.—and quenched with a satisfactory quenching oil the necessary initial hardness is developed. But the inevitable stresses caused by rapid cooling render spring steel unsatisfactory for service in this condition. In order to render spring steel ready for service a further transition is necessary. This is brought about by further application of heat, which will now accomplish two things. It will relieve the hardening strains and so permit the transition of the spring steel from its Martensitic or hardened form to that known as Troostite. By properly adjusting the temperature of this reheating process the desired stage in the Martensitic Troostictic transition may be obtained. This stage is developed in spring steel between 650 deg. to 750 deg. F. (343 deg. to 399 deg. C.).

If spring steel has been properly heated and quenched so that it is composed of Martensite without grain growth developing the highest initial hardness, Troostite will begin to form at approximately 400 deg. F. (204 deg. C.). As the tempering or drawing temperature is progressively increased, the Troostite increases in amount until 750 deg. F. at which point it begins a further transition into Sorbite. To carry spring steel over into Sorbite causes set; to neglect the development of Troostite encourages fracture provided the heating and quenching operation has been carried out to that point.

Hence, we arrive at the necessity for the control of temperature on the drawing or tempering operation. The old flash back method proved unsatisfactory due to the inability of the operator to control temperature. Dry heat, such as was and is used, has a very low heat conductivity. Temperatures between 680 deg. to 750 deg. F. cannot be indicated by sight and recording instruments are not satisfactory for this purpose.

When the spring leaves are introduced into the bath the temperature falls and when it assumes the pre-determined temperature the leaves can then be removed and quenched in water, the water bath being used only to wash the excess salt adhering to the leaves.

By maintaining the bath at the proper temperature there can be no over-heating, developing Sorbite. The heat must penetrate all parts of the steel alike and the personal equation is as nearly eliminated as is possible. This method has the further advantage of cutting down labor costs and increasing output, since a number of leaves may be heated at the same time.

Oftentimes what is known as initial set causes misunderstanding. Initial set is developed in all heat-treated work, due to lack of molecular cohesion, and allowances for this set should be made in setting springs of both the elliptic and coil type. If this is appreciated no springs need be rendered useless, due to permanent set. Coil springs that have taken a set should be heated to 1,600 deg. F. (871 deg. C.) and expanded approximately one-quarter to one-half inch above the specified height to allow for the initial set and then again be processed as described.

Springs when removed due to leaf failure by fracture should be dissembled and all leaves subjected to the same heat treatment as the untreated steel for the reason that the spring in service being subjected to repeated stresses has partially crystallized, causing an attendant weakened condition. The assembled spring then has all the physical characteristics of the new spring and should give the same life in service.

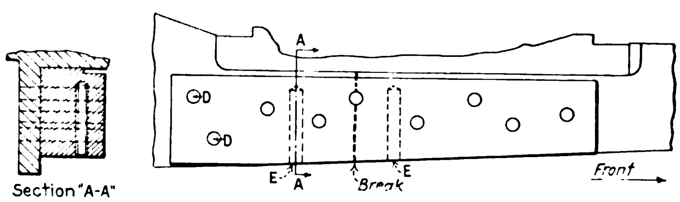
Forming operation

It is common practice to heat the leaf, form and quench it. It is impossible to produce a quality spring in this manner. The leaves should be heated to a forging heat, 1,600 deg to 1,650 deg. F. (871 deg. to 899 deg. C.), and formed. They should then be reheated to 1,340 deg. to 1,400 deg. F., quenched, reheated to 650 deg. to 750 deg. F. in a salt bath and then quenched in water. This practice might incur a slight additional expense in manufacturing but should be paid for many times by the increased life in service.

Temporary repairs to a one-piece locomotive frame

The splice illustrated in the sketch was used in repairing a broken one-piece frame on a 4-6-2 type locomotive. The break occurred a short distance back of the center of the cylinder bearing, being in contact with the cylinder casting at the top and running thence along the outside of the frame. Owing to the position of the break, and for other reasons, it was not considered advisable to weld the frame in place, but to try splicing with a heavy plate.

A piece of material of approximately half the thickness of the frame was forged and faced on one side to make a bearing against the frame. The four bolts ahead of the break, the one at the break, and the two to the rear were



The break occurred a short distance back of the center of the cylinder bearing

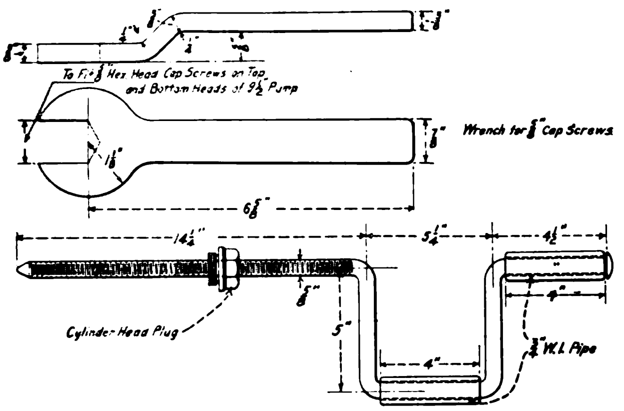
removed. The piece was laid out and drilled, with two extra holes added near the rear. These were later drilled through the frame making the arrangement as shown, with four holes on each side of the break. After the bolt holes were reamed and the bolts fitted, two holes were drilled, one forward and one back of the break, as shown at *E*. These were reamed and plugged, the center line of the plug being at the inner face of the plate at the bearing against the frame. The plugs acted as keys to overcome any possible shearing of the bolts. After they were driven slightly beyond the surface, the ends of the holes were closed over the plugs to prevent their dropping out in case the splice should work.

No trouble was experienced with the patch loosening after the locomotive was placed in service.

Device for forcing up pistons on air pumps

By E. A. Miller

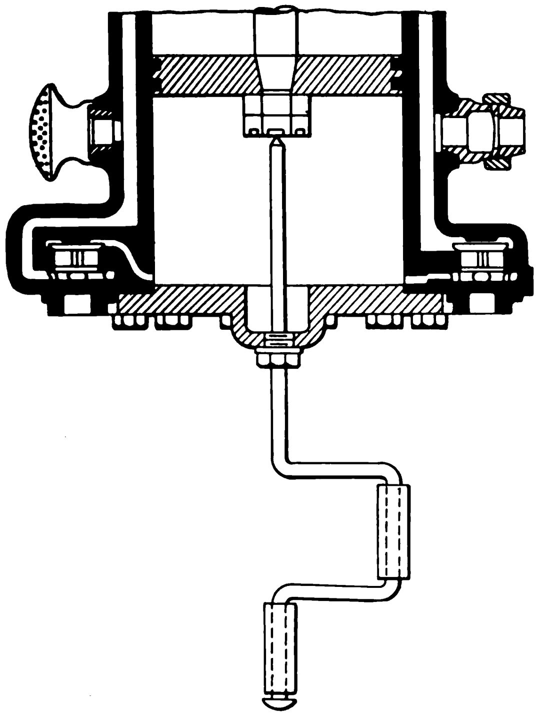
THE operation of removing the top head gaskets, reversing valves and rods from air pumps while on a locomotive is somewhat difficult. To do this it is necessary to remove the reversing valve stem which extends down into the piston rod



A device for facilitating the removal of top heads and gaskets from air pumps

which is drilled a certain distance from the upper end. This makes it necessary to force the pump pistons about half way up in the cylinder.

The device shown aids greatly in performing this work. It is made of 5/8-in. round iron or steel, threaded and bent.



Application of device for forcing up air pump pistons when removing top head or gasket

It is necessary to put the center handle on prior to making the final bends. A regular air cylinder head plug is drilled and tapped 5/8 in. to suit the threaded portion of the handle. The illustration shows the method of using the device to force up a piston. After the piston is once forced up it can be held there indefinitely. This is an improvement over the old method of pushing up the piston by putting an iron bar through the cylinder plug hole. If the friction of the piston rings and piston rod packing was not great enough, the pistons would settle back into place before the work on the pump could be completed.

Progress boards for the wheel gang

By J. Robert Phelps

Apprentice instructor, Atchison, Topeka & Santa Fe, San Bernardino, Cal.

A BOARD kept at the crank pin and axle lathes, for following up the work on crank pins and axles is shown in Fig. 1. It shows the locomotive number and date of wheeling and what is to be made for it. It keeps the machinist informed as to what work is to be done next and, as he completes the job, he draws a circle around the item on the board, indicating the completion of that particular job.

Fig. 1—Progress board located at the crank pin and axle lathes

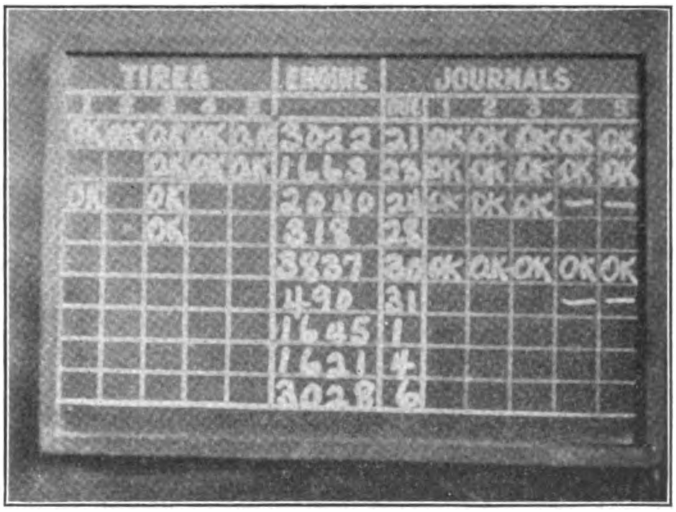


Fig. 2—Chart board which indicates the progress of the repairs to tires and journals

Fig. 2 applies in the same way to the turning of tires and journals. This arrangement helps to keep the foremen and the machinists posted as to what should be done next. For

example, all the tires may be turned for a locomotive except one pair, these being delayed because there are some broken spokes in a wheel which are being welded. Additional delays may be caused by the gas welders bringing a pair of wheel centers up to standard size, a journal waiting for a hub liner to be applied, or the store house slow in furnishing a main pin. The boards are changed each week on line-up day. They act as a check so that the right job is done first and no important part of the work is overlooked.

Fixtures for holding distributing and triple valves

By H. J. Duernberger

Air brake repairman, Michigan Central, Niles, Mich.

THE common practice when repairing distributing and triple valves, is to hold them in a bench vise. At best, this is an awkward method of holding the valves and considerable time is lost in changing them from one position to another to repair a particular part. In order to eliminate the time lost in making so many changes in the vise and also to make the job much easier, the writer developed a fixture for holding these valves which is used at all the principal repair points on the Michigan Central.

Fig. 1 shows a general assembly and detail view of the various parts of the fixture for holding the distributing valves. The base *J* of the fixture is bolted to the work bench with the removed portion flush with the front of the bench, and not over four feet from the regular bench vise so as to have it convenient for holding small parts from the valves. The stud at the center of the base passes through a hole in the bottom of the fixture. It then can be clamped in any position by the handle *P*. The distributing valve is bolted

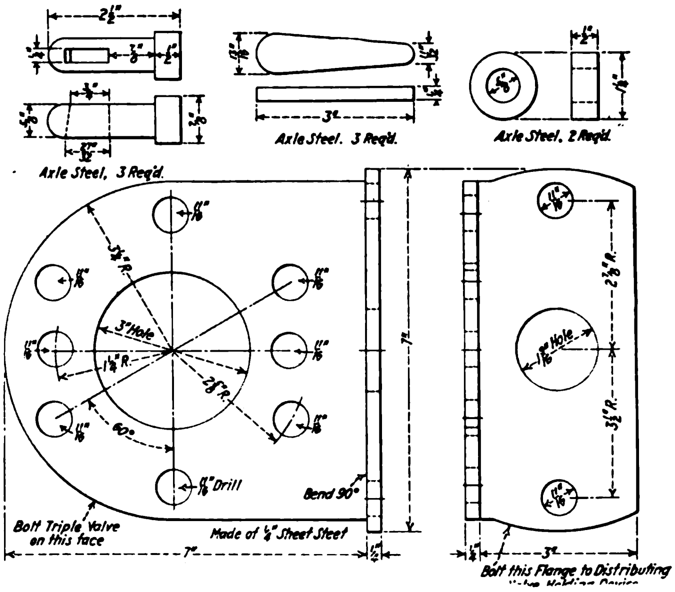

Fig. 2—Attachment used on the distributing valve device for holding quick action triple valves when making repairs

to the revolving head *B* in the fixture. It can be turned in any position by loosening the handle *I* and dropping it to the vertical position. The entire device can be turned to any

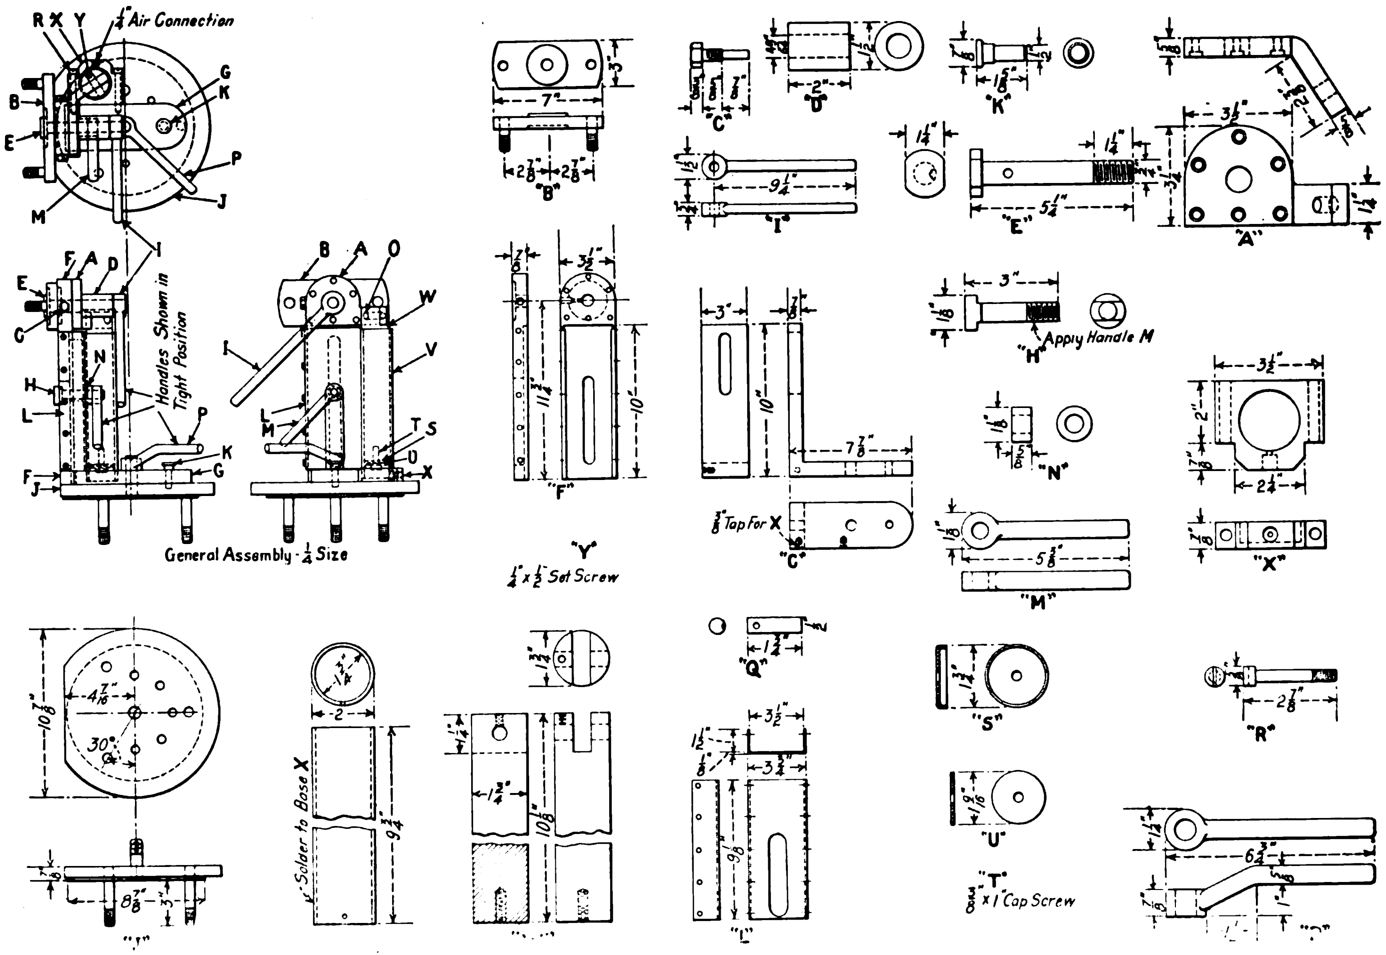

Fig. 1—Fixture for holding distributing valves in any position when making repairs

horizontal position by loosening the handle *P* and pulling out the pin *K*.

It is also provided with a raising feature which is very desirable when spotting in exhaust valve or equalizing slide valve seats. For all other work the lowered or normal position is the better. The fixture is raised by using compressed air. This is accomplished by using two 1/4-in. street ells at the point marked for an air connection. One ell should stand in a vertical position and the other be screwed into it so that it will face the rear of the work bench. Into this ell screw a 1/4-in. three-way cock. Then take a 1/4-in. drain cock and drill a 3/32-in. hole in one side of it and in the other side a 1/16-in. hole. By using a 1/16-in. side opening a more gradual lowering movement can be obtained than with a larger opening. The three-way cock is connected to the shop air line with a piece of welding hose which should have enough stock in it to allow for swinging the device. The full raised position is 7 1/2-in. higher than the normal which is desirable for the work mentioned.

Triple valve holding fixture

Fig. 2 shows an attachment for holding quick action triple valves while making repairs. It will hold valves with either two or three holes in the flange. It can also be used by a right or left handed workman. The one flange of the device bolts to the revolving head on the distributing valve jig. The two washers shown go on the two 5/8-in. studs on the revolving head plate and are held in place by two 5/8-in. nuts. The triple valve is then bolted to this plate with the bolts and wedges shown. These are used instead of threaded bolts as quicker results are obtained. This attachment, used on the distributing valve fixture, gives the latter the same advantage in repairing triple valves as when utilized for repairing distributing valves.

Replacing crank pins equipped with eccentric arms

How to eliminate the possibility of errors and reduce the cost of application

By R. B. Robinson

Machine shop foreman, Atlantic Coast Line, Hot Springs, Fla.

WHEN replacing main crank pins having eccentric arm connections, there are two general methods used:

First.—The crank pin is pressed into the driving wheel blank at the eccentric arm end and then, after the valves are set and the required position of the eccentric arm on the crank pin is found, the keyway is cut, the holes drilled and the eccentric arm is fastened to the crank pin.

Second.—The keyway is cut, the holes drilled in the crank pin and all work on the crank pin necessary to complete the fastening of the eccentric arm is done before pressing the pin into the driving wheel. Of this method there are two cases, *A* and *B*, referred to in accompanying illustrations.

Case *A* is the one generally used. This method will be compared with Case *B* to show the saving of time, the possibilities for the elimination of error, the simplification of method and the reduction of cost in the application of Case *B*.

Application of Case A

The first step of this method is that of scribing a line on the driving-wheel fit of the crank pin and continuing it to the eccentric arm fit at that end of the pin. This line is scribed before the crank pin is taken from the lathe and, when correctly scribed, is the line that would be made by the intersection of a plane through the centers of the crank pin, with the surfaces of the fits involved. It is this line which determines the position of the eccentric arm on the pin and the position of the crank pin. It also acts as a guide as the pin is being pressed into the driving wheel.

After this center line is scribed on the pin, the next step is to locate on the edge of the crank pin bore of the eccentric arm the point through which passes the line on the eccentric arm connecting the center of the eccentric pin with the center of the crank pin bore. This is the center line of the eccentric arm, and, when the arm is placed on the crank pin, is made to coincide with the scribed center line on the crank pin. The eccentric arm, after being fastened temporarily to the crank pin, has located on it the position of the keyway and its outline scribed on the crank pin. If the key way is the least bit out, the key must have an offset to make necessary corrections, for it is essential that the eccentric arm retain its position relative to the scribed longitudinal line on the crank pin, as this line is the one by which the crank pin is located in the driving wheel.

After the key is fitted and the eccentric arm is in the correct position on the crank pin, the pin is ready to be drilled for the eccentric arm bolts and then pressed into its place in the driving wheel.

After being slotted, drilled and otherwise prepared, the position of the crank pin in the driving wheel is determined by the longitudinal center line scribed on the crank pin intersecting at right angles another line scribed on the face of the driving wheel. This line is found by scribing a line through the center of the crank pin hole in the driving wheel and the point on the eccentric pin circle corresponding to the location which the center of the pin end of the eccentric arm is to have. This line is also made use of in the same manner in Case *B*.

The length of the eccentric arm and the diameter of the eccentric pin circle determine the location of the eccentric arm on the crank pin, and with this data, the position in which the finished crank pin is to be pressed into the driving wheel is found.

In the first method, that of fitting the eccentric arm to the crank pin after pressing the crank pin into the driving wheel, an error is not so likely to occur, but other complications arise. In small shops, not equipped for drilling and slotting outside of the machine shop, the situation becomes awkward. The cost of the work in preparing the

crank pin for the eccentric arm is much less if the work on the pin is all done in the machine shop before the pin is pressed into the driving wheel. While it becomes a simple matter to do all the necessary work on the crank pin before it is in place in the driving wheel every care in Case *A* must be taken in laying out the work.

Method of using Case B

In Case *B,* the laying out of the work becomes simplified and there is hardly any likelihood of an error. The length of time required to prepare the crank pin is less, as is the cost of the operation.

All that is required when using this method is to remove the turned pin from the lathe without any determining mark having been established on it (except, of course, the two center holes) and then to place the eccentric arm in position on the pin. Then run a scriber along the edge of the keyway in the eccentric arm, scribing its outline on the pin, remove the arm, cut the keyway in the pin, replace

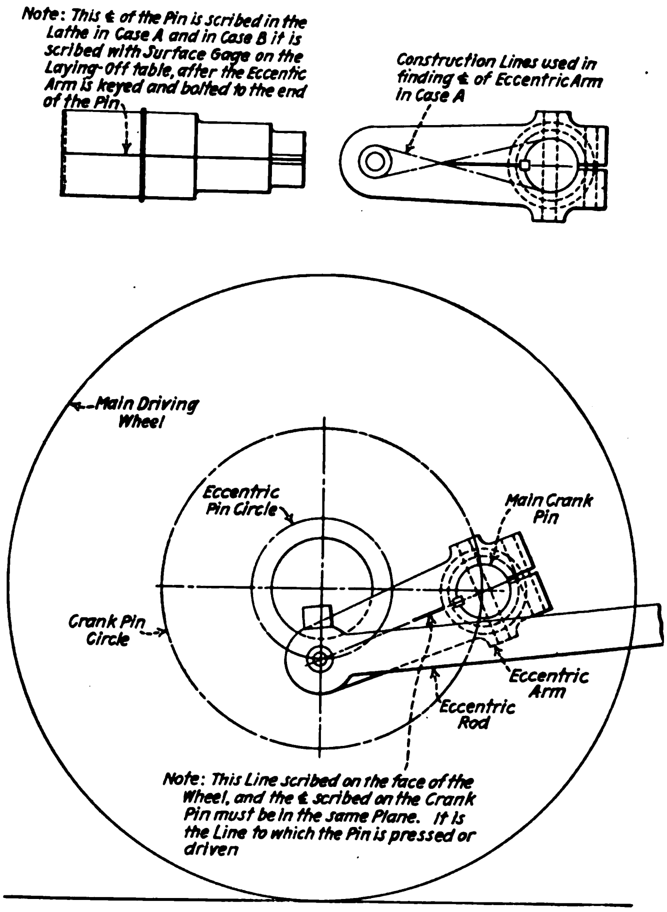

Diagram showing the method of scribing lines on crank pins and eccentric arms preparatory to replacing on the wheels

the arm on the pin and key it. After this, clamp the arm, drill the necessary holes, and fit the bolts in the pins. The next step is simply to place the assembled crank pin and eccentric arm on the laying-off table, and level it up so that the two centers of the crank pin and the center of the eccentric arm are all in the same plane parallel to the plane of the table surface. Then, with the surface gage set to the height of this plane, scribe one line along the driving wheel fit of the crank pin, allowing it to extend just over on the rod bearing fit so as to be visible for use in checking purposes after the pin is driven into place in the driving wheel.

The eccentric arm is then removed and the crank pin pressed into place, with its scribed line kept coincident with the end of the scribed line on the surface of the driving wheel, or, as already mentioned, in the same plane with it. Should the pin twist out of place before the act of pressing it in is completed it can be coaxed back into line with a chain and lever. This turning force is, of course, applied simultaneous with that of the pressing-in force.

The above description covers three ways of replacing a main crank pin when the valves are actuated from the movement of the crank pin by means of an eccentric arm fastened to it. The goal is to accomplish the installation of this pin in the simplest, most economical, and at the same time the most accurate, way.

The first method described is simple in plan but expensive in labor, time and power utilized. The second way, Case *A,* is economical as regards machine work, but requires the utmost care in laying out and, if the keyway on the crank pin and the subsequent drilling of the pin is not exact, troublesome and expensive allowances will have to be made. The third way, Case *B,* eliminates possible errors to a minimum and does not require the painstaking time of laying out the work that is required in Case *A.* The eccentric arm is simply keyed and bolted to the main crank pin in any radial position, then leveled up on the laying-off table and scribed. It is then ready to be pressed in the main driving wheel.

Eliminate guesswork in metal cleaning

THE days of guesswork are over. Industry of all kinds today is operated by accurate systems and rules that leave little room for deviation.

Present day business conditions demand that rigid economy be practiced, that the needless worker be dismissed, the needless machine junked, and needless expense stopped. This economy is perhaps of necessity even more rigid in the railway shop than in some industrial organizations.

Railway shops of every kind have cleaning of one sort or another to perform, such as the cleaning of air pumps, injectors, sheet metal, small parts, and the hundred and one materials that must be freed of their coating of oil or grease before inspection or before repair work can be undertaken. Modern cleaning materials have proved their superiority to commercial chemicals and ancient systems, but the economy to be gained from modern methods can only be greatest when a minimum of cleaning material is used. Modern metal cleaners, which may combine both chemical and mechanical action, cost more than lye or soda ash, but the quickness and thoroughness of their action outweigh the difference in price. In checking up the economy of each shop, some way must be devised to see that those actually putting metal cleaning material in the tanks do not waste it.

Proper amount of cleaner important

It has been proved that more time is lost in metal cleaning operations by the use of too much cleaner than by using too little. Aside from the time lost, the cost of the needlessly used cleaner soon totals a considerable sum. It is true that in many non-railway shops both of the above factors are far overbalanced by the use of improper and inefficient methods—no cleaning material is economical unless it is used in the way in which it was intended. The addition of air agitation, for instance, may materially reduce cleaning time and expense.

It would seem impossible that a cleaning tank operated under ordinary supervision could become so clogged with

cleaner that its effectiveness could become less than half normal. Such, however, is a frequent happening and until such conditions are eliminated, and until the practice of shoveling into the tank unrestricted amounts of cleaner is stopped, cleaning expense will be far above what it should be.

It does not take a trained chemist or mathematician to determine what amount of cleaner to add to a solution to maintain its efficiency. On the other hand, when a cleaner is costing six, eight, or ten cents a pound it is hardly wise to allow some unskilled laborer to shovel in more cleaner when things do not just suit him. Such methods frequently slow up cleaning instead of speeding it up.

The surest method of maintaining a metal cleaning solution at efficient and economical cleaning strength is by the normality test. The operation of this test is easily accomplished by any worker of average intelligence, and the apparatus required should cost but a few dollars. Unfortunately, the hydrometer test does not show the actual strength or alkalinity of a cleaning solution, inasmuch as it gives only specific gravity, which is affected in proportion to the amount of foreign matter in the solution. The hydrometer reading of a newly made cleaning solution is fairly accurate. Hydrometer readings are not, however, sufficiently accurate upon which to base computations for the recharging of a used solution.

Method of testing

After making up a solution of an alkali cleaning material, a simple method of determining the proper amounts of cleaner to add from time to time to maintain the original strength is as follows: When the solution is first made—for sake of illustration say three ounces to the gallon—obtain by means of a graduate marked according to the Metric system a 10 c.c. sample and allow it to cool. Then add a couple of drops of methyl orange solution (this may merely be labeled bottle No. 1), which turns the cleaning solution an orange color. Then, using a graduated burrette with a glass valve (and this is not nearly as technical as it sound in print) a solution of 10 per cent normal sulphuric acid is very slowly added until the cleaning solution in the beaker changes from orange to red. Sulphuric acid of this strength is readily obtainable and may merely be labeled bottle No. 2. A record must be kept of the number of graduations of acid required from the burrette to turn the sample of cleaning solution from orange to red.

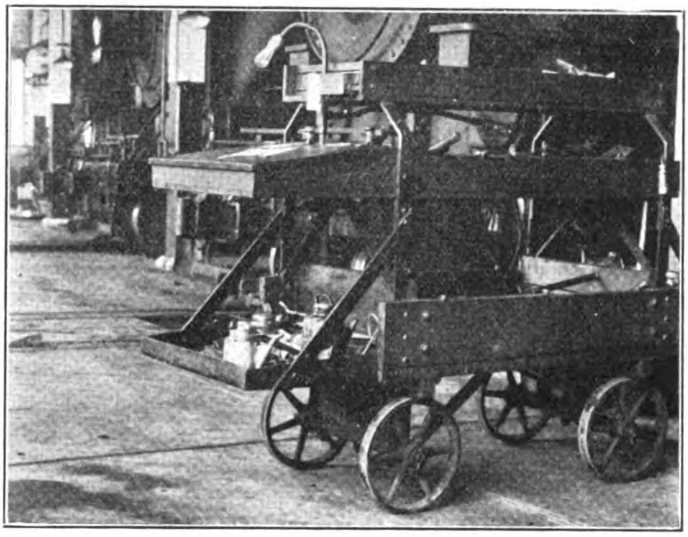
For example: If the initial test of the new solution required ten graduations of acid to turn the solution from orange to red, and if after using the solution and again testing as outlined above, it only takes nine graduations of acid to change the color of the solution, it shows that the cleaning solution has lost one-tenth of its original strength. It will therefore require but one-tenth of the original charge of cleaning material to bring the solution back to its original strength.

But how much chance is there of getting only the necessary amount of cleaner in the solution if someone is shoveling it in the tank by guess? And as the average person overguesses, the tank may soon be so supercharged with cleaner as to seriously retard the action; and then, of course, the particular cleaner being used is immediately pronounced unsatisfactory.

You do not guess in paying your men, or in paying for your various materials or supplies. Why guess at your cleaning operations? Why not know what amount of cleaner is needed to run a certain tank for a specified time or some certain operation, and then see that that amount is used, and no more.

Convenient wagon for the locomotive inspector

A WAGON which has been especially designed to meet the needs of the locomotive inspector is shown in the illustration. It is provided with three trays or boxes for tools, a shelf for oil containers and lubricants and a desk equipped with an electric light which can be plugged in at the nearest available wall socket. The lower tool tray has sufficient overhead clearance to permit it to be utilized for heavy tools and certain locomotive parts which can be quickly repaired or replaced by the locomotive inspector and his helper. The two top trays are convenient for the lighter hand tools such as hammers and wrenches, which are used more frequently. The desk has a lifting lid with compartments inside for the various forms and stationery necessary in making out work reports.



An inspector's wagon which may be moved to any place desired—Accommodations are provided for a desk, tools and necessary equipment

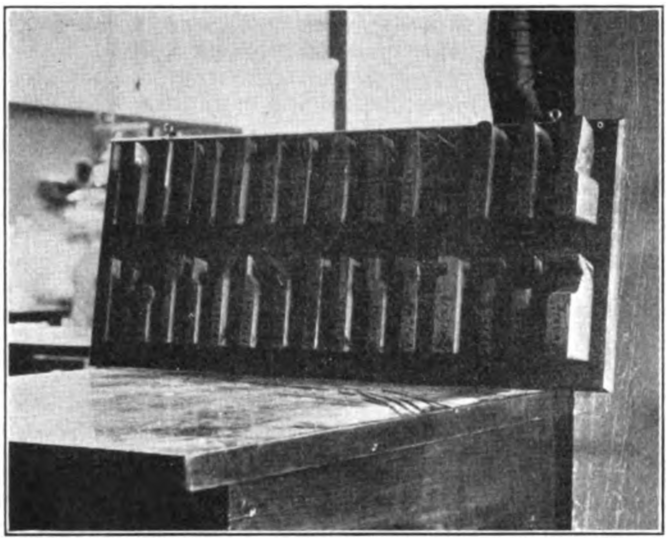
Wooden models for forging machine cutting tools

IT has been found from experience that the average blacksmith can forge out a better piece of work from an actual sample of the work than when he has to work from a drawing. One of the exacting jobs which a railway blacksmith has to do is the forging out of machine cutting tools preparatory for grinding.

It was found at the Billerica shops of the Boston & Maine that the blacksmiths were unable to satisfactorily forge these tools from blue prints. In order to overcome this trouble the drawings of 31 different types of lathe, planer, sharper and slotters tools were collected and taken to the pattern shop. The pattern maker carved to size, out of wood, exact duplicates of the actual tools and mounted them on a board. On the top edge of each tool it painted the dimensions of the steel from which the tool is to be forged. These tool models are also numbered from 1 up to 31.

This board is placed near the forge of the blacksmith who makes the tools. When a machinist needs a new tool he has his foreman make out a shop order on which is

written the number of the tool he wants made. This slip comes to the blacksmith who matches the number of the tool on the slip with the corresponding number on the

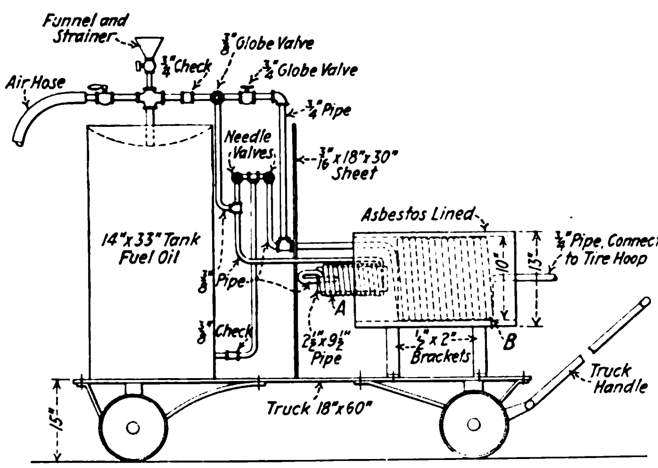


Models of 31 machine cutting tools to be used as guides by the blacksmith

board. This gives him a full size model to work from which has resulted in more accurate forgings. Thus less grinding by the machinist is required.

Fuel oil tire heater

Among the various labor saving devices described in the report of the convention of the General Foremen's Association, published in the October, 1924, number of the *Railway Mechanical Engineer*, was a portable fuel oil tire heater. This heater, which is shown in the sketch, has been adopted as standard on one of the western railroads. It may be used for removing and applying tires in engine-



Sketch of portable fuel oil heater

houses as well as in back shops. It is claimed to be an economical consumer of oil and simple to operate.

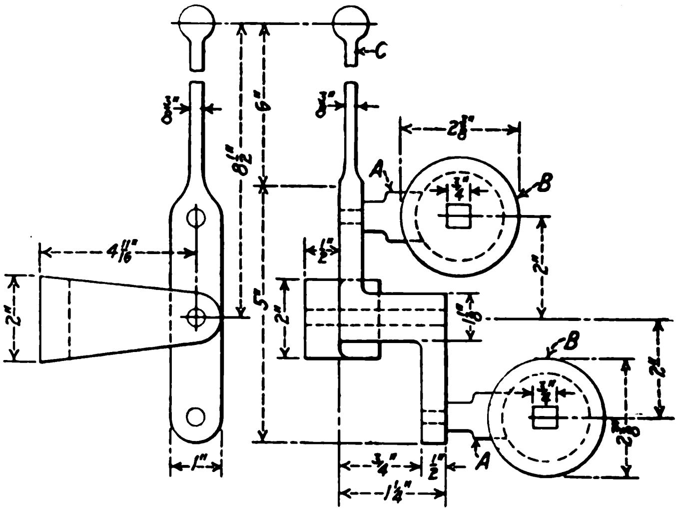
Referring to the sketch, the tank is filled with fuel oil through the funnel and strainer. Air pressure is supplied from the shop air line through the air hose shown at the extreme left. The air pressure forces the oil to the preheating torch *A*, which heats the main coil *B*. The circulation of the oil and air through the coil *B* causes the oil to be broken up into small particles and it is passed in this condition to the tire hoop. The rate of combustion is regulated by the globe and needle valves shown in the sketch.

This device can heat a tire for removal or application in 12 min. The heating process is so rapid that the wheel center does not absorb sufficient heat to interfere with the rapid expansion of the tire which makes it a most effective heater.

Feed gear shifting lever for Morton shaper

In order to facilitate the shifting of the feed gears on a Morton draw-cut shaper an operator employed in a large eastern railroad shop has devised the safety lever shown in the sketch.

A bracket and lever was bolted to the cross rail of the machine to eliminate the necessity of having to reach while sliding the feed gears into place. The gears *B*

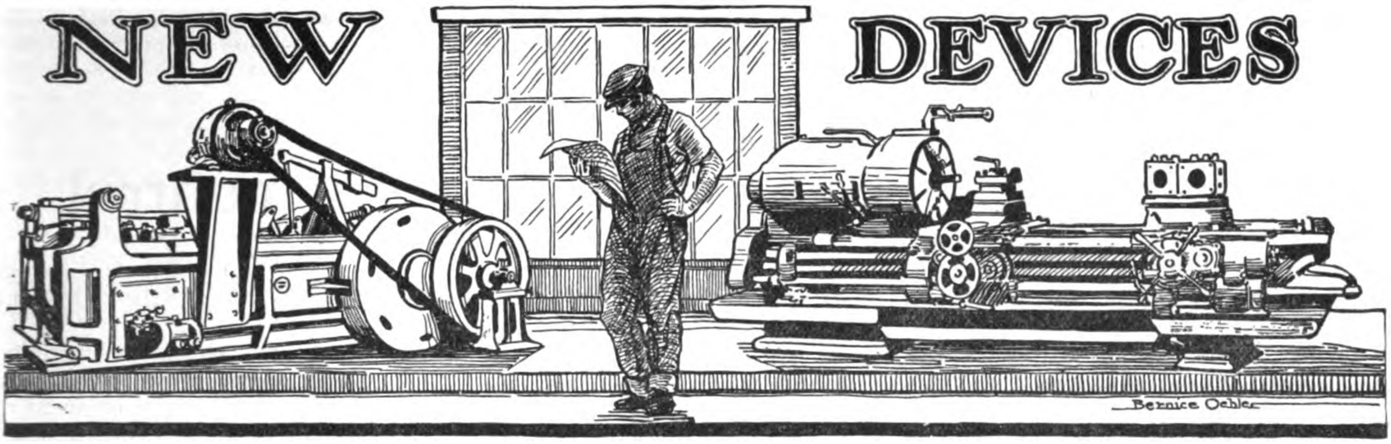


Safety lever designed to facilitate shifting the feed gears on a Morton draw-cut shaper

are grooved to receive the lugs *A* which are manipulated by the lever *C*.

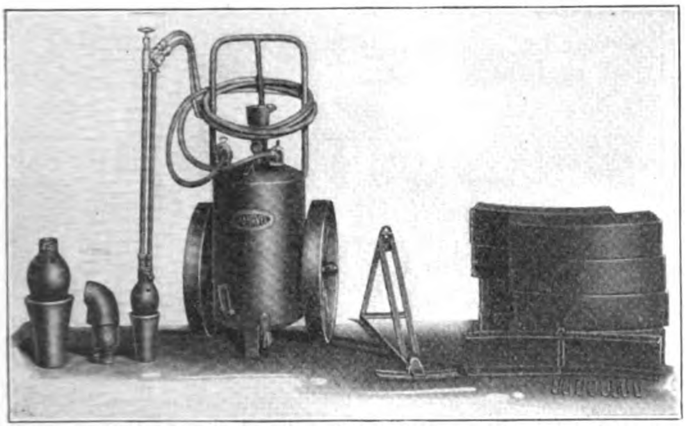
Only one gear is needed at a time to feed the table across the rail. The function of the other gear is to raise or lower the table. When one gear is in use the other gear is held in its proper position so that it will not accidentally slip into mesh.

Handling heavy castings without adequate crane service is expensive



Mahrvel vacuum torch and tire heater

THE Mahr Manufacturing Company, Minneapolis, Minn., has recently added a tire heating unit to its list of oil burning equipment. This equipment operates without pressure on the oil tanks or hose lines and therefore, removes the risk of fire or accident from bursting.

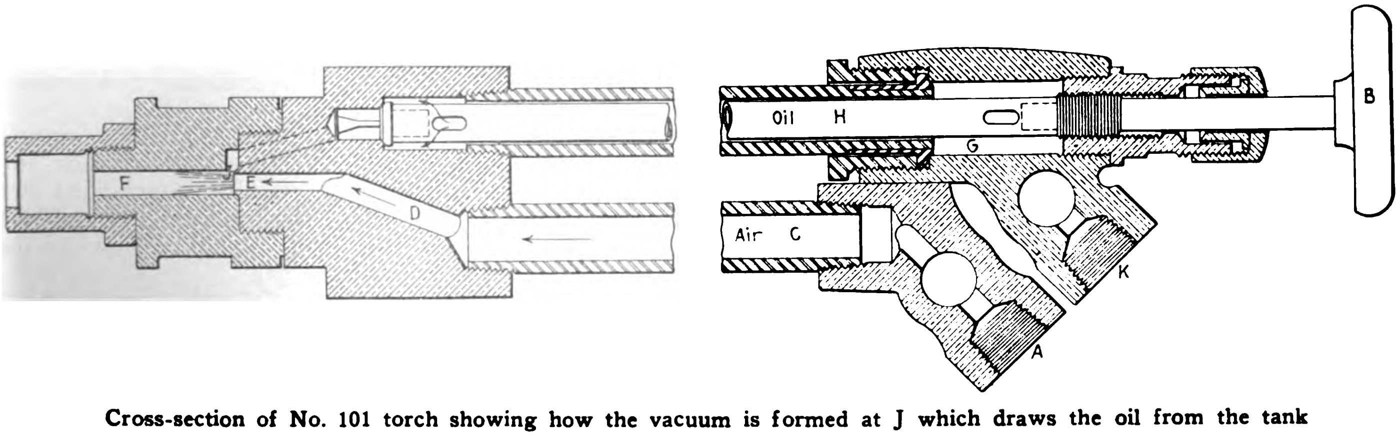


Vacuum torch and tire heater which operates without pressure on the oil tanks or hose lines

This feature can be understood by referring to the cross sectional view of the torch. A compressed air line carrying pressures ranging from 50 to 125 lb. per sq. in. is connected at *A*. The flow is regulated by the handwheel *B*, allowing it to pass through the drilled passages *C*, *D* and *E* and the air expands into passage *F*. This sudden expansion creates a vacuum at the points *J* in the corners of passage *F* which are untouched by the air as it leaves the passage *E*. The oil supply is led to the torch through a hose connected at *K*, enters the chamber *G* and is conducted to the valve seat through the seamless tube *H*. After passing the valve it is drawn into the air stream by the vacuum at *J*, where it is atomized and delivered from the torch end in a nozzle where combustion is started and completed with the addition of atmospheric air drawn in by the action of the jet.

It is essential that there be no leaks in the oil line between the point where the vacuum is created and the source of oil supply, as otherwise, air is admitted which breaks up the continuous column of oil and causes a sputtering flame, or if large enough, breaks the vacuum entirely and prevent any oil from being drawn up. A vacuum capable of lifting ordinary fuel oil 18 ft. is about the maximum for practical operation.

This type of torch is used in connection with the No. 101 Mahrvel safety vacuum tank. The unit consists of a light stand, special nozzle and steel housing. The housing is assembled by sections around the periphery of the tire to be removed and two flames, from the bottom of the tire and in opposite directions, are forced around its entire circumference within the housing. The major portion of the heat is confined in contact with the rim which increases the rapidity of heating.



Cross-section of No. 101 torch showing how the vacuum is formed at J which draws the oil from the tank

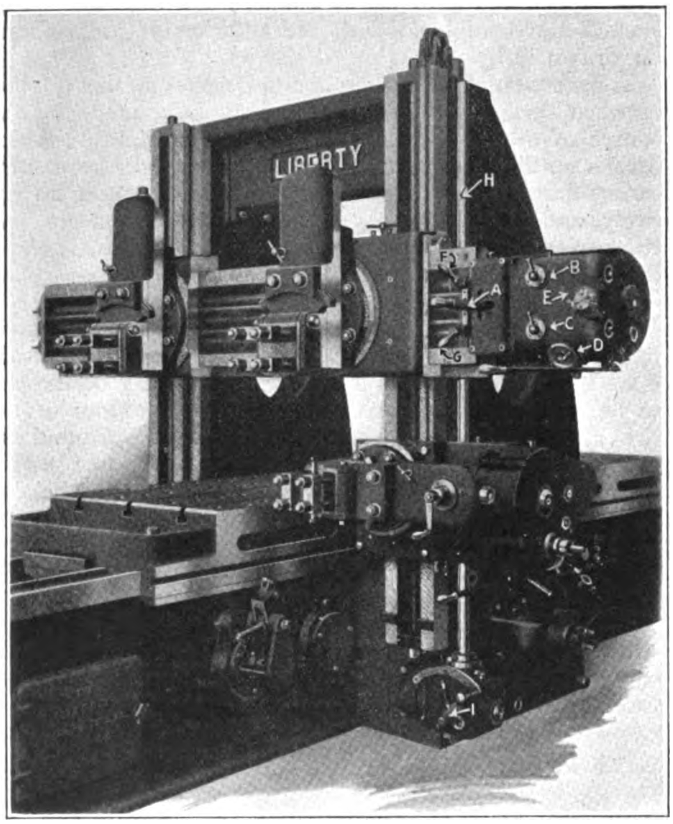
The combination of the torch and tire heater is especially convenient at terminal points where the torch has a variety of other uses. It can be used for thawing

out locomotive ashpans, etc. It can be used for firing up locomotives; for heating parts to be straightened and preheating parts to be welded; for thawing out frogs, switches, and other mechanisms around terminals. The compressed air may be supplied from the air pump on a locomotive.

Heavy-duty planer with compact control

A NUMBER of features in the planer recently designed and built by the Liberty Machine Tool Company, Hamilton, Ohio, are interesting departures from current practice. The cross rail is a self-contained unit, carrying all the mechanism necessary for power rapid traverse of the heads vertically and horizontally, as well as for elevating or lowering the cross rail. The unclamping, elevating, lowering and reclamping of the rail, as well as the power rapid traversing of heads vertically and horizontally are accomplished by the manipulation of lever *A*. To be able to accomplish these various movements with one lever eliminates the possibility of two movements at one time; making the control of the rail fool proof.

The levers *B* and *C* are the feed controls of the two heads vertically and horizontally, while by turning the hand wheel *D*, any desired amount of feed can be obtained as registered by indicator *E*. The 1½-hp. motor for power rapid-traversing and elevating the rail is built in and is located directly back of the rail. It receives

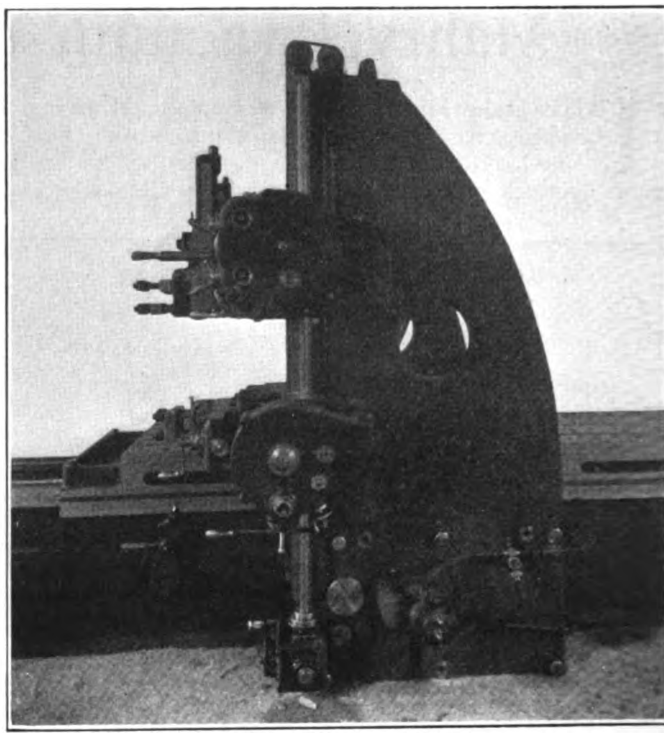


Liberty planer showing compact control mechanism

its current from protected trolleys and can be used on either alternating or direct current. If necessary, power may be obtained from a lamp socket. Both heads are moved on a single stationary screw which is in tension at all times. The nuts are revolved around the screw.

Lever *F* engages or disengages the horizontal feed of the left hand head or engages and disengages the vertical feed of the left hand tool slide, making it unnecessary for the operator to go to the opposite side of the machine for this adjustment, while the lever *G* controls the right hand head in a similar way.

Lever *A* controls an ingenious mechanism for clamping the rail to the housing, these clamps being located and operated on the inside of the housing. The movement of the tool slide vertically is accomplished by revolving a nut around a stationary screw which is stretched in tension.



Side view of Liberty planer showing motor for power rapid traversing head and elevating rail

The screws for elevating and lowering the cross rail serve a double purpose. These screws are also stationary and in tension, and so can be used for the purpose of feeding and power rapid traversing one or two side head thus eliminating two screws for operating a four-head planer.

The vertical shaft *H* is used only for transmitting power to the feed mechanism for both rail heads and side head, the transmission gears being so arranged that by moving lever *I* into one of two different positions, the feed may be made to take place either at the end of the cut, or just before entering the cut.

All gearing and mechanism on the end of the cross-rail for controlling the feed and power rapid-traverse, the gearing on the side head and also the feed mechanism at the bottom of the housing, run in oil. Gages indicate the oil level.

The housings extend entirely to the floor and are attached to the bed by means of reamed holes and bolts with additional heavy dowel pins for the purpose of eliminating any movement. The bed is of the double-wall type, ribbed lengthwise and crosswise and webbed

in on top. It is arranged for forced-feed lubrication to the Vs and is of double length, so the table at no time passes beyond the ends of the bed. Between the double walls of the bed are oil reservoirs for the horizontal shafts, the bearings of which are attached to the walls of the bed. Wick inserts extend the full length of the bed which convey oil, under pressure, to the bearings at all times. All oil entering these bearings must first be filtered through filtering stations in the bed, in addition, to passing through a ½-in. felt wick before entering the bearing. The machine is also equipped with a two-way pump located near the operator with a sight feed attachment so that he can make sure at all times that the oil is working properly.

The bed is also equipped with a tool cabinet for tools and clamps. A gear box is cast in the bed, in which heat-treated steel gears run continually in a bath of oil.

The table is of the box type construction provided with wide openings at the bottom of the T slots which allow the chips to fall through. This eliminates the necessity of clearing the chips from the slots before inserting clamping bolts. No mechanism appears on top of the machine, with the exception of the sheave wheels necessary to carry the counterweight for the side head.

Duplex spiral fluted staybolt tap

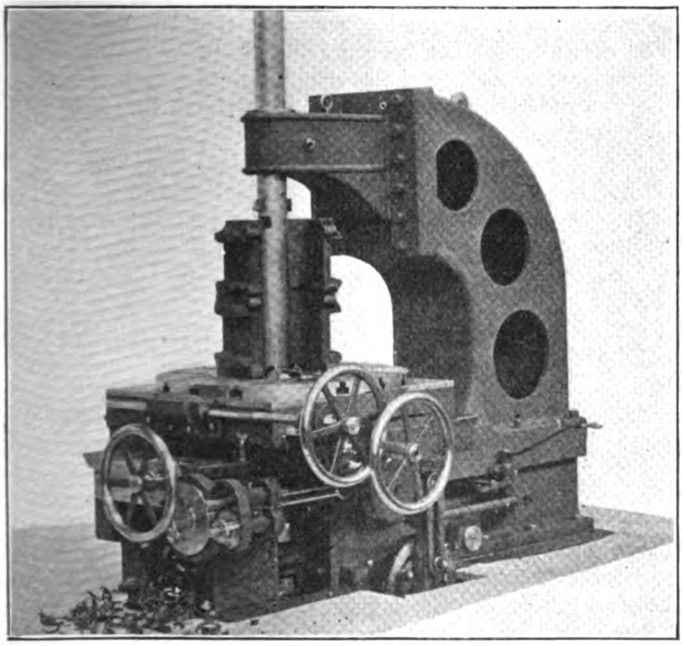
A STAYBOLT tap which consists of two spirals, opposite in direction, has recently been placed on the market by the W. L. Brubaker Brothers Company, Millersburg, Pa., under the trade name of Brubaker duplex spiral fluted staybolt tap.

Brubaker staybolt tap with the reamer portion made with a right-hand spiral

The tap is divided into five parts. Starting with the reamer end, they are the reamer, taper, thread and shank respectively. The reamer portion is made with a right hand spiral, thus giving it the action of a drill and reamer combined, while the tap is a left hand spiral, which gives it the same action as that of the regular Brubaker left hand spiral tap. It is claimed that the life of the tools are greatly increased by this design. They are manufactured by a special operation and are made of a steel carefully selected for this style of tool.

Draw stroke driving box slotting machine

A DRAW cut slotting machine primarily designed for machining locomotive driving boxes, but also adapted to a great variety of other slotting work in forgings or castings from which a large amount of metal is to be removed, or in long deep holes where the regular slotter cannot reach is a recent product of Baker Brothers, Inc., Toledo, Ohio. It will also do shaper work on the ends of long pieces of irregular shapes which are difficult to chuck on a planer. In addition it can be used for keyseating wheel centers up to 72-in. diameter.



Baker Brothers draw cut slotter set up for machining driving boxes

A 38½-in. diameter table with a 19¾-in. hole is placed low on the machine so as to be convenient for the operator. It is 32 in. above the floor level.

The bar carrying the cutting tool can be any size up to and including 4½ in. in diameter. The bar in the machine can be readily replaced by one of another size, by the substitution of suitable bushings. The support of the bar is very rigid. It is fixed at one end by clamping it in a long bearing in the driving ram, is supported by a bushing in the lower table directly below the work, and in a bushing in the upper arm directly above the work. The tool relief on the return stroke is secured by a clapper box in the cutter-bar. A 2-in. by 1-in. working tool can be used in the largest size cutter-bar.

Full automatic feeds are provided in all directions. All feeds are readily engaged by the operator when standing in front of the machine, all hand feeds being operated in the same manner. The length of the feed is adjusted at the right side of the machine.

The counterbalanced ram is driven by a rack and pinion through a heavy train of steel gearing. The reverse is accomplished by means of shifting belts which, for heavy duty, have been found very superior to any form of friction device. The shifting is actuated automatically which is an essential feature for smooth operation.

When so desired, the machine can be arranged for direct connected motor drive. A 20-hp. reversing planer type motor not to exceed 750 r.p.m. is recommended. The distance from the center of the cutter-bar to the box column is 35¼ in. The bar has a working stroke of 30 in. and an actual stroke of 33 in. The diameter of the table is 38½ in. The net weight of the machine is 18,000 lb.

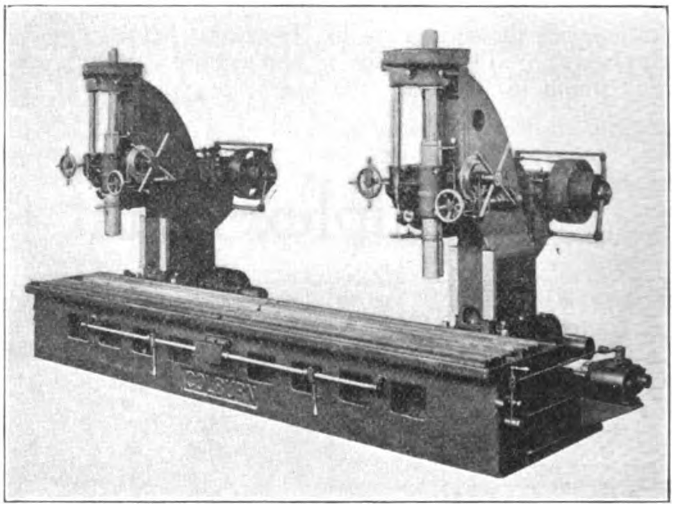
Adjustable spindle rod boring machine

THE advanced type of rod-boring machine shown in the illustration is a late product of the Colburn Works of the Consolidated Tool Corporation of America, Wilmington, Del. The machine is adapted not only to the boring of side rods, but on account of its great range, quick adjustment of heads to any desired position and the large number of speeds and feeds available, it can be used on a variety of work where holes are to be bored, drilled, faced, reamed or tapped simultaneously, or where one operation may be performed on the first spindle and another operation on the other spindle.

Each spindle is operated independently. If desired a tapping attachment may be applied to either head. Each spindle has an independent motor drive which travels with the head. These motors also furnish power for moving the heads longitudinally. The driving and feed gears run in oil. The driving shafts and the spindles are provided with ball bearings, and each spindle has a steady support and cutting compound pump. A cutting compound trough surrounds the bed.

The specifications of the machine are as follows:

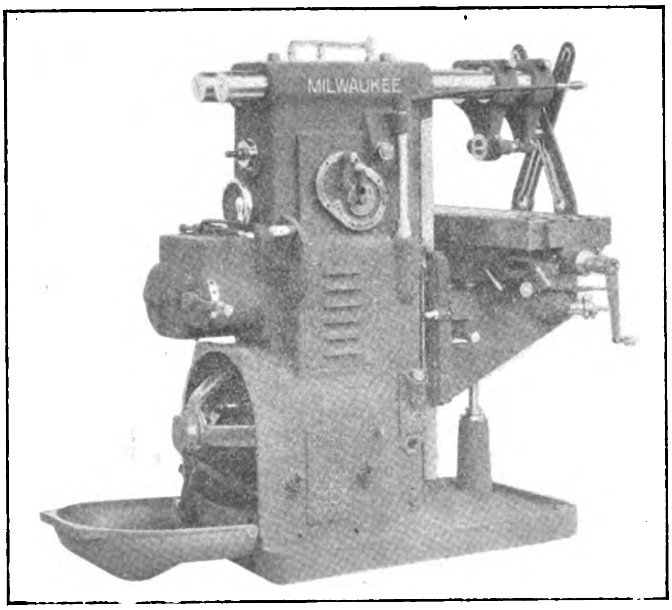
Drilling capacity in steel, 5 in.; swing, 36 in.; working surface of the table, 28 in. by 173 in.; vertical travel of the spindle 18 in.; maximum distance, the nose of the spindle to the table, 30 in.; eight speeds and six feeds for each spindle; taper in spindle, Morse No. 6; motors, two 15-hp., constant speed, to run at 1,200 r.p.m. The motors are not part of the regular equipment. The net weight of the machine is 35,000 lb.



Colburn two-spindle, locomotive rod-boring machine

Milling machine with the motor in the base

REALIZING that the modern tendency in machine design is to make each tool a simplified, compact unit, the Kearney & Trecher Corporation, Milwaukee, Wis., has added to its list of milling machines one which contains the motor drive in the base of the machine.



Milwaukee milling machine with the motor in the base

This feature utilizes the space in the lower part of the column and puts the motor out of the way, protecting it from dirt and dust. It also gives a quieter, more compact and economical installation, and follows the trend of the individual motor driven machine.

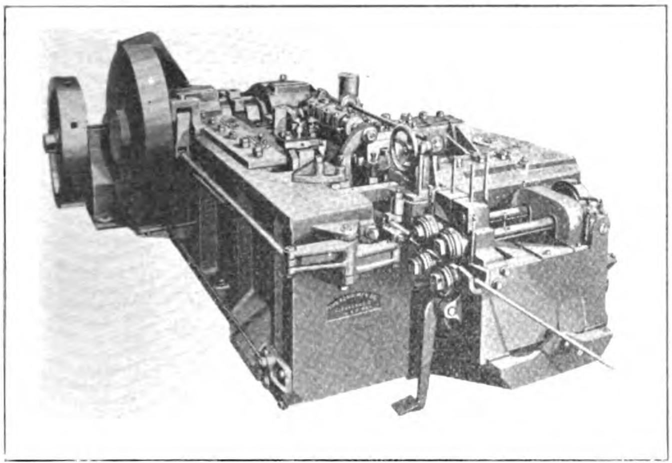
A direct geared drive, using no chain or belts is used. The driving pinion, mounted on the armature shaft, meshes directly with the driving gear leading up through the gear train in the column. The motor is placed with the driving pinion toward the front of the machine. In this position the brushes and commutator can be reached by removing the hinged cover at the rear of the column. The entire motor can be quickly slid out of its housing if any adjustments or repairs are required. Lubrication of the motor bearings are taken care of from the outside of the machine.

The drive is through a newly designed friction clutch, with the control lever extended and brought out to the front of the machine. This control lever may be adjusted to any angle desired for the convenience of the operator, or may be swung completely out of the way for very large work.

Another improvement consists of a new built-in power rapid traverse for the table. Table movements are readily controlled without any chance of confusion. A lever directly at the front of the table engages the table power feed in a direction determined by the lever movement. A second lever, conveniently located to the right hand of the operator as he stands in a normal operating position, may be shifted to change the table movement from the feed to the power rapid traverse rate. The levers are separated and the movements cannot be confused. Other levers controlling the engagement of cross and vertical feeds are located in convenient positions and completely separated from the table control levers. The other features common to the manufacturer's other millers remain unchanged, including an all-geared drive, automatic lubrication of column gearing, double overarm, etc. While this type of machine may be considered as particularly adapted to manufacturing rather than tool needs, it is built for toolroom accuracy and therefore can be used for this service.

Automatic bolt and rivet heading machine

A continuous motion bolt and rivet making machine which is designed for either hand or automatic feed and belt or motor drive has recently been developed by The Ajax Manufacturing Company, Cleveland, Ohio. The general arrangement has been improved by transferring the die-slide operating mechanism from the left to the right hand side, making it possible for the operator to feed the stock, watch the quality of the bolts or rivets as they come through the discharge port on the left, and adjust the stock gage all from one position. This arrangement leaves the left side of the machine clear, materially expediting the setting of the dies and tools.

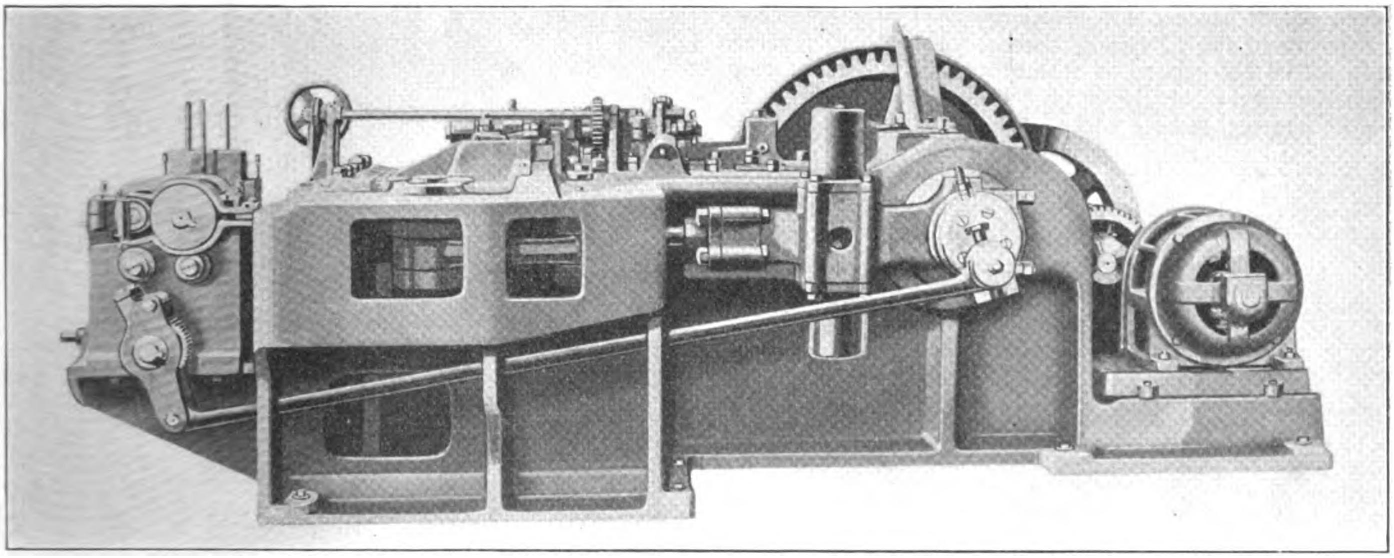


Automatic roll feed, motor driven, heavy duty, continuous motion heading machine

With the hand feed machine, rods heated to four or five feet in length are fed into the machine against the stock gage by the operator by hand, the machine shearing off a blank, heading and ejecting it. Outputs range from 14,000 to 18,000 counts every 10 hours. With the automatic roll feed, mill length rods are heated in a long furnace set about three feet from the front of the machine. The operator need only start the rod into the rolls, which feed it into the machine so that a piece is produced on each revolution. Outputs vary from 30,000 to 50,000 counts every 10 hours, depending on the length and size of rivets produced. The automatic roll feed mechanism is operated from an adjustable crank pin at the end of the crankshaft. The eccentricity of this pin is changed by means of an adjusting screw so that the rolls feed the correct amount of stock to produce any given length bolt or rivet.

The gears of this mechanism are completely enclosed in the feed housing. The ratchet arm is fitted with two dogs, staggered to give refinement of feed. The feed rolls which carry the heated bar stock consist of rings with the circumference grooved to suit the various sizes of stock. They are mounted in holders on the roll shafts so as to be easily changed for different sizes of stock and adjusted laterally for different shear center distances. The roll pressure is controlled by removable weights mounted on the bearings of the upper roll shafts which are movable vertically. In case of a sticker the feed can be stopped and locked out by depressing the foot pedal. An adjustment of distance between the feed rolls and the backing plate reduces waste from crop ends to a minimum. Finished pads on the front of the hand feed machines make it possible to attach this automatic roll feed mechanism at any time.

The belt driven machines are not geared, the flywheel being mounted directly on the end of the crankshaft. A clutch countershaft is provided as a standard accessory with all belt driven machines. Motor drive by direct gearing is provided for by extending the main bed casting to the rear to carry the pinion shaft and motor. A safety friction clutch coupling between this shaft and the main drive pinion cushions the motor from shocks and protects both the machine and the motor from damage should anything prevent a complete revolution of the crankshaft. The steel bed is of the ribbed type with continuous housings for the crankshaft bearings. It is extremely heavy and its deep sections and liberal flanges make it so rigid between crankshaft and backing plate, that it is not necessary to pack up excessively behind the



Automatic roll feed mechanism attached to the machine, showing the adjustable crank pin, the feed rod, the ratchet arm and the roll housing

heading tool to bring rivet or bolt heads down to the proper thickness. All wearing surfaces are suitably bushed and lined so that there is no direct wear of moving parts on the bed proper.

The header slide is top-suspended from V-type bearings. The trough ways of the bed, in which the header-slide bearings operate, are above the scale line. They are roll lubricated from two reservoirs and drain at the front, so that good lubrication with clean oil is maintained. The bearings on the header-slide and the ways in the bed are both removable for re-alinement. The die slide is top-suspended from plain bronze-faced bearings. A wedge liner on the crankshaft side, adjustable without removing any parts, makes it possible to keep the moving die back tight on the cutter, so as to shear the stock squarely. The self-adjusting side arm relief of the die slide actuating mechanism fully protects the machine in case a bolt or rivet lodges in or is caught between the faces of the dies. As soon as the obstruction is removed, the side arm automatically resets itself. The ejector is of the walking beam type operated from a cam on the inside of the flywheel. The cam is adjustable to control the time of kick-out and to offset any wear.

The stock gage can be adjusted by means of the hand wheel while the machine is running. The hand wheel is convenient to the operator as he watches the product being headed so that adjustments can be made quickly, for a slight variation in the stock diameter so that all heads will be properly filled out. The cam on the header-slide which actuates this gage is adjustable to change the timing for different shear center distances. Three types of gage arms are furnished for use when making short, medium and long rivets.

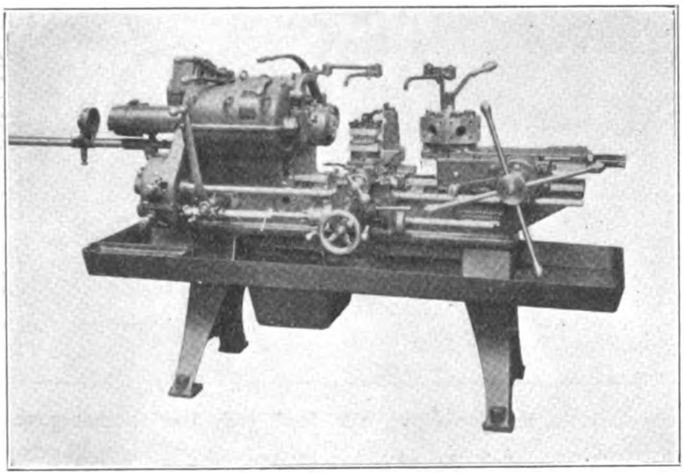
Both hand and automatic feed machines operate on the same principles so far as the heading mechanism is concerned. The heated bar is advanced through the breast plate until it strikes the stock gage which is so set that just enough of the bar projects through the breast plate to make a finished rivet. The moving die then travels across the breast plate shearing off the blank on the cutter, and gripping it against the stationary die. The header-slide moves forward, a cam on the top swings the stock gage out of the way and the heading tool in the toolholder heads the stock which projects from the dies, against the face of the dies. The heading tool then backs off and the dies open, whereupon the headed piece is kicked out of the dies by the ejector and drops out through the discharge port, completing the cycle. Water from overhead pipes is directed into the dies and the heading tool to keep them cool and carry away scale.

The power of the motor required is from 7½ to 20 hp. for machine sizes varying from ¾ in. to 1½ in. in the case of hand feed, and from 10 to 30 hp. for the same sizes in the case of automatic feed.

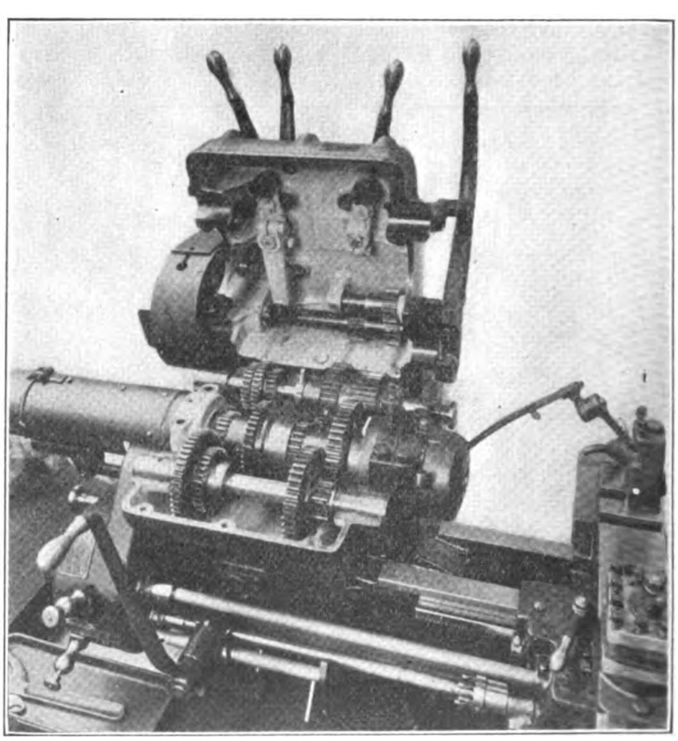
All geared head universal turret lathe

The Warner & Swasey Company, Cleveland, Ohio, has developed a universal turret lathe particularly adapted to small work. The distinctive features of this small machine are the tool carrying units with independent power feeds. The standard cross slide has five cutter positions, four on the square turret and one on the rear tool post. Cutters in their positions often operate simultaneously with the tools on the hexagon turret, which has six tool positions.

Any one of the 12 spindle speeds, forward and reverse, from 30 to 760 r.p.m., is instantly available by moving convenient levers on the head. This gives a wide selection of cutting speeds for all diameters and classes of work. The hardened gears run in oil and provision is made for easy adjustment of the frictions. The wide range of speeds and power of the all geared head enables this machine to pull stellite cutters to their capacity. It also makes possible the combining of a greater number of cutters to operate at the same time.



Warner & Swasey No. 4 universal turret lathe



Turret lathe with all geared head giving 12 spindle speeds

The machine is well suited to individual motor drive. The motor may be mounted at the rear of the machine or on the head-end leg, driving to the pulley by means of a belt. Where it is necesary to conserve floor space, the motor can be mounted on the head. The machine, when arranged for motor drive, may be placed where con-

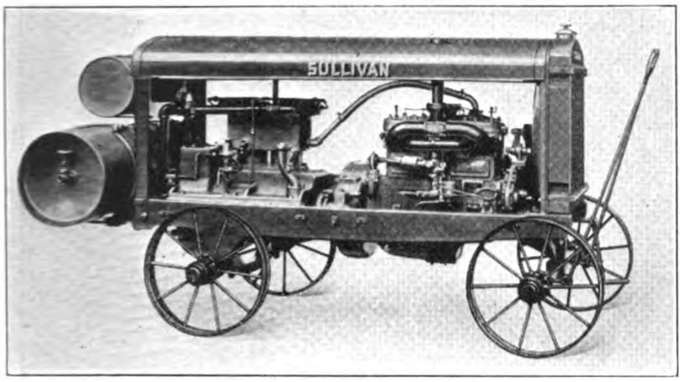
venient regardless of line shaft conditions. Waste space can often be utilized in this way, and if changes require moving, the machine may be quickly transferred.

Over seventy-five standard small tools are carried in stock for this machine. These tools greatly increase the productive possibilities of the turret lathe for all classes of work, and reduce the cost of tooling. The machine is claimed to be rapid in operation, easily handled and quickly tooled. It is, therefore, suitable not only for quantity production, but for use in the repair shop and the tool room where only a very few pieces are made at one time. The tooling is easily adjusted from one job to another and the twelve spindle speeds readily provide the right surface speeds for economical cutting.

The lathe is designed to be equally efficient for bar and chucking work. Round bars up to 1½ in. in diameter can be chucked through the automatic chuck. Ten inches is the maximum length which can be turned at any one setting of the turret saddle along the bed. For chucking work, a geared scroll chuck holds the piece. The maximum swing over the ways is 16 in. and over the carriage guides, 14¼ in.

Portable motor driven air compressor

THE rapid increase in the application of compressed air in railway practice, especially where the air cannot be readily piped, has called for the development of portable air compressors in a great variety of types and capacities. The machine shown in the illustration is a 103-cu. ft. gasoline engine driven, portable unit developed by the Sullivan Machinery Company, Chicago.



Sullivan portable, gasoline engine driven air compressor

The compressor is directly connected to a Buda, four cylinder, four cycle gasoline engine, and as stated, has a rating of 103 cu. ft. per min. against 100 lb. pressure, requiring 17 hp. for this duty. The compressor is a vertical, two cylinder, single acting, single stage unit, designed especially for this service. Lubrication is automatic and the cooling water for the engine and the compressor are supplied by a circulating pump in the same system. The air valves are the Sullivan "wafer" type, characterized by simplicity, strength, low clearance losses and quietness in action. The compressor, engine and equipment are mounted on a one-piece steel casting of rigid construction. The 12-gal. gasoline tank and the 18-in. by 48-in. air receiver are carried horizontally in cradles at the rear of the truck body, and all working parts of the compressor are protected, when not in use, by sheet steel sides which are locked in place against the base and the steel canopy top, thus protecting the outfit from the weather and from the theft of equipment.

This machine is mounted on a steel wheel truck and weighs 3,235 lb. in this form.

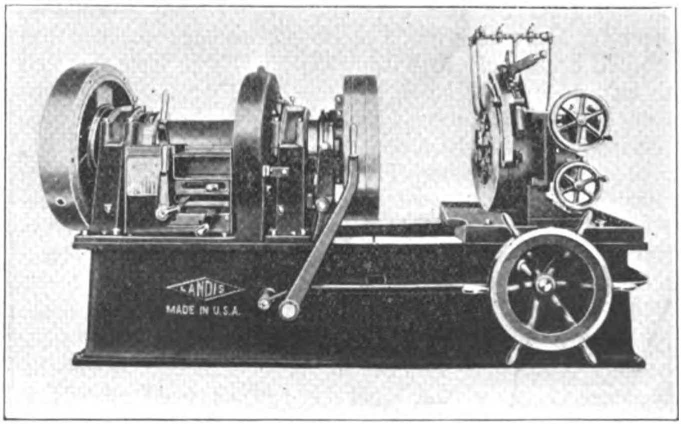
A six-inch pipe threading and cutting machine

A PIPE threading machine with a range from one inch to 6 in. has been added to its line by the Landis Machine Company, Waynesboro, Pa. Two die heads are employed for covering this range; one 2-in. head for a range from 1 in. to 2 in. inclusive, and a 6-in. head for a range from 2½ in. to 6 in. The entire range of each head is covered by one set of chasers. The travel of the carriage is 22 in. and has eight speeds. The speed of the 14-in. driving pulley is 300 r.p.m. The machine is 9 ft. 8 in. in length by 4 ft. 9¾ in. in width and weighs 8,800 lb.

The machine has a geared headstock and a single pulley drive. The variations in speed are obtained by means of a self-contained gear box, located beneath the main spindle. All the gears are cut steel and run in an oil bath. All bushings are bronze. The shaft bearings are lubricated automatically by a forced feed system. The main bearings are lubricated by flat link chains which run in oil contained in large reservoirs.

The front three-jaw chuck has a universal adjustment and is lever operated which permits the gripping and releasing of the pipe while the chuck is in motion. A universal geared, three-jaw chuck is employed at the rear of the machine and is fitted with flange grips for screwing flanges on and off. A reverse drive is obtained by a shifting lever for this operation.

The cross rail supports the die head, and is also fitted with cutting-off and reaming tools and a length gage. The die lubricating system includes a rotary pump, a by-



Operating side of the Landis 6-in. pipe threading and cutting machine

pass for the surplus oil and a special control valve at the head and cutting-off tools. All levers are located on the operating side of the machine in convenient reach for the operator.

This machine is very easily adapted to motor drive which can be applied after the machine is in service. The motor is mounted on a plate over the gear box and a silent chain transmits the power from the motor to the machine. A 7½-hp. constant speed motor, wound for an approximate speed of 1,200 r.p.m. is recommended which enables the machine to be operated at its maximum efficiency whenever desired.

The Landis stationary die head and long life tangential chaser is used on this machine.

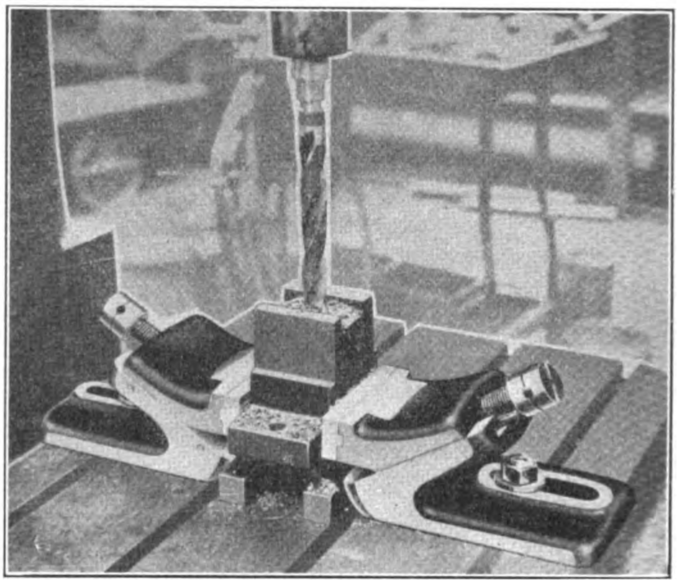
Coats divided machine vise

IT is not an uncommon sight in a railway shop to see a mechanic trying to set up on a machine an irregular shaped piece of work with all kinds of bolts, packing pieces, straps and wedges, because it is impossible to hold it in the machine vise. The Coats Machine Tool Company, New York, has developed a divided machine vise which apparently overcomes this difficulty. It is designed to hold parallel, tapered or irregular work. It combines adjustability in height with an unlimited span and beds the work truly on its supports, because of the compound parallel and downward movement of the jaws, eliminating the use of a hammer.

The body and jaws of the vise are made of close grain cast iron. The jaws are faced with hardened steel with serrated surfaces to insure a good grip. The screws are of steel and have right and left-hand threads, the left-hand thread running in a solid nut on the moving jaw, and the right-hand in the nut which is secured to the body. For each revolution of the screw, therefore, a movement of the jaws is obtained equal to twice the pitch of the screw, thus resulting in double action. The jaw is fitted to the body in V-guides, properly fitted, and an adjustable steel gib and screws furnish the necessary adjustment for wear.

They can be used either singly or in pairs, or three, four or more at a time may be employed for clamping irregular shapes. The jaws may be placed in any off-set position required by the shape of the work. Their main field of usefulness is on the tables of milling, drilling, shaping, slotting and planing machines which may be found in all railway shops.

The vises are made in three sizes, the width of the jaw ranging from 2½ in. to 10 in. and the diameter of the screw from ½ in. to 1½ in. The approximate weight per pair is 6 lb., 40 lb. and 220 lb., respectively, which takes care of all sizes of irregular work.

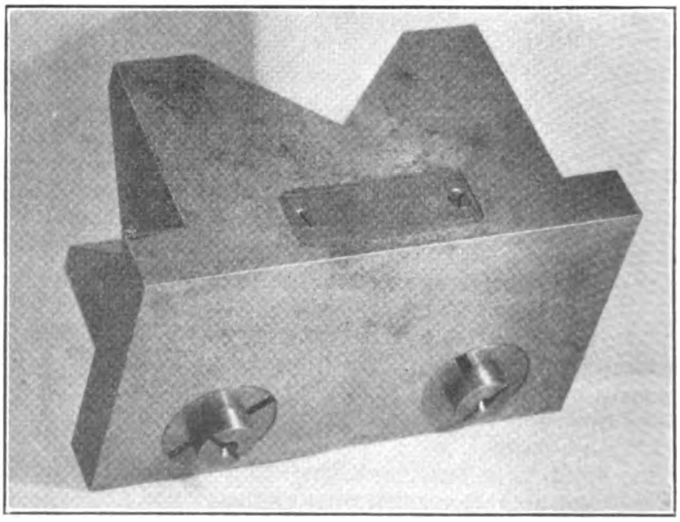


Divided machine vice for holding any irregular piece of work

Crescent V-type work support

THE use of V-blocks has always proved a time-saving device on lay-off tables and on all types of machines. A useful type of V-block has recently been designed by the Crescent Engineering Company, Baltimore, Md. It is made of close grained, grey iron and machined accurately to within .001 in. The base is fitted with two ⅝-in. tool steel, hardened and ground pins, operating in steel bushings. They can be locked up or down as desired, and can be changed in a few seconds with the use of a screw driver. The pins on the support shown in the illustration are off center which is very desirable as it enables the operator to use the block partly overhanging a machine edge, and still have sufficient base for clamping solidly.

With the pins extended, the tool can be used in connection with the service slots of any machine for quick alinement with the spindle or table travel. With the pins screwed up in the block, it can be used anywhere as a regular V-block. It has suitable clamping flanges and is made in three sizes.



V-type work support provided with clamping flanges

General News

The suggestion plan placed in effect by the Missouri Pacific last August, under which its employees are encouraged to submit plans for bettering shop practices, has been accorded the enthusiastic support of employees throughout the system. Under the plan the employees elect production and executive committees to pass upon the suggestions submitted. At Sedalia, Mo., where the suggestion plan first went into effect, approximately 90 per cent of all those employed at the Sedalia shops indicated their interest by casting ballots for members of the committees.

Howell-Barkley bill again passed by

A fourth day on which the Howell-Barkley railroad labor bill might have been considered in the House of Representatives was allowed to pass by on January 19 without any effort being made by the advocates of the bill to have it taken up. The bill is on a House calendar that comes up only every other Monday but so far at this session of Congress no effort has been made to have the bill considered. The Senate committee, having reported the bill with an amendment, is giving it no further attention, although some of the advocates of the bill say they are still hoping to have the amendment put in a more desirable form.

General Atterbury becomes mechanical division representative on A. R. A. board

According to the articles of organization of the American Railway Association, a member of the board of directors is to be selected by the board to represent it in the work of each division and, in effect, to represent the division on the board of directors of the parent association. The members of the board so selected form the Executive Committee.

At a meeting of the board of directors held on January 6, Gen. W. W. Atterbury, vice-president of the Pennsylvania System, was elected to succeed W. B. Storey, president of the Atchison, Topeka & Santa Fe, as Mechanical Division representative. Mr. Storey has served in this capacity since the establishment of the present form of organization of the A. R. A.

Mr. Atterbury is succeeded as the representative of the work of Division 1—Operating, by Carl R. Gray, president of the Union Pacific System, the newly elected member of the Executive Committee. H. E. Byram, president of the Chicago, Milwaukee & St. Paul, is also a newly elected member of the Executive Committee, representing Division VII—Freight Claims, which, until his selection, had been without Executive Committee representation. The complete list of division representatives is as follows:

Division I........... Operating, C. R. Gray, president Union Pacific System.
Division II.......... Transportation, E. J. Pearson, president, New York, New Haven & Hartford.
Division III......... Traffic, C. H. Markham, president, Illinois Central.
Division IV.......... Engineering, J. Kruttschnitt, chairman, Southern Pacific.
Division V........... Mechanical, Gen. W. W. Atterbury, vice-president, Pennsylvania System.
Division VI.......... Purchases and Stores, W. G. Besler, president, Central of New Jersey.
Division VII......... Freight Claims, H. E. Byram, president, Chicago, Milwaukee & St. Paul.

Wage statistics for October

In the month of October, 1924, the employment on Class I railroads reached the highest point since November, 1923, according to the Interstate Commerce Commission's monthly bulletin of wage statistics. The total number of employees reported was 1,822,616, an increase of 21,320 or 1.2 per cent over the number reported for September, 1924. The total compensation increased $14,825,589 or 6.2 per cent. The ratio of increase in the compensation is greater than the ratio of increase in employment because of the fact that October had 27 working days while September had only 25.

Compared with the corresponding month last year, the employment in October, 1924, decreased 5.9 per cent and the total compensation shows a decrease of 5.7 per cent.

Labor news

SHOP EMPLOYEES of the Delaware, Lackawanna & Western have finally called off the strike which has been effective since July 1, 1922. The Lackawanna has issued a statement that the men will not be given their old jobs back but will have to apply for work as new men.

THE GULF, COLORADO & SANTA FE has negotiated an agreement with the engine service employees similar to that made by the Southern Pacific which grants wage increase of approximately six per cent and changes a few minor working rules. The Atchison, Topeka & Santa Fe, Eastern, Western and Coast Lines, are now meeting the representatives of Brotherhood of Locomotive Engineers and Brotherhood of Locomotive Firemen and Enginemen to reach agreements affecting the employees of those lines. The Terminal Railroad Association of St. Louis has also signed an agreement with engine service brotherhood on the Southern Pacific basis, calling for the wage increase without changes of working rules.

LABOR BOARD REPORTS ON DECISIONS RENDERED.—In a report furnished to the congressional appropriations committee, the railroad labor board announced that it had rendered 706 decisions during 1924, of which 333 favored the railways; 323 favored the employees and 50 either decided nothing or decided partly for the managements and partly for the employees. Most of the organizations, with the exception of the four train and engine service brotherhoods, were given a majority of the favorable decisions on disputes in which they took part.

WESTERN PACIFIC WAGE INCREASE FOR ENGINEMEN.—The Western Pacific has made an agreement on wage increases with its engine service employees, represented by the Brotherhood of Locomotive Engineers and the Brotherhood of Locomotive Firemen and Enginemen, similar to that made by the Southern Pacific with its enginemen. The agreement awarded a wage increase of approximately six per cent to the men without changes of working rules. Like the Southern Pacific, the Western Pacific was one of the roads which were parties to the recent dispute before the Railroad Labor Board, in which the board approved the wage advance only on condition that certain burdensome working rules be amended.

C. & S. UPHOLDS DECISION IN ENGINEMEN'S WAGES.—Demands of the Brotherhood of Locomotive Engineers and the Brotherhood of Locomotive Firemen & Enginemen, that the engine service employees of the Colorado & Southern receive a six per cent wage increase without changes in working rules, have been flatly refused by W. P. Hayden, assistant general manager of the Colorado & Southern. He declared that the Colorado & Southern would stand squarely behind the decision of the United States Railroad Labor Board which granted the wage increase only on condition that the brotherhoods accept changes in some of the more burdensome rules. Although negotiations are continuing and no strike vote has been taken, the brotherhoods are expected to take the same action on the Colorado & Southern as they took on the Southern Pacific to enforce compliance with their demands. On the Southern Pacific an overwhelming majority of the employees are said to have voted to strike if the agreement they had proposed was not approved by the management.

AN AGREEMENT CALLING for a wage increase of approximately six per cent without changes in important working rules, similar to that made on the Southern Pacific, has been approved by the Chicago & North Western and its engine service employees represented by the Brotherhood of Locomotive Engineers and the Brotherhood of Locomotive Firemen and Enginemen. Although the North Western was one of the roads involved in the recent Labor Board decision which granted the wage increase to the

enginemen only on condition that they accept a number of changes in important working rules, it followed the example of the Southern Pacific and the Western Pacific in not insisting that this decision be made the basis of an agreement. The policy of the brotherhoods has been to ignore the board's decision and to force agreement to their demands of wage increases without changes in working rules through negotiations with individual managements in which strike threats are freely made. So far as is known, no railway has succeeded in making an agreement with its engine service employees on the basis of the Labor Board's decision, although one road, the Colorado & Southern, is known to have insisted that it will make no agreement on any other terms.

Power of labor board again upheld.—The right of the United States Railroad Labor Board to compel witnesses to appear and testify before it, was upheld for the second time by Federal Judge Wilkerson of the United States District Court at Chicago on January 12. The suit was brought by the Labor Board against J. Maguire, chairman on the Chicago & North Western of the Brotherhood of Locomotive Engineers, who refused to testify in the board's hearing of the dispute between the western railways and their engine service employees. In spite of the fact that the representatives of the employees did not testify at the board's hearing, a decision on the dispute was rendered sometime ago, awarding a wage increase of six per cent to the employees on condition that they accept a number of changes in working rules.

The Labor Board had previously won a similar decision in the United States court in the case of D. B. Robertson, president of the Brotherhood of Locomotive Firemen and Enginemen. As was done following the court's ruling on the Robertson case, counsel for Mr. Maguire will appeal Judge Wilkerson's decision. The Robertson case is now pending in the United States Supreme Court.

The brotherhoods took the position that the Labor Board's orders had been held unenforceable by the United States Supreme Court and that it was a mere arbitrary body without power to compel testimony. They also charged that Ben W. Hooper, chairman of the board, was prejudiced against them.

"The Labor Board does not act as an arbitrator in the proper sense of the word but as an administrative body," said Judge Wilkerson in considering these contentions. "Its acts, if arbitrary, are void. Whether its acts are arbitrary is to be determined, not by the state of mind of one of the members, but by the acts themselves." Judge Wilkerson declared that in his opinion the proposed compulsion of testimony does not violate the fifth amendment of the constitution and that the interest of a witness in a dispute does not preclude the board's making him testify in connection with it.

Meetings and Conventions

General Foremen's Association

The International Railway General Foremen's Association has appointed committees to report on the following topics at the annual convention in Chicago next September.

Automatic train control—Charles C. Kirkhuff, Atchison, Topeka & Santa Fe, Chicago, chairman.

Supervision and repairs of special appliances, boosters, reverse gears, feedwater heaters, etc.—J. H. Armstrong, Atchison, Topeka & Santa Fe, Topeka, Kans., chairman.

Straight line or spot system of car repairs—G. P. Hoffman, Baltimore & Ohio, Baltimore, Md., chairman.

What can the general foreman contribute to obtain more ton-miles per shop man-hour?—F. B. Harmon, Atchison, Topeka & Santa Fe, San Bernardino, Cal., chairman.

Reclamation of material, car and locomotive—A. J. Larrick, Baltimore & Ohio, Chillicothe, Ohio, chairman.

Best routing system to increase shop output—Wallace Murray, Chicago, Rock Island & Pacific, Silvis, Ill., chairman.

Additional information may be obtained from the secretary-treasurer of the association, William Hall, Winona, Minn.

An appreciation of Secretary Kline

The January meeting of the Car Foremen's Association of Chicago was held at the Great Northern hotel on Monday evening, January 12. The first part of the meeting was devoted to a discussion of the new A. R. A. rules under the direction of the association's committee on that subject. The latter part of the meeting was given over to a celebration of the twenty-fifth anniversary of the election of Aaron Kline as secretary of the association. Mr. Kline was given a rising vote of thanks for his faithfulness and effective work in increasing the association's membership and influence among railroad car foremen, car inspectors and other car department employees. Instead of making Mr. Kline some gift in token of his long and faithful service, the board of directors voted to grant him an increase of salary as a more effective way of showing their appreciation. Photographs of past presidents were posted around the walls of the meeting room and Mr. Kline received personal letters of appreciation from all living past presidents.

The following list gives names of secretaries, dates of next or regular meetings and places of meeting of mechanical associations and railroad clubs.

Air-Brake Association.—F. M. Nellis, Room 3014, 165 Broadway, New York City. Next meeting May 5-8, Los Angeles, Cal.

American Railroad Master Tinners', Coppersmiths' and Pipefitters' Association.—C. Borcherdt, 202 North Hamlin ave., Chicago.

American Railway Association, Division V.—Mechanical.—V. R. Hawthorne, 431 South Dearborn St., Chicago.

Division V.—Equipment Painting Section.—V. R. Hawthorne, Chicago. Business meeting to be held in Chicago during week commencing June 15. No exhibit of railway supplies and machinery will be held.

Division VI.—Purchases and Stores.—W. J. Farrell, 30 Vesey St., New York.

American Railway Tool Foremen's Association.—G. G. Macina, 11402 Calumet Ave., Chicago.

American Society of Mechanical Engineers.—Calvin W. Rice, 29 W. Thirty-ninth St., New York. Railroad Division. A. F. Steubing, Bradford Corp., 25 West Forty-third street, New York.

American Society for Steel Treating.—W. H. Eiseman, 4600 Prospect Ave., Cleveland, Ohio.

American Society for Testing Materials.—C. L. Warwick, 1315 Spruce St., Philadelphia, Pa.

Association of Railway Electrical Engineers.—Joseph A. Andreucetti, C. & N. W., Room 411, C. & N. W. Station, Chicago, Ill.

Canadian Railway Club.—C. R. Crook, 129 Charron St., Montreal, Que. Regular meetings second Tuesday in each month, except June, July and August, at Windsor Hotel, Montreal, Que. Next meeting February 10. Paper will be read on Foundation Brakes, by W. H. Clegg, chief inspector, air brakes and car heating equipment, Canadian National, Montreal.

Car Foremen's Association of Chicago.—Aaron Kline, 626 N. Pine Ave., Chicago, Ill. Meeting second Monday in month, except June, July and August, Great Northern Hotel, Chicago, Ill.

Car Foremen's Association of St. Louis.—R. E. Giger, 721 North 23rd street, E. St. Louis, Ill. Meetings, first Tuesday in month, except June, July and August, at the American Hotel Annex, St. Louis.

Central Railway Club.—H. D. Vought, 26 Cortlandt St., New York, N. Y. Next interim meeting February 12. Paper on "Locomotive Feed Water Heating," will be presented by L. G. Plant, assistant to the president, National Boiler Washing Company, Chicago.

Chief Interchange Car Inspectors' and Car Foremen's Association.—A. S. Sternberg, Belt Railway, Clearing Station, Chicago.

Cincinnati Railway Club.—W. C. Cooder, Union Central Building, Cincinnati, Ohio. Meetings second Tuesday, February, May, September and November. Next meeting February 10. Paper on "Three Cylinder Locomotives" will be read by Perry T. Egbert, representative, American Locomotive Company. Illustrated by moving pictures.

Cleveland Steam Railway Club.—F. L. Frericks, 14416 Adler Ave., Cleveland, Ohio. Meeting first Monday each month at Hotel Cleveland, Public Square, Cleveland. Next meeting February 2. Discussion of A. R. A. Rules.

International Railroad Master Blacksmiths' Association.—W. J. Mayer, Michigan Central, 2347 Clark Ave., Detroit, Mich. Next convention, Hotel Winton, Cleveland, Ohio, August 18, 19 and 20.

International Railway Fuel Association.—J. B. Hutchinson, 6000 Michigan Ave., Chicago, Ill. Next annual convention May 26-29, Hotel Sherman, Chicago.

International Railway General Foremen's Association.—William Hall, 1061 W. Wabash St., Winona, Minn.

Master Boiler Makers' Association.—Harry D. Vought, 26 Cortlandt St., New York, N. Y. Next convention May 19-25, Hotel Sherman, Chicago.

New England Railroad Club.—W. E. Cade, Jr., 683 Atlantic Ave., Boston, Mass. Regular meeting second Tuesday in month, except June, July, August and September. Copley-Plaza Hotel, Boston, Mass. Next meeting February 10. Methods of Analyzing Shop Output and Costs will be discussed by J. E. Slater, special assistant to general manager, New York, New Haven & Hartford.

New York Railroad Club.—H. D. Vought, 26 Cortlandt St., New York. Meeting third Friday of each month except June, July and August at 29 West Thirty-ninth St., New York.

Niagara Frontier Car Men's Association.—George A. J. Hochgreb, 623 Brisbane Building, Buffalo, N. Y. Regular meetings, January, March, May, September and October.

Pacific Railway Club.—W. S. Wollner, 64 Pine St., San Francisco, Cal. Regular meetings second Thursday in month, alternately in San Francisco and Oakland, Cal.

Railway Club of Greenville.—F. D Castor, clerk, maintenance of way department, Bessemer & Lake Erie, Greenville, Pa. Meeting last Friday of each month, except June, July and August.

Railway Club of Pittsburgh.—J. D. Conway, 515 Grandview Ave., Pittsburgh, Pa. Regular meeting fourth Thursday in month, except June, July and August. Fort Pitt Hotel, Pittsburgh, Pa.

St. Louis Railway Club.—B. W. Frauenthal, Union Station, St. Louis, Mo. Next meeting February 13. Moving picture entitled, "Oxygen, the Wonder Worker," produced by the United States Bureau of Mines in connection with the Air Reduction Company, will be shown. Oxy-acetylene application will also be demonstrated.

Southeastern Carmen's Interchange Association.—J. E. Rubley, Southern railway shops, Atlanta, Ga.

Traveling Engineer's Association.—W. O. Thompson, 1177 East Ninety-eighth St., Cleveland, Ohio. Annual meeting September, 1925, Chicago.

Western Railway Club.—Bruce V. Crandall, 189 West Madison St., Chicago. Meetings third Monday in each month, except June, July and August. Annual meeting May 23, Edgewater Beach Hotel, Chicago.

Supply Trade Notes

Henry W. Jacobs, formerly president of the Oxweld Railroad Service Company, Chicago, died on January 6 in Chicago.

The United Alloy Steel Corporation plans the construction of two one-story brick and steel factory buildings at Canton, Ohio.

William S. Estell, who retired as secretary of the Adams & Westlake Company, Chicago, in 1923, died on January 4 in Chicago, of pneumonia.

John Heller, for a long time one of the directors of the International Oxygen Company, Newark, N. J., has been appointed sales manager.

The McMyler-Interstate Company, Cleveland, Ohio, has removed its Detroit office from 1701 Washington Boulevard building to 1156 Book building.

Glenn G. Howe, for many years senior vice-president of the Link-Belt Company, Chicago, died at his home in Muskegon, Mich., on December 25.

The DeVilbiss Manufacturing Company, Toledo, Ohio, has opened an office and display room at 1006 Republic building, State and Adams streets, Chicago.

The Truscon Steel Company, Youngstown, Ohio, is contemplating the erection of a one-story factory branch and district plant at Jacksonville, Fla., to cost approximately $25,000.

O. D. Hays, district manager of the Oxweld Railroad Service Company, with headquarters at Atlanta, Ga., has been transferred to the Southwestern district, with headquarters at St. Louis, Mo.

Daniel O'Rourke, superintendent at the east portal of the Moffet tunnel, has been appointed special representative of hammer drills of the Sullivan Machinery Company, with headquarters in Chicago.

E. J. Costello, Jr., representative of the Truscon Steel Company, with headquarters at Pittsburgh, Pa., has been appointed sales engineer in the railroad department, with headquarters in New York.

The St. Louis Forgings Company, a subsidiary of the Standard Forgings Company, Chicago, has purchased the forging plant of the Laclede Steel Company, East St. Louis, Ill., and plans to expand the new plant.

O. L. Chapman has joined the sales organization of the Scott Valve Manufacturing Company, Detroit, Mich. Mr. Chapman will devote his time to the application of valves to manufacturing plans and similar lines of industry.

The business heretofore conducted under the name of the Franklin Railway Supply Company of Canada, Ltd., Montreal, Quebec, will be continued under the same management in the name of the Franklin Railway Supply Company, Ltd.

William P. Kirk, district manager of sales of the Niles-Bement-Pond Company, with headquarters at Cincinnati, Ohio, has been transferred to New York and will be succeeded by E. H. Gates, manager of Rochester, N. Y., branch office.

The Wanner Malleable Castings Company has been organized under the laws of Delaware with a capitalization of $1,850,000 and will take over and expand the plant and business of the Wanner Malleable Castings Company at Hammond, Ind.

Joseph W. Irwin, until recently president of the Mitchell Spring & Manufacturing Company, Johnstown, Pa., has resigned to become connected with his former associates as general superintendent of the Fort Pitt Spring & Manufacturing Company, Pittsburgh, Pa.

D. Maxwell, district manager of the Williams Tool Corporation, with headquarters at Chicago, has been transferred to Cleveland, Ohio, and will be succeeded by William J. Eberlien, store manager of the Greenfield Tap & Die Corporation, with headquarters at Chicago.

Henry W. Darling, for more than 30 years treasurer of the General Electric Company, Schenectady, N. Y., has resigned, and has been succeeded by R. S. Murray, who had been assistant treasurer of the company since 1910. In accepting the resignation of Mr. Darling as treasurer, the board of directors elected him a vice-president, with such duties as shall be assigned to him by the president.

A. E. Huckins, vice-president of the Burr Company, engineers, founders and machinists, specializing in the manufacture of dynamometer apparatus for railways, with headquarters at Champaign, Ill., has resigned. This company has also discontinued its Chicago office.

William H. Utz, vice-president and formerly European director of Jenkins Bros., Limited, with headquarters at London, England, has been appointed director of sales of Jenkins Bros., valve manufacturers, New York. Mr. Utz will have general charge of the selling activities of the company.

E. P. Essley, secretary of the E. L. Essley Machinery Company, Chicago, has taken over the duties of sales manager, formerly carried on by James J. Shanahan, general manager, resigned. Other departments of the general manager will be under the direct supervision of E. L. Essley, president.

C. T. Knissely, president of the Knissely Brothers Manufacturing Company, manufacturers of hollow metal fireproof doors and window sills, has been appointed sales manager of the Railway Brakeshoe & Foundry Company, with headquarters in the newly opened office, 5 South Wabash avenue, Chicago.

Col. Eugene C. Peck, who has served for almost 25 years as general superintendent and later as works manager of the Cleveland Twist Drill Company, Cleveland, Ohio, has retired from active management. He will continue, however, as a stockholder in the company and as a member of the board of directors.

The Brown & Sharpe Manufacturing Company, Providence, R. I., at a recent meeting of the stockholders, elected the following officers: William A. Viall, Henry Buker and Paul C. DeWolf, vice-presidents; John A. Cave, secretary; John Sharpe Chafee and Richmond Viall, assistant secretaries. Henry D. Sharpe continues to hold the office of president and treasurer.

Lawrence Richardson, sales engineer of the Whiting Corporation, Harvey, Ill., and Col. C. H. Crawford, general representative of the Baldwin Locomotive Works in Brazil, with headquarters at Rio de Janeiro, have joined the Dwight P. Robinson Company, Inc., New York. Mr. Richardson will be located in New York for about a month until definite plans are formed.

Ambrose N. Diehl, general superintendent of the Duquesne Works of the Carnegie Steel Company, has been elected a vice-president in charge of operations in the Pittsburgh district, with headquarters at Pittsburgh, Pa. J. Lamont Hughes, general superintendent at Youngstown, Ohio, has been elected a vice-president in the Youngstown, Ohio River and Valley district; Samuel G. Worton, assistant superintendent, succeeds Mr. Diehl, and David C. Burroughs, superintendent of the electrical department, has been appointed assistant general superintendent at the Duquesne Works.

The Associated Machine Tool Dealers has been organized by manufacturers and dealers in machine tools to promote a closer relationship and co-operation between manufacturers and dealers. Officers of the new organization are: president, G. E. Merryweather, of the Motch & Merryweather Machine Company, Cleveland, Ohio; vice-president, Marshall Prentiss, of Henry Prentiss & Company, New York; secretary, T. W. Carlisle, of the Strong, Carlisle & Hammond Company, Cleveland; and treasurer, G. H. Cherrington of the Brown & Zortman Machinery Company, Pittsburgh, Pa.

Francis C. Pratt, vice-president in charge of engineering of the General Electric Company, has been appointed to fill the vacancy caused by the resignation of G. E. Emmons, as vice-president in charge of manufacturing and chairman of the manufacturing committee. Mr. Pratt's new title will be vice-president in charge of engineering and manufacturing. H. F. T. Erben has been appointed assistant vice-president on the staff of Mr. Pratt. He will continue as vice-chairman of the manufacturing committee. Mr. Pratt's engineering assistant is E. W. Allen, appointed to the position of manager of the engineering department in April, 1924.

S. D. Hutchins, representative of the Westinghouse Air Brake Company at Columbus, Ohio, died on January 5 in the Mt. Carmel Hospital, following an operation. Mr. Hutchins was born at Cleveland on May 25, 1855. He entered the service of the Springfield, Mt. Vernon & Pittsburgh, now a part of the Cleveland, Cincinnati, Chicago & St. Louis, in 1871, as a fireman, and was promoted to

engineman in 1873. On May 15, 1896, Mr. Hutchins entered the service of the Westinghouse Air Brake Company as assistant on its air brake instruction car, and in 1905 was promoted to the position of representative, with headquarters at Columbus, which position he held until his death.

E. B. Perry, vice-president and general manager of the Industrial Works, with headquarters at Bay City, Mich., has been elected president and general manager to succeed W. L. Clements who has been elected a member of the board of directors. H. H. Perry, assistant to the vice-president and general manager, has been promoted to manager. C. R. Wells, secretary and treasurer, has been elected a member of the board of directors and will be succeeded by N. D. Platt, office manager, who in turn will be succeeded by J. L. Trudell, advertising manager, who will be succeeded by A. R. Olson. Walter Perry, superintendent, has been promoted to general superintendent.

The business of the T. H. Symington Company, manufacturers of railway equipment, has been conducted by a new corporation since December 17, 1924, organized under the laws of the State of Maryland, known as the Symington Company. The reorganization involves merely a readjustment of capital coincident with the placing of Charles J. Symington, who for five years was president of the T. H. Symington Company, in complete control of the policies of the new company. Including the election of Donald Symington, first vice-president; J. A. Sauer, vice-president, and P. P. Meade, secretary-treasurer, all with offices in New York, the same management of the old company continues. LeRoy Kramer, vice-president, remains in charge of western sales, with headquarters at Chicago, and Robert H. Gwaltney, vice-president, remains in charge of eastern and southern sales, with headquarters at New York. The operation of the Symington Company's works at Rochester, N. Y., will continue in charge of Donald S. Barrows, operating vice-president.

Safford S. DeLano, treasurer of the American Car & Foundry Company, New York, died at his home, 137 Riverside Drive, New York City, on December 27. Mr. DeLano was born in Waverly, N. Y., on January 24, 1856, and received his education in the public schools of Towanda, Pa. He entered the employ of the Michigan Car Company, Detroit, when sixteen years of age, and was advanced steadily until September, 1892, when a consolidation with the Peninsular Car Company was effected under the name of Michigan-Peninsular Car Company and he was appointed assistant treasurer of the new company. In 1899, upon the formation of the American Car & Foundry Company, the Michigan-Peninsular Car Company entered the consolidation, and in 1900 Mr. DeLano became a director and comptroller. In 1901 he was appointed treasurer, holding that office continuously until his death. He was also a director and treasurer of the American Car & Foundry Export Company and treasurer of the Sligo Furnace Company.

S. S. DeLano

The National Car Wheel Company and the Southern Wheel Company have been merged and are now operating under the name of the Southern Wheel Company, which is a subsidiary of the American Brake Shoe & Foundry Company. The merged company has plants at Pittsburgh, Pa.; Rochester, N. Y.; Cleveland, Ohio; Sayre, Pa.; St. Louis, Mo.; Birmingham, Ala.; Atlanta and Savannah, Ga., and Portsmouth, Va. The general offices are in the Keystone building, Pittsburgh, Pa., and the officers are as follows: W. F. Cutler, president, New York City; Frank C. Turner, first vice-president, Pittsburgh; J. Brookes Spencer, vice-president in charge of sales, Pittsburgh; C. C. Esdale, operating vice-president, Birmingham; C. M. Bower, vice-president, New York City; H. E. McClumpha, operating vice-president, Pittsburgh; J. Francis Weisbrod, assistant vice-president, Pittsburgh; Andrew Muirhead, treasurer, Pittsburgh; W. M. McCoy, controller, New York City; E. C. Hof, assistant controller, Pittsburgh, and G. M. Judd, secretary, New York City.

The Bethlehem Steel Corporation celebrated its 20th anniversary on December 10. During its 20 years of progress the management has adopted a policy, in acquiring new plants, of dividing and subdividing work so that each plant makes special steel products selected in accordance with the layout of the plant, the supply of raw materials and the market for the products. As a result, the corporation has an ingot capacity sixty times greater than it had in 1904 and only eight times as many employees. In 1904 the entire ingot capacity, all of which was in one plant, amounted to 120,000 tons a year, while at the present time the capacity amounts to 7,600,000 tons, distributed among seven steel plants.

George E. Doke, engineer of materials and equipment tests of the New York Central, at New York, has resigned his office and has been elected president of the Association of Manufacturers of Chilled Car Wheels, with headquarters at Chicago, to succeed George W. Lyndon, who died on October 7 in Chicago. George E. Doke was born in Tecumseh, Mich., on August 19, 1877, and was educated in the elementary and high schools of Elkhart, Ind. From 1897 to 1900 he served on the Indiana, Illinois & Iowa (now a part of the New York Central). He also served on the Lake Shore & Michigan Southern as yard clerk, telegrapher, bill clerk and timekeeper. He then entered the shops of the Lake Shore & Michigan Southern as an apprentice, and while serving in this position completed a special course in mechanical drawing and mechanical engineering. In 1905 he entered the chemical and physical laboratory of the Lake Shore & Michigan Southern at Cleveland as a laboratory assistant, becoming chief material inspector of that road's material inspection force in 1906. In 1912 he was promoted to assistant engineer of tests in charge of the locomotive and car department's service tests, and in 1916, following the consolidation of the Lake Shore & Michigan Southern with the New York Central, was promoted to assistant engineer of tests in charge of material inspection for the car and locomotive departments for the New York Central System. Four years later he was promoted to engineer of materials, with headquarters at Cleveland, Ohio, in charge of materials inspection and the creation and development of material specifications, and two months later was made engineer of tests of the New York Central Railroad in New York City, in charge of chemical and physical laboratories, material inspection bureau, service test department and dynamometer car tests. Since 1922 he has served as engineer of materials and equipment tests of the New York Central Railroad, in which position he has had charge of the service test department, dynamometer car tests, examination of failed materials and the creation and development of the equipment engineering department's material specifications. Mr. Doke for several years past has been an active committee member of the American Society for Testing Materials and the Mechanical Division of the American Railway Association. He is also a member of the Cleveland Engineering Society and the American Society of Mechanical Engineers.

George E. Doke

The Okonite Company has opened an office at 310 South Michigan avenue, Chicago, and has taken over the sale of Okonite products in the western territory. Charles E. Brown, vice-president of the Central Electric Company, has been appointed vice-president in charge of the territory west of Pittsburgh and east of the Rocky Mountains of the Okonite Company, with headquarters in Chicago. A. L. McNeill, manager of the railroad department of the Central

Electric Company, has been appointed manager of the railroad department. E. H. McNeill, railroad sales representative of the Central Electric Company, has been appointed sales engineer. Roy N. Baker, railroad sales representative of the Central Electric Company, has been appointed sales engineer. L. R. Mann, sales representative of the Central Electric Company, with headquarters at St. Louis, has been appointed manager of the St. Louis office. Joseph O'Brien, railroad sales representative of the Central Electric Company, has been appointed sales representative, with headquarters in Chicago. C. E. Brown, Jr., country sales manager of the Central Electric Company, has been appointed manager of the light and power department.

Manning, Maxwell & Moore, Inc., New York, has made the following changes in personnel in its sales organization, machinery department: Joseph Wainwright, district sales manager at Philadelphia, Pa., has been appointed eastern sales manager, with headquarters at New York; D. M. McDowell has been transferred from the New York office to the Philadelphia office as acting district sales manager; W. A. Deems, formerly master mechanic, Baltimore & Ohio Railroad, has been appointed sales engineer to cover eastern and southeastern territories. A new sales office has been opened at Los Angeles, Cal., with J. Fontes in charge of that office. Thomas A. Rees, formerly with Motch & Merryweather and the Treadwell Engineering Company, is now salesman at the Pittsburgh office. James W. Barr, formerly with the American Tool Works and the Van Dyck-Churchill Company, and Herbert S. Lester, formerly with the Hendey Machine Company, are now salesmen at the New York office. The sales force at the Buffalo office has been increased by the addition of C. O. Watson, formerly of Syracuse, and Henry I. Knickerbocker has been appointed general office manager, machinery department, in the New York office.

The Superfuel Corporation, New York, has been organized and has acquired control of the stock of the Trent Process Corporation, which owns the United States and foreign patent rights to the process of manufacturing an amalgam of fuel oil and bituminous or pulverized anthracite coal, which eliminates to a large extent the ash and clinker forming content of the coal. This product is now produced by several companies operating under license. Guy M. Standifer, identified with Pacific coast shipbuilding interests, has been elected president, and Francis R. Wadleigh, formerly United States fuel distributor, and commercial engineer of the U. S. Department of Mines and head of the Coal Division of the U. S. Department of Commerce, has been elected vice-president and general manager. J. A. Vandegrift, president of the Slope Mountain Coal Company, is also a vice-president, and Frank R. Peyton, secretary and treasurer of the Trent Process Corporation, is secretary and treasurer. In addition to Messrs. Standifer, Wadleigh and Vandergrift, the following have been elected as directors: Charles M. Barnett, president, Clinchfield Navigation Company, New York; R. M. Atwater, Jr., consulting engineer, New York; Walter E. Trent, combustion engineer, Washington, D. C., and Charles L. Parmelee, consulting engineer, New York.

F. A. Merrick, vice-president and general manager of the Canadian Westinghouse Company, has been elected vice-president and general manager of the Westinghouse Electric & Manufacturing Company. He will have general executive charge of the activities of the parent company, with offices at East Pittsburgh, Pa. The office of President E. M. Herr has been moved to the Westinghouse building, New York. Frank A. Merrick received his technical education at Lehigh University. Shortly after graduation he served with the Steel Motors Company, a subsidiary of the Lorraine Steel Company, and later became chief engineer. He subsequently joined the Westinghouse Electric & Manufacturing Company at East Pittsburgh, Pa., where he had charge of the production of street railway motors and after the formation of the Canadian Westinghouse, Ltd., in 1903, he was its superintendent, and later became manager of works and finally vice-president and general manager. During the war Mr. Merrick had charge of the factory of the New England Westinghouse Company, which was engaged in turning out rifles for the Russian government, and later supplying the United States with machine guns. After the war Mr. Merrick was located in London for two years as special representative of the Westinghouse Electric International Company, and then returned to Canada to resume his original duties as vice-president and general manager

Trade Publications

Pipe threading machines.—The characteristic features of Williams pipe threading machines are listed in a bulletin recently issued by the Williams Tool Corporation, Erie, Pa.

Chain block.—The Morris worm-gear chain block built for loads of 2,240 lb. to the ton, is described in a six-page, illustrated folder issued by Herbert Morris, Inc., Buffalo, N. Y.

Mono-rail cable conveyor.—A six-page, illustrated folder descriptive of the newly designed American mono-rail cable conveyor for handling coal, has been issued by the Conveyors Corporation of America, Chicago.

Steel mine timber.—Tables and data on the properties and uses of mine timber sections are included in the 46-page booklet descriptive of steel mine timber, which has been issued by the Carnegie Steel Company, Pittsburgh, Pa.

Machine tools.—A four-page guide for the selection of a variety of makes, types and sizes of re-manufactured machine tools, has been issued by Hill, Clarke & Company, Chicago. About 2,000 machines, including lathes, drills, boring machines, planers, millers, etc., are listed.

Fabroil gears.—The General Electric Company, Schenectady, N. Y., has issued a four-page folder descriptive of fabroil gears which have been designed to cushion transmission shocks and to eliminate the noise incident to the operation of machines equipped with metallic gears.

Portable electric hoists.—Bulletin 76-E, descriptive of single drum and double drum portable electric hoists, which are modeled on the turbinair compressed air hoists of similar type and are interchangeable in operation and many particulars of design and construction, has been issued by the Sullivan Machinery Company, Chicago, Ill.

Compressed air equipment.—A 16-page booket, entitled "You Can Do It Quicker with Air," has been issued by the Sullivan Machinery Company, Chicago. Steel work riveting, wood and metal drilling, spray painting and other compressed air operations are featured, as well as the portable air compressors and air equipment used in the performance of this work.

Engineering achievements.—An attractive 52-page brochure, Publication No. 1717, entitled "The Engineering Achievements of the Westinghouse Electric Company during 1924," has been issued by the Westinghouse Electric & Manufacturing Company, East Pittsburgh, Pa. As the name implies, the publication is a record of many of the major achievements of Westinghouse engineers in various fields, including railway traction.

Welding and cutting apparatus.—Welding and cutting apparatus manufactured by the Burdett Oxygen & Hydrogen Company, Chicago, and sold under the trade name "Burco" is described in a new 32-page catalogue issued by this company. The catalogue describes both oxy-acetylene and oxy-hydrogen welding and cutting apparatus and explains in detail the function of the Burco multiple mixer in promoting efficient flame propagation. Different types of torches with their respective parts are shown, also regulators and tank connections. Two full-page illustrations of particular interest to railroad men show the use of a Burco welding torch in building vestibules for passenger coaches and a cutting torch used in scrapping car frames.

The chilled iron car wheel.—A 68-page book, the object of which is to disseminate information as to the manufacture and service of car and locomotive wheels has been published by the Association of Manufacturers of Chilled Car Wheels, Chicago. The superior qualities of the chilled wheel are pointed out and discussed in detail. The various methods and operations used in manufacturing car wheels followed by a technical discussion of the various methods of inspecting and testing car wheels are thoroughly discussed. The importance of the proper machining and mounting of the wheels is emphasized. The various defects which the wheels develop while in service and the agencies for improving the manufacture of chilled car wheels are two factors discussed at length. The subject matter is well illustrated.

Personal Mention

General

D. S. ELLIS has been appointed assistant engineer of the New York Central, succeeding W. L. Lentz.

E. P. MOSES has been promoted to general equipment inspector (rolling stock) of the New York Central.

J. E. ENNIS has been appointed general equipment inspector (motive power) of the New York Central.

E. H. TROTTNOW has been appointed assistant engineer of rolling stock of the New York Central, succeeding E. P. Moses.

W. S. LAMMERS has been appointed assistant valuation engineer of the Atchison, Topeka & Santa Fe, with headquarters at Topeka, Kan., succeeding F. H. Adams.

W. L. LENTZ, assistant engineer, has been promoted to engineer of motive power of the New York Central, with headquarters at New York, succeeding P. W. Kiefer.

K. F. NYSTROM, engineer of car design of the Chicago, Milwaukee & St. Paul, with headquarters at Chicago, has been promoted to engineer of motive power and rolling stock, with the same headquarters, a newly created position. Mr. Nystrom was born in Sweden in September, 1881, and graduated from a university in that country in 1904 as a mechanical engineer. He came to the United States in November, 1905, and was employed as a draftsman by the Pressed Steel Car Company in 1906. In February, 1909, he was employed by the engineering department of the Pullman Company. In September of the same year he entered the service of the Southern Pacific. He was appointed assistant mechanical engineer of the American Car & Foundry Company in June, 1911, and in July, 1912, was appointed mechanical engineer of the Acme Supply Company of Chicago. Mr. Nystrom re-entered railway service in September, 1913, when he was appointed chief draftsman in the car department of the Grand Trunk at Montreal, Que. He was appointed chief draftsman on the Canadian Pacific in November, 1918, returning to the Grand Trunk in January, 1920, to become engineer of car construction. Mr. Nystrom entered the service of the Chicago, Milwaukee & St. Paul in January, 1922, as engineer of car design.

K. F. Nystrom

F. H. ADAMS, assistant valuation engineer of the Atchison, Topeka & Santa Fe, has been promoted to mechanical valuation engineer, with headquarters at Topeka, Kan., a newly created position.

N. J. BOUGHTON, engineer of tests of the Missouri-Kansas-Texas, with headquarters at Parsons, Kan., has been promoted to mechanical engineer, with the same headquarters, succeeding B. B. Milner, resigned.

P. W. KIEFER, engineer of motive power of the Lines East and West of Buffalo of the New York Central, with headquarters at New York, has been promoted to engineer of rolling stock, with the same headquarters, succeeding F. S. Gallagher, deceased.

T. M. KIRKBY, mechanical assistant to the general superintendent of motive power of the Chicago, Milwaukee & St. Paul, with headquarters at Chicago, has been promoted to special representative with the same headquarters. Mr. Kirkby was born in Norway on July 4, 1883, and graduated from the University of Christiania. He has been employed in various capacities on the Chicago, Milwaukee & St. Paul since 1905, with the exception of the period from 1911 to 1916, when he worked in the mechanical department of the Duluth & Iron Range at Two Harbors, Minn., as draftsman. He returned to the Chicago, Milwaukee & St. Paul in July, 1916, as draftsman in the mechanical engineer's office, with headquarters at Milwaukee, Wis., being subsequently promoted to chief draftsman in 1918, shop schedule engineer of the Milwaukee shops in 1920, and mechanical assistant to the general superintendent of motive power, with headquarters at Chicago, on January 1, 1922. He held the latter position until his recent promotion as special representative to the general superintendent of motive power.

Master Mechanics and Road Foremen

GEORGE E. DOUGHERTY has been appointed master mechanic of the Buffalo division of the Delaware, Lackawanna & Western, with headquarters at East Buffalo, N. Y.

J. J. KELLER has been appointed assistant master mechanic of the Salt Lake division of the Southern Pacific, with headquarters at Sparks, Nev., succeeding J. E. Stone.

J. E. MORRIS, general foreman of the Florida East Coast, has been appointed master mechanic, with headquarters at New Smyrna, Fla. This is a newly created position.

W. W. JONES, JR., general foreman of the Florida East Coast, has been promoted to master mechanic, with headquarters at Buena Vista, Fla. This is a newly created position.

J. E. STONE, assistant master mechanic of the Salt Lake division of the Southern Pacific, with headquarters at Sparks, Nev., has been promoted to master mechanic of the Salt Lake division, with headquarters at Ogden, Utah, suceeding D. Hickey, who has retired.

W. C. MILAR, night foreman of the Eola roundhouse of the Chicago, Burlington & Quincy, has been appointed road foreman of engines, with headquarters at Aurora, Ill., succeeding J. S. Ford, whose appointment as assistant master mechanic of the Galesburg division was noted in the January issue of the *Railway Mechanical Engineer*.

Car Department

F. SUDDETH has been promoted to night foreman of the Atchison, Topeka & Santa Fe, succeeding M. L. Hartigan.

WILLIAM GOVERT has been appointed master car builder of the Gary division of the Elgin, Joliet & Western, with headquarters at Kirk yard, Gary, Ind.

A. L. MERRILL, car foreman of the Atchison, Topeka & Santa Fe, at Argentine, Kan., has been promoted to a similar position, with headquarters at Emporia, Kan.

R. B. CRAIG has been appointed general car foreman of the Atchison, Topeka & Santa Fe, with headquarters at Chanute, Kan., succeeding L. H. Klein, who has retired.

M. L. HARTIGAN, night foreman of the Atchison, Topeka & Santa Fe, has been promoted to car foreman, with headquarters at Argentine, Kan., succeeding A. L. Merrill.

Shop and Enginehouse

P. P. CURTO, day roundhouse foreman of the Atchison, Topeka & Santa Fe, with headquarters at Gallup, N. M., has been promoted to division foreman.

E. J. CYR, day foreman of the Eola roundhouse of the Chicago, Burlington & Quincy, has been appointed general foreman, with headquarters at Centralia, Ill.

RALPH WILSON has been transferred from Richmond, Cal., to Gallup, N. M., as day roundhouse foreman of the Atchison, Topeka & Santa Fe, succeeding P. P. Curto.

P. P. HETTINGER, roundhouse foreman of the Chicago, Burlington & Quincy, with headquarters at Aurora, Ill., has been promoted to foreman of the Eola roundhouse, succeeding E. J. Cyr.

G. V. HEMMER, assistant supervisor of production of the Chicago, Burlington & Quincy, at Chicago, has been promoted to roundhouse foreman, with headquarters at Aurora, Ill., succeeding P. P. Hettinger

Entered at the Post Office at New York, N. Y., as mail matter of the second class.

Request for change of address should reach the New York office two weeks before the date of the issue with which it is to go into effect. It is difficult and often impossible to supply back numbers to replace those undelivered through failure to send advance notice. In sending us change of address, be sure to send us your old address as well as the new one.

Subscriptions, including the eight daily editions of the Railway Age published in June, in connection with the annual convention of the American Railway Association, Mechanical Division, payable in advance and postage free: United States, Canada and Mexico, $3.00 a year; foreign countries, not including daily editions of the Railway Age, $4.00. Foreign subscription may be paid through our London office, 34 Victoria Street, S. W. 1, in £ s. d. Single copy 35 cents.

The *Railway Mechanical Engineer* is a member of the Associated Business Papers (A. B. P.) and the Audit Bureau of Circulation (A. B. C.).

Railway Mechanical Engineer

Vol. 99 March, 1925 No. 3

Increased efficiency of shop operation

An article on another page of this issue describes the operation of the Finley locomotive shops of the Southern Railway at North Birmingham, Ala. It is an excellent illustration of what may be accomplished by proper inspection and control of labor and material expenditures. These shops have been in operation for approximately five months. During that time, a reduction of from 45 to 50 per cent in labor and material expenditures has been accomplished for Class 3 repairs as compared to the cost of performing the same kind of repairs in the old shops which the new plant has superseded. A large proportion of this reduction is due, of course, to the installation of modern machine tools and shop facilities. However, this reduction would be considerably less if it were not for the functioning of an efficient system of inspection and control of labor and material expenditures. The quality of workmanship and rapidity of production is checked by frequent inspections throughout the day, and by weekly meetings of the supervisory forces. Labor and material expenditures are checked by a daily report which is laid on the master mechanic's desk each morning. This work requires a minimum of clerical assistance; in other words, the overhead cost has not been increased in order to reduce the cost of shop operation.

There are, undoubtedly, numerous shops in which similar systems are in operation and excellent results being accomplished. It is not, however, a universal practice and mechanical department officers in charge of shops performing classified repairs will find many constructive suggestions in the system in operation at the Finley shops.

It's the little things that count

Marked improvements in locomotive performance are, in the majority of instances, brought about by persistent attention to what are often looked upon as relatively unimportant details of operation. The reduction in the number of pounds of fuel used per thousand gross ton miles for freight service and per passenger car mile in passenger service is a factor to which attention is being directed by the majority of mechanical and operating officers. In many instances elaborate road tests are often undertaken at great expense in an effort to discover methods whereby fuel saving may result. The real opportunity to accomplish this is quite often obscured by an effort to determine a single factor by changing which, the result can be obtained. On the other hand, attention concentrated upon a number of small elements in every day operating practices may produce a cumulative saving which will be greater than could be accomplished by a single radical change. Elsewhere in this issue will be found an article dealing with the methods which have been followed for the past several months on the Chicago Great Western which during the third quarter of the past year resulted in an actual saving in fuel consumption of 13.5 per cent per 1,000 gross ton miles in freight service and 9.9 per cent per passenger car mile in passenger service. The methods used were successful in reducing the number of pounds of coal consumed per 1,000 gross ton miles in freight service during the above mentioned period from 172 in 1923 to 149 in 1924, which performance compares very favorably with the fuel records made by other roads handling a similar class of traffic. There was an actual saving of $62,609.43 during this period, all of which was attributed to the nine methods outlined in the article. These methods are worthy of thoughtful consideration and it will be interesting to watch the results obtained by their continued use when future figures for fuel performance on the Chicago Great Western are available.

Take the circular letter seriously

It is the general practice on most railroads to issue from time to time circular letters which contain instructions pertaining to some phase of railway operation. Although these letters are issued in all departments of the railroads, we are chiefly concerned with those put out by the mechanical department. There is an old adage to the effect that for everything done, there is a reason, and the circular letter is no exception. The background for many of these letters is the consistent failure of certain parts of a locomotive or car. These failures are thoroughly investigated to ascertain the cause and the remedy, and the results are set forth in a circular letter for the purpose of instructing the mechanical department as to what procedure to take to overcome these defects. Again it is often found that the workmen are incorrectly making repairs which ultimately lead to failures. In order to standardize the methods of making repairs, a circular letter is issued which sets forth the correct practice to be used. Changes in safety appliance rules often result in the issuance of this form of instructions, which are of vital importance as they act as a safeguard to those using safety appliances such as grab iron, steps, etc.

It should be realized by those for whom the letters are intended that they are compiled at a considerable expense. Considerable time is expended in making investigations and tests in order to ascertain just what instructions these letters should contain.

But, after they are issued, do they serve their purpose? We will assume that the master mechanic and his foremen understand and fully appreciate the purpose of the letters, but do the workmen for whom they are primarily intended? They are generally placed on the bulletin board with the understanding that the men will read them. No

doubt the men do take the time to read them, but do they understand them and do the supervisors know that they understand them?

The mechanical officer in charge of the shops must first make sure that the supervisors under him thoroughly understand the meaning of the letters. They in turn, must determine by personal interview whether the workmen can interpret the instructions given in the letters. Thus, if these letters are understood by all those concerned, car and locomotive failures should decrease, with a corresponding reduction in maintenance costs. Otherwise, they might as well not be issued.

Proper maintenance of machine tools

Why is it that the general practice in railway shops is to run machine tools until they completely break down? Why is it that in the final analysis the mechanical officers find that the cost of machine tool maintenance is considerably more than it ought to be? One reason, and perhaps the most important, is that with attention concentrated on keeping cars and locomotives in repair they overlook the needs of their shop tools until the matter is forcibly brought to their attention by a failure which takes a machine completely out of service.

A supervisor of shop equipment should be made responsible for the proper maintenance of all machine tools. He should have a record of the history of every machine tool under his charge. This record should be kept from the date of purchase of each machine and should include information pertaining to the parts liable to failure along with the date and the character and cost of every repair made.

This officer should provide an organization to take care of every shop containing machine tools. In the larger shops, repair gangs should be organized, the duties of which are to look after the machines in the shops for which they are held responsible. For the small shops one man may be designated to look after the machine tools. He may be included in the millwright gang, but should report to the supervisor of shop equipment. This officer should solicit the co-operation of the foremen in charge of the shops, for it is to their advantage to eliminate machine failures. Again, the foremen should solicit the co-operation of each machine operator for it is to his advantage that his machine be kept in constant operation, particularly if he is working under a piecework or bonus system.

Now, the purpose of this organization is to keep a constant vigilance over the machines to prevent breakdowns and to anticipate failures of the parts most likely to give way. Regular periods of inspection could be advantageously established, at which time the repair men should carefully go over each machine in order to ascertain if there are any parts needing renewal to insure against failure. As time goes on, the officer in charge of this work will have a comprehensive record of the performance of each machine. If a certain part of a particular type of machine is the one that always fails, he should decide whether it is advisable to carry this repair part in stock or whether it would be cheaper to make it in the shops. The best of judgment and common sense will have to be exercised in deciding as to what repair parts should be kept on hand as a considerable sum of money could be quickly tied up in these parts.

It has generally become an established fact that the lack of the proper maintenance of locomotives and cars results in heavy repair costs. Is this just as true with respect to machine tools? Just as the human body needs to be examined carefully and prescribed for by a doctor before rather than after it breaks down, so does the machine tool require timely inspection and proper repairs.

An opportunity —and a challenge!

The following table, taken from an editorial which appeared in a recent number of the Railway Age, is deserving of the most careful thought and study by those who are interested in the continued development and prosperity of the railroads and the communities served by them.

Year	Average number of employees	Wages: Average	Wages: Per cent (*)	Cost of living (In December of each year) (*)	Net ton miles per employee (revenue and non-revenue)	Passenger miles per employee
1913	1,759,000	$761	100	100	186,503	19,258
1916	1,647,097	892	117	118	234,574	20,998
1917	1,732,876	1,004	132	142	248,309	22,779
1918	1,841,575	1,419	186	174	238,872	23,168
1919	1,913,422	1,486	195	199	206,837	24,233
1920	2,022,832	1,820	239	200	211,210	23,158
1921	1,659,513	1,666	219	174	205,340	22,477
1922	1,626,834	1,623	213	169	228,608	21,801
1923	1,855,260	1,619	213	173	245,950	20,462
†1924	1,780,772	1,610	212	170	240,260	20,507

†Estimate based on first eleven months of 1924.
*1913 = 100.

The railways have almost the same number of employees today as they had in the year 1913. These employees are relatively much better paid now than they were 12 years ago, as is indicated by the fact that while their wages have increased 112 per cent, the cost of living has increased only about 70 per cent. The individual employees are apparently giving a better account of themselves, as measured by the increase in the net ton-miles of freight per employee, or the passenger miles per employee, particularly if we take into account the shorter working day. There is, however, some question as to just what part of this increase is due to a greater degree of co-operation on the part of the employees, or to the exercise of a greater degree of individual effort on their part. There has been an increase in property investment of between five and six million dollars in this time, a considerable part of which has undoubtedly been used for facilities and equipment primarily designed to promote more efficient operation. There is little question, also, but what improved methods and practices have been responsible for a much better utilization of equipment and rolling stock.

Railroad managements have no control over the rates which they charge for passenger or freight service, or as to the wages which they pay the employees. They have been handicapped in many of the states and communities by restrictive regulations and legislation of a questionable nature. Taxation has increased at a rapid rate—for the past four years taxes have exceeded the amount of money paid out in dividends. Although the Interstate Commerce Commission was instructed by the Transportation Act to see that the railroads were allowed to earn a reasonable return, they have not, since the Act became effective, been allowed to earn anywhere near as much as the rather low percentage which was established by Congress as reasonable.

The railroad managements are anxious to make additional improvements in the plant and facilities, but their credit has been so impaired that it has been difficult to secure money for these improvements. Most roads have already issued too large a proportion of bonds as compared to the amount of stock outstanding. Something must be done to further improve their credit in order that they may be able to sell stock at par and secure funds with which to carry on improvements which will make for increased efficiency and improved service.

There is probably not a mechanical department officer on any of our railroads but could show where the expenditure of money for much needed improvements would

pay splendid returns. The question is where to get the money with which to make these improvements.

What can the management do to secure a greater utilization of equipment and enlist the interest of all of the employees in cutting out inefficiency and waste and making the best possible use of their energies? Have we given all the attention that we should to getting the best service from all of the workers in the organization—officers and foremen as well as the men in the ranks? Do all of the employees understand the relation of the railroad to the continued prosperity and development of the country? Do they take a real pride in the railway for which they work? Are they doing all they can to boost it and to help in a constructive way to improve its service and to operate it more efficiently and economically?

The art of management is a most complicated problem. Research and study have done much in recent years to reduce it to a science. This does not mean that it must be applied in a mechanical fashion according to certain rule or formulæ. It does mean that the officer with some natural executive ability can greatly increase his effectiveness by getting a better understanding of how best to deal with his fellows and lead them. No more striking development has taken place on the railroads in recent years than the growing understanding of the importance of giving more attention to the human element, and the fact that the interests of the employees, the managements, the public and the investors are mutual.

Never were the conditions so favorable for developing a greater degree of co-operation on the part of all concerned. The responsibility is clearly up to the officers and foremen to make the best of this opportunity and to use all their tact and diplomacy, and the growing fund of valuable information that is at their disposal for developing and improving their leadership ability. With the rates at which the railroads must sell their products and the wages they pay fixed by government agencies, and with the other restrictions that are placed upon them, this would seem to be the only avenue which will lead them out of the difficulties with which they have been so sorely beset for many years.

Steam for blower lines

One considerable fuel waste which can be eliminated or at least reduced at most engine terminals is in connection with the steam blower lines. The amount of steam utilized in these lines and consequently coal burned to generate it in the course of 24 hours, is totally unappreciated except by those who have made a study or test of the actual consumption. As a result, the importance of keeping blower lines tight, insulating them and using blower tips of the correct design and correctly placed to produce the greatest draft in the locomotive front end is often overlooked. Tests made some months ago at the Western Avenue, Chicago, enginehouse of the Chicago, Milwaukee & St. Paul indicate the rate of discharge of steam into the atmosphere at varying steam pressures from blower pipes of different sizes. For example, at 125 lb. pressure, steam will be discharged through a 3/4-in. pipe at the rate of about 107 boiler hp.; through a 1-in. pipe, 188 boiler hp.; through a 1 1/4-in. pipe, 294 boiler hp. The velocity and hence effectiveness of the escaping steam as a draft inducer increases rapidly with the gage pressure up to 75 lb. or possibly 100 lb. when the increase is more gradual and uniform. Most engine terminal blower lines consist of 1/4-in. pipe which, with unrestricted volume back of it at 150 lb. gage pressure, will discharge steam at the rate of 345 boiler hp. On account of the smaller pipe commonly used in the drop lines, much less steam than this is actually used. However, the test showed that with a boiler gage pressure of between 125 and 150 lb. the average steam consumption of the blowers is not less than 50 boiler hp. Figuring 6 lb. of coal for a boiler hp. hour and with the blower on for 45 min., this represents about 225 lb. of coal. The entire practice regarding the methods and equipment for blowing up locomotives can well be reviewed at many engine terminals to make sure that avoidable fuel wastes are not being incurred daily.

New Books

Diesel-Electric Locomotives for Standard Gage Railway Service. *By Dr. Eng. Herbert Brown, Baden, Switzerland,* 68 *pages. Published by Ernst Waldman Press, Zurich, Switzerland.*

This short treatise, in German, considers the possibility of utilizing the Diesel motor for locomotives. In the first general part the currently proposed methods of power transmission—direct drive, change gears, electric and the combined Diesel-steam locomotive—are mentioned and the outlook for the possible application of each discussed. In the second part follows a more detailed study of the Diesel locomotive with electric transmission, which the author considers to be the most promising solution at the present time. The pecularities of the Diesel motor are discussed from the point of view of the demands which are made in locomotive service. Special stress is laid on the problem of cooling, which is discussed on the basis of the known laws of conductivity in so thorough a manner that the author's conclusions are applicable to the cooling problem generally, as well as to its special application on the Diesel engine. The author is a member of the firm of Brown Boveri, Baden, Switzerland.

Railway Pipe Fitters Handbook, *By Frank J. Borer, acting general foreman, freight car department, Central Railway of New Jersey,* 223 *pages, illustrated.* 4 1/2 *in. by* 7 1/2 *in. Price* $2.50. *Published by the Simmons-Boardman Publishing Company, 30 Church street, New York.*

This volume contains 19 well illustrated chapters which cover the subject of pipe fitting from every angle of interest for a practical man. The first nine chapters cover fundamental knowledge which every pipe fitter should know. They contain information pertaining to iron and steel pipe, pipe threading, various kinds of pipe fittings and holding tools, measuring pipe and fittings and the hot and cold bending of pipe.

The tools and methods used when stripping pipes from locomotives and cars are covered in chapters X and XI. The drilling and tapping of pipe is discussed at length in chapter XII which is well illustrated for the purpose of clarity. The important subject of shop inspection is next considered by the author. In connection with this subject the importance of air leaks and what they cost in actual money is clearly set forth.

The author leaves the car and locomotive for a time and goes into the subject of estimating radiation for steam and hot water systems. This is followed by a discussion of the various forms of radiating surfaces and how they should be covered, when necessary to prevent radiation. Chapter XXII covers in detail the various types of power cutting and threading machines. The care and repair of dies is also given consideration. The last chapter covers in a thorough and practical manner the specifications for the installation of all types of air brakes including the U. C. equipment. This chapter, if carefully studied, will provide the pipe fitter with sufficient knowledge of the subject to enable him to handle any kind of air brake repairs with dispatch. The book is concluded with an appendix covering instructions on pressure gages.

What Our Readers Think

Derailments of locomotives on curves

A number of letters have been received since the publication of an article, discussing derailments of locomotives on curves, in the December, 1924, and January, 1925, issues of the *Railway Mechanical Engineer,* in which questions have been asked relative to this subject. These questions have been referred to the authors and the questions and answers will be published in this and subsequent issues.—EDITOR.

A question

CLEVELAND, Ohio.

TO THE EDITOR:

The article on Derailments of Locomotives on Curves, part I of which was published in the December, 1924, issue of the *Railway Mechanical Engineer,* states that the greatest number of derailments of Santa Fe type locomotives is due to the number one drivers leaving the rail. Fig. 7, page 724, shows the reactions in the rockers of the engine truck, which I believe is a product of the Commonwealth Steel Company. Assuming that the Santa Fe type referred to in the article is equipped with this type of engine truck, do many derailments occur when the locomotive is running at low speed around curves or through frogs, neither the locomotive or track showing evidence of mechanical defects?

In the case of a Mikado type locomotive equipped with an engine truck of the constant resistance type, would you not be inclined to think that the horizontal thrust would be increased? What conclusion could be arrived at if a similar resistance device were used on the engine truck of a Pacific type locomotive? Occasional derailments of the engine truck have recently occurred on this road with Mikado type locomotives but none have occurred with the Pacific type.

At a recent derailment of Mikado type locomotive in which the engine truck had left the track, an officer of the maintenance of way department stated that he could easily lift one of the engine truck wheels by means of a bar. In this case is it possible that the load on the engine truck is not sufficient to withstand the vertical reaction of the horizontal thrust? Should the load on the engine truck be increased by moving the equalizer pin? A READER.

The answer

GREENVILLE, Pa.

TO THE EDITOR:

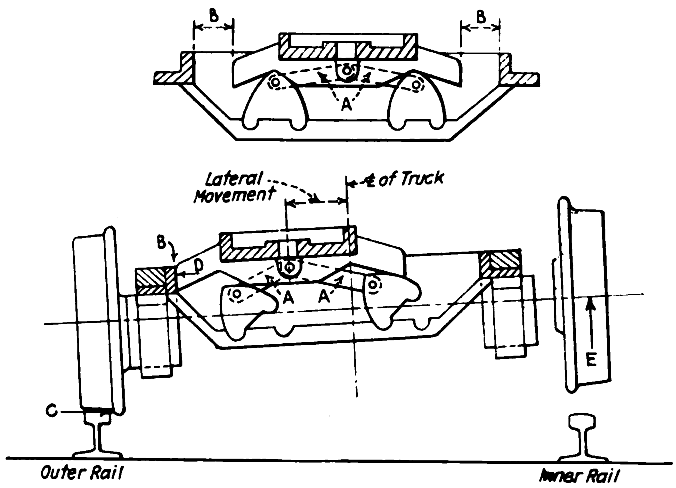
In the article referred to in the letter from "a reader," the authors chose to confine the discussion to the derailments of driving wheels. However, the statement was made that the same method could be employed for the investigation of the factor of wheel bearing on engine trucks as well. In order to do this, it is necessary to assign a calculated value to the horizontal component of the vertical load on the driving wheel and then solve for the vertical reaction on the engine truck wheel. From personal observation, it has been found that engine truck wheels seldom derail because the factor of wheel bearing is too low, but derailments occur more often on account of some rigid or defective condition in the truck.

The Santa Fe type locomotives referred to in the article, are equipped with Franklin Railway Supply Company's constant resistance engine trucks, sometimes known as the Economy truck which were formerly built by the Economy Devices Corporation. There is nothing inherently wrong with this type of truck, in fact it is a very good one, and gives satisfactory performance. Some derailments have occurred with these trucks, but in all cases, the causes have been discovered and corrected.

Referring to the upper figure of the sketch, one of the derailments was found to be due to the absence of the link *A*. This allowed one of the rockers to get out of place, causing a rigid condition of the engine truck which led to a derailment. It is important that these links, pins and cotters be carefully inspected and properly maintained.

Another condition sometimes found is that the clearance *B* is all taken up, which results in a rigid condition, making it practically impossible for the locomotive to round a sharp curve.

The most frequent cause of trouble has been found to be on account of the engine truck being out of square; that is, when one wheel leads the other. This is sometimes due to the radius bar being improperly made, or bent. For example, a case was found where a radius bar had been broken on one side and welded. The welded side was ¼-in. longer than the other, but this was not



Sketch showing the forces set up in an engine truck when all the lateral is taken up

discovered until a derailment had taken place. Sometimes the pedestals become bent, probably due to a previous derailment. In the case of a locomotive which was being derailed frequently, a ⅜-in. shim was inserted between the left back pedestal and the pedestal wearing plate which accomplished the desired result.

It is essential that the engine truck be carefully trammed and squared so that the wheels will line up properly. The distance from the front driver to the engine truck wheel should be the same on both sides and the center line of the engine truck axle should be at right angles with the longitudinal center line of the trucks through the radius bar pin. A condition such as this usually shows itself first in excessive wear of the flange on one wheel, but the condition which allows the flange to wear, also causes the wheel to crowd the rail on that side with the result that it is liable to derail on a switch or frog point or on a curve-worn rail. This condition is aggravated the sharper the flange becomes.

What has just been stated is not peculiar only to the Franklin Railway Supply Company's truck, but also applies to any two-wheel engine truck. This is a disadvantage of the two-wheel truck as compared with the four-wheel engine truck. Perhaps this condition may have something to do with the Mikado type locomotives be-

coming derailed on curves where the Pacific type gives no trouble.

Relative to the question on the horizontal thrust of the engine truck. The function of this thrust is to assist in the rotating of the driving wheel base. There must necessarily be enough weight on the outer truck wheel to overcome the vertical component of the horizontal thrust. One of the features of the engine truck is that the greater the curvature, the greater will be the weight on the outer wheel of the truck. There are some locomotives equipped with interchangeable front and trailing trucks. From conclusions resulting from this investigation, it is believed that this is a mistake, for if the trucks have the same side thrust and are approximately the same distances from the center of the locomotive wheel base, then the thrust of one will offset the thrust of the other. All the trucks will do is to carry weight and not assist in guiding the locomotive. The side thrust of the engine truck should be greater than that of the trailing truck in order to favor the locomotive while running forward.

The statement made by the officer of the maintenance of way department is undoubtedly true. Instances have been seen where the inside wheel of a two-wheel engine truck has risen off the rail as high as two inches, traveling through the air for some distance and then dropping back on the rail again. Being the inside wheel, no harm was done. This is caused by all of the clearance at *B*, in the lower figure of the sketch, being taken up, so that the thrust of the locomotive at *D* and the thrust of the rail at *C*, produces a couple which causes the reaction *E*, which, if the curvature is sufficiently great, will overcome the weight on the truck and lift the inside wheel from the rail or relieve it of enough weight so that it may be lifted by a bar. If the wheel does not rise, and the curvature is sharp enough, the flange of the outer wheel will break, the rail will turn over or the track will move in the ballast.

It may seem strange, nevertheless it is true, that there are some conditions at the rear of a locomotive that have a bearing on engine truck performance. It is sometimes a good thing to see if there is any fouling of the stoker trough, binding of buffer between locomotive and tender, tight safety chains, a fouled trailing truck, etc.

The track also has considerable bearing on the situation. The gage should be standard up to 8 deg. of curvature and then increased 1/8 in. for each 2 deg. up to a maximum of 4 ft. 9 1/4 in. The gage through frogs should be, regardless of curvature and the guard rail distance, maintained at 1 3/4 in. These figures are important and failure to maintain them properly is frequently the cause of a derailment.

ROY C. BEAVER,
Assistant mechanical engineer, Bessemer & Lake Erie.

Systematic terminal inspection of locomotives

PRESCOTT, Ariz.

TO THE EDITOR:

Good terminal inspection of locomotives has long been recognized as having an important bearing on locomotive performance as well as in reducing engine failures. I have known of instances where inspectors were allowed to us their own judgment as to the method of inspection. As a result, each man had a system of his own, or possibly, had no system at all, other than to commence at the front of the engine and inspect the several parts in the order in which they come and then go underneath the locomotive and follow the same procedure. With such a procedure the inspectors usually make note of defects as they are found, or depend upon memory until the whole locomotive is inspected before noting defects on paper.

Considering the size and tonnage rating of the modern locomotive something more than a general or promiscuous inspection of parts is needed. There is no doubt that a simplified system of inspection which will aid the inspector to concentrate on each part inspected will give better results. This can be accomplished by grouping the parts and concentrating inspection on each group separately; "O. K.ing" or making note of the defects found at the conclusion of the inspection of each group.

Noting on paper the results of the inspection of each part on a locomotive would necessitate a long itemized list. Checking each part as "O. K." or "Defective" is impracticable as well as cumbersome. However, inspection by groups has been found to be practicable. It requires

Report form for inspectors—The various parts of a locomotive are assigned to groups to facilitate systematic inspection

little time and as the various groups become associated in the mind of the inspector, it insures more thorough inspection. It also gives him a check at the conclusion of an inspection by which he can assure himself that nothing has been overlooked.

Group inspection forms, like the one shown, can be made up into pads or in book form similar to the Car Inspector's Record book, which can be conveniently carried and used as a note book. The information on this form may be transferred to the work report form later.

The grouping of parts shown on the form has been found to be well suited for machinery inspection. The arrangement of groups is such that all the outside inspection can be completed before going underneath the locomotive. These groups can be rearranged or added to as desired. A similar grouping of parts may also be used to good advantage by boiler inspectors.

Assistant master mechanic, A. T. & S. F.

Diesel-electric locomotive for freight service

Excellent results are obtained in a comparative test with a modern steam locomotive

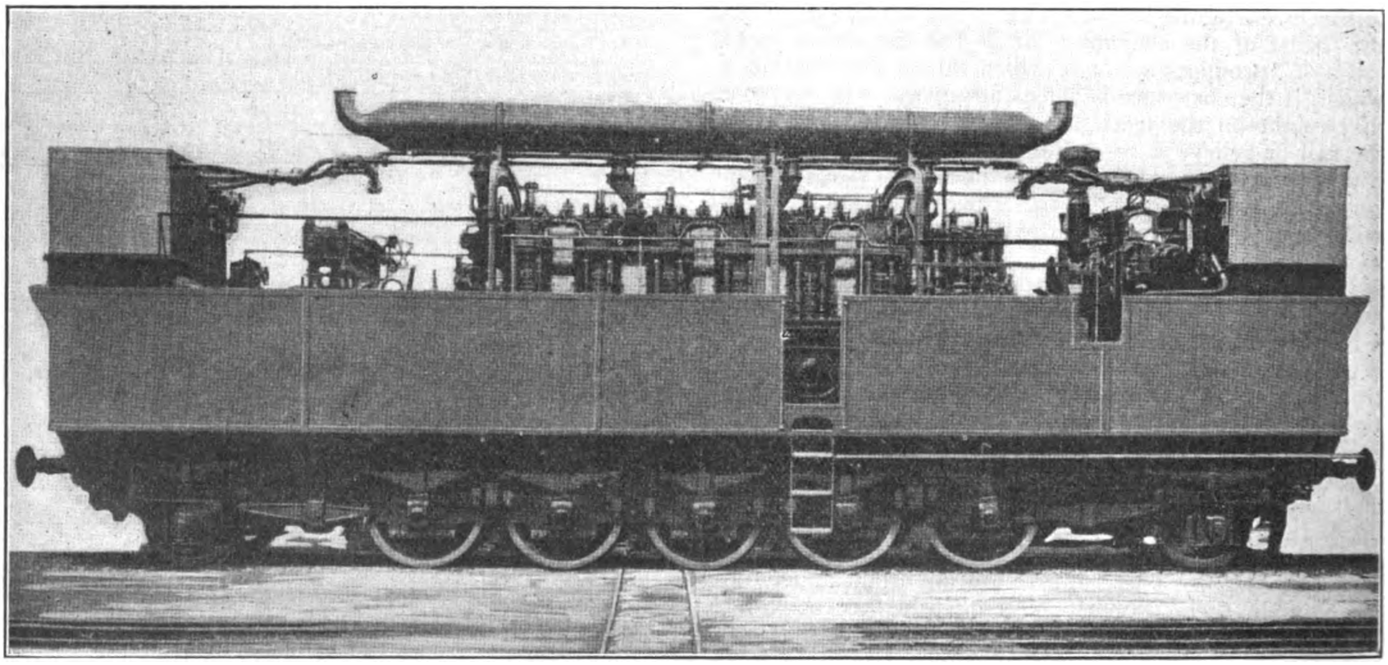
By Dr. J. Stumpf
Privy Counsellor, Berlin, Germany

PROF. GEORGE LOMONOSOFF, technical adviser on railway questions to the Russian government, and his staff have designed a Diesel-electric locomotive for the Russian government. It was built by the Hohenzollern Locomotive Works, Dusseldorf, Germany, at the Esslingen Locomotive Works in collaboration with the Augsburg-Nurulerj Machine Works and the machine works of Brown, Boveri & Company. The locomotive was tested on a device in Esslingen which was also designed by Professor Lomonosoff.

The engine is a six-cylinder, four cycle Diesel type and a result only the most reliable features were selected in the design of the four cycle, single-acting air injection and forced feed oil lubrication. Tests proved the electric transmission device to be most reliable.

The Diesel engine is generally supposed to be in continuous operation. Power is adapted to the requirements of the service by adjusting the voltage of the exciting current of the exciter dynamo. This control has proved to be close and reliable.

The testing plant on which this locomotive was tested is similar in design to that of the Pennsylvania at Altoona,



The engine is located at the center of the car with the air compressors at one end and a dynamo at the other

it is located on the center line of the car with the air compressors for oil injection on one end and a continuous current dynamo on the other. The current from the dynamo operates five motors connected by 1 to 6.14 gearing to each of the driving axles. The hot jacket water of the Diesel engine is cooled in a cooler which is located at one end of the locomotive. The water flows through a piping system cooled by a draft of air forced around the pipes by a fan. This cooler has sufficient cooling capacity to answer all requirements for ordinary air temperatures. However, when operating in hot climates, a second cooler, operated by an independent Diesel engine, may be located on a tender attached to the locomotive.

The cooling device was the most difficult problem in the design of the locomotive. In actual service the Diesel engine proved to be the most critical part, and as Pa. The drivers are run on wheels located in the casement and placed on shafts equipped with water cooled brakes at one end. A continuous adjustment of these interconnected brakes is necessary as the clutches of the brakes showed considerable wear and tear. Sand was always blown between the wheels to prevent slipping. The pull at the drawbar was taken up and measured by a dynamometer device. This, in connection with the circumferential speed of the driving wheels, disclosed the power developed by the driving wheels on the rails.

The resistance and speed were adjusted by the brakes to suit the conditions on the railway from Petrograd to the Caucasus, where the locomotive will later be in service. The first slope on this line is an ascending grade of 2.3 per cent which the locomotive is scheduled to cover in 55 min. The next slope is a descending grade of 0.5 per cent to be covered in 60 min. and the third slope is

an ascending grade of 6.3 per cent to be covered in 94 min. The speed in the three cases is to be 15.69 miles, 18.64 miles and 8.7 miles an hour with a pull at the drawbar of 19,845 lb., 9,922.5 lb. and 33,500 lb. respectively. At the end of the test an exaggerated load was put on the locomotive which brought the pull at the drawbar up to 44,100 lb. and the output of the Diesel engine up to 1,100 hp.

Excellent Results Are Obtained on the Test Plant

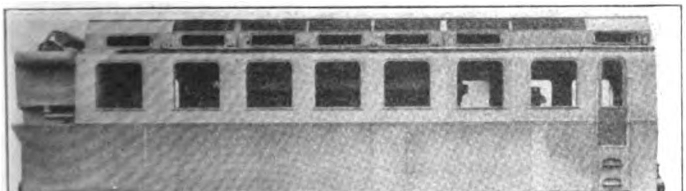
At 8:00 a.m. on November 4, 1924, the Diesel-electric locomotive was put in operation on the test plant. The first test began at 8:30 a.m. and ended at 9:25 a.m. The average drawbar pull was stated to be 20,062 lb., the average output to be 857 hp., the average oil consumption per horsepower hour to be .507 lb. or 42 per cent less than the .88 lb. stipulated in the contract between the Russian government and the Hohenzollern Locomotive Works. The average total efficiency was calculated from the following equation,

$$\frac{\text{circumferential work at the driving wheels}}{\text{heat value of the oil}}$$

which was found to be 27.4 per cent, a result which had never been reached before. The load was varied from 830 hp. to 880 hp. or about 6 per cent. The fan on the cooling tender was not in operation during the tests as the cooling apparatus on the locomotive was sufficient. The cooling water in this apparatus reached a temperature of 117.5 deg. F. with an air temperature of 51.8 deg. F.

The second test started at 9:25 a.m. and was finished at 10:25 a.m., in which time 250.12 lb. of oil were consumed. The average drawbar pull was 9,534.9 lb., the average speed was 18.4 miles an hour, the average capacity was 474 hp. and the average oil consumption per horsepower hour was .522 lb., or 41 per cent less than guaranteed. The average over-all efficiency was calculated from the previous formula to be 26.5 per cent. The load was varied from 440 hp. to 490 hp. or about 9.5 per cent. The fan on the cooling tender was not in operation.

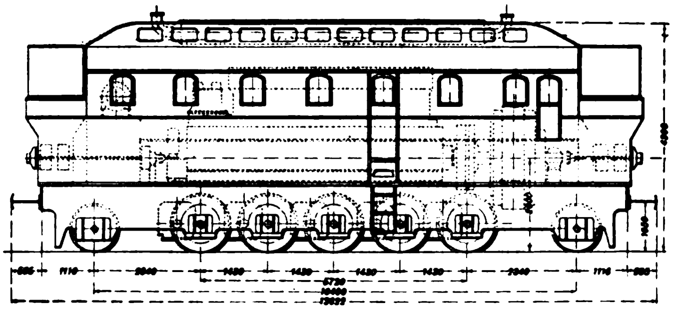
The third test started at 10:35 a.m. The load was



Diesel-Electric locomotive designed by Prof. G. Lomonosoff in collaboration with the Hohenzollern Locomotive Works, Düsseldorf, Germany

increased gradually between 10:25 a.m. and 10:35 a.m. and the test was completed at 12:09 p.m. During that time the main Diesel engine and the auxiliary Diesel engine which operate the fan on the cooling tender, consumed 767.3 lb. of oil. The average drawbar pull was 33,598 lb., the average speed, 9.82 miles an hour, the average output, 890 hp. and the average oil consumption .55 lb. per horsepower-hour, or 37 per cent less than agreed upon in the contract. The total efficiency was calculated to be 25.3 per cent. The load was varied during this test between 860 hp. and 944 hp. or 9.5 per cent. The fan on the cooling tender was in operation for 33 min. The water temperature, at the end of the test, however, was not higher than 150.8 deg. F. with an air temperature of 55.4 deg. F.

The last test was started at 12:09 p.m. and completed at 12:33 p.m. The fans of the cooling tender were in operation during the entire time, decreasing the water temperature from 150.8 deg. F. to 134.6 deg. F. The oil consumption of the main and auxiliary Diesel engine was 234.79 lb. The speed changed from 7.77 miles to 22.49 miles an hour with an output from the locomotive from 645 and 1,066 hp., and the over-all efficiency was calculated to be between 21.1 per cent and 24 per cent. The highest efficiency was stated to be 24 per cent at a



Elevation drawing of the Lomonosoff Diesel-Electric locomotive (Dimensions are in millimeters)

speed of 14.54 miles an hour. The temperature of the electric motors at the end of the test was 149 deg. F. The Diesel engine was stopped at 12:40 p.m. and all parts of the locomotive were found to be in good condition.

Heat values of the fuel oil were determined in the laboratory of the Technical University at Hullgard. A report was made at 3:00 p.m. which stated the upper heat value of the oil to be 42,700 B.t.u. and the lower heat value of the oil, which was Russian naptha, to be 39,820 B.t.u. These calculations were based on a heat value of 39,700 B.t.u.

Observers, consisting of approximately 50 prominent engineers of Russia, Germany and other European countries, who were attending these tests convened at 3:57 p.m. in the conference room of the Maschinenfabrik Esslingen. It was agreed that the Diesel-electric locomotive conformed to all of the stipulations in the contract, that the Diesel-electric locomotive was found to be completely reliable during the operation of 4.5 hrs., and that the low fuel oil consumption exceeded all expectations. The over-all efficiency was found to be between 21 per cent and 27.4 per cent at a load of between 440 hp. and 1,060 hp. during a part of which time the auxiliary Diesel engine on the cooling tender was in operation.

A comparative test with a steam locomotive, having five driving axles, was started at 8:00 a.m. on November 6, 1924. This locomotive was built by R. Wolf, Erfurt, Germany, and the boiler was built by Henschel & Son, Kassel. A membrane of the dynamometer broke at 8:04 a.m. It was the fourth fracture caused by the steam locomotive, whereas no fracture was experienced with the Diesel-electric locomotive. The membrane was replaced and the test was again started at 9:39 a.m. and completed at 10:36 a.m. The average drawbar pull was 19,999 lb., the average speed 15.35 miles an hour and the average output was 835 hp., with the power varying between 810 hp. and 869 hp. or 7 per cent. The boiler was heated with fuel oil, the consumption of which was 1247.8 lb. or 1.62 lb. per horsepower-hour, during the entire test. The total efficiency was calculated to be 8.67 per cent. The gage pressure of the boiler was 180 lb.

Without any interruption, a new test was started at 10:36 a.m. and completed at 11:35 a.m. The average

drawbar pull was 9,479.8 lb., the average speed 18.31 miles an hour and the average output was 468 hp. The output varying between 460 hp. and 505 hp. or 9.3 per cent. The oil consumption during the entire test was 855.5 lb. or 1.84 lb. per horsepower-hour. The over-all efficiency calculated as explained above was found to be 7.6 per cent. The gage pressure of the boiler was 170 lb.

A third test was started at 12:09 p.m. and completed at 12:50 p.m. The average drawbar pull was 31,900 lb., the average speed 10.56 miles an hour and the average output 910 hp., varying between 778 and 925 hp. or 18 per cent. The oil consumption during the entire test was 1,132 lb. or 1.83 lb. per horsepower-hour. The over-all efficiency was calculated to be 7.62 per cent. At the end of the test the gage pressure of the boiler was 180 lb. The test was interrupted on account of the spring of the safety valve on the front cover of one cylinder releasing and allowing a part of the steam to escape. At 12:50 p.m. the speed was brought up to 31.07 miles an hour. At 12:54 p.m. the locomotive was stopped and all parts, with the exception of the above mentioned spring, were found to be in order.

The observers convened at 3:25 p.m. and decided that this locomotive operating with the superheater could be considered as economical, as the total efficiency averaged between 7.6 per cent and 8.67 per cent. This locomotive did not have a feedwater heater. The fuel consumption of the Diesel-electric locomotive was about one third of the steam locomotive and it showed an unusual ease and flexibility of adjustment and also steady operation which should have a favorable effect on the rails.

The author believes that the Diesel-electric locomotive has been realized by the construction of this locomotive and the results of its tests at Esslingen. The engine may be considered as especially adapted for freight traffic. It also exhibits a favorable efficiency in the electric transmission. Professor Lomonosoff, however, does not consider this locomotive to be final, as he is planning to build another Diesel locomotive with spur gearing, for which the Krupp Company has guaranteed a machine efficiency of 96 per cent. As this efficiency is considerably higher than that of an electric transmission and also more simple and cheaper to construct, a Diesel locomotive equipped with spur gearing may be an improvement. However, the flexibility in adjustment is considerably less and a change in gear ratio is not at all safe while running.

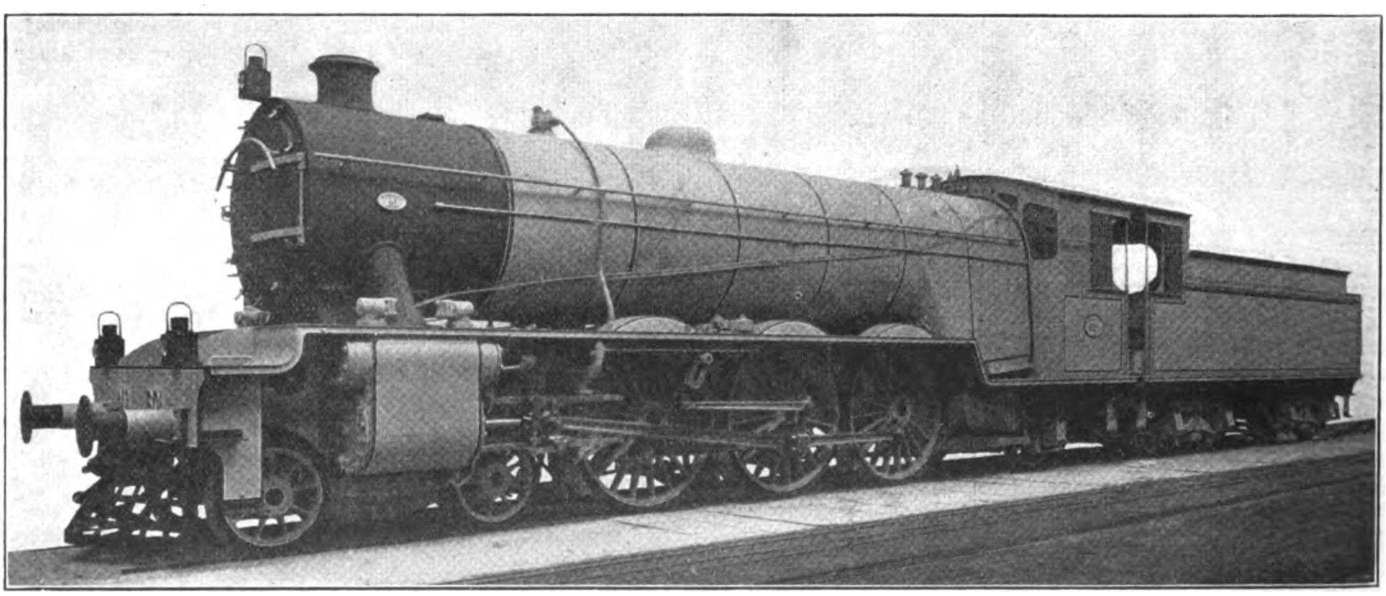
Broad gage locomotives for India

Largest and most powerful two-cylinder types ever built for service in that country

By E. C. Poultney

THE two large locomotives which are shown in the illustrations are examples of new types recently supplied to the Bombay, Baroda and Central India for heavy traffic on the broad gage (5 ft. 6 in.) section of that system.

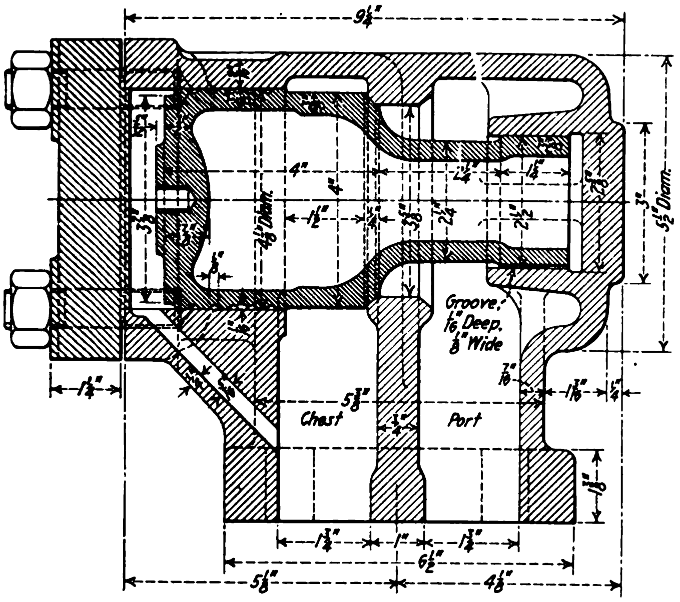
With the exception of some 2-10-0 freight locomotives placed in service on the Great Indian Peninsula about 1921 having four cylinders, each 20 in. by 26 in., a tractive force of 50,000 lb., a total combined heating surface of 3,585 sq. ft., and weighing, without tender, 241,875 lb., these new locomotives are the largest and most powerful so far built for any of the Indian railways. The two locomotive types described here are alike in many important details, the chief differences being that one is of the Pacific type having 74-in. drivers for passenger service, and the other is a Mikado with 56½-in. drivers for heavy freight service. In the design of both the engines and tenders interchangeability has been closely studied. The boilers with their



Pacific type passenger locomotive built for the Bombay, Baroda and Central India

fittings, grate bars and ash pans, are duplicates, as well as the cylinders, valve motion, pistons, piston rods, crossheads, connecting rods, driving boxes, spring rigging, and the trailing trucks. The tenders for both designs are alike in constructional details.

The boilers are of generous proportions, having a total combined heating surface of 2,909 sq. ft., of which 550 sq. ft. is contributed by the 30 element flue tube superheater, which is provided with the Marine and Locomotive Superheater



Detail of Hendrie by pass valve

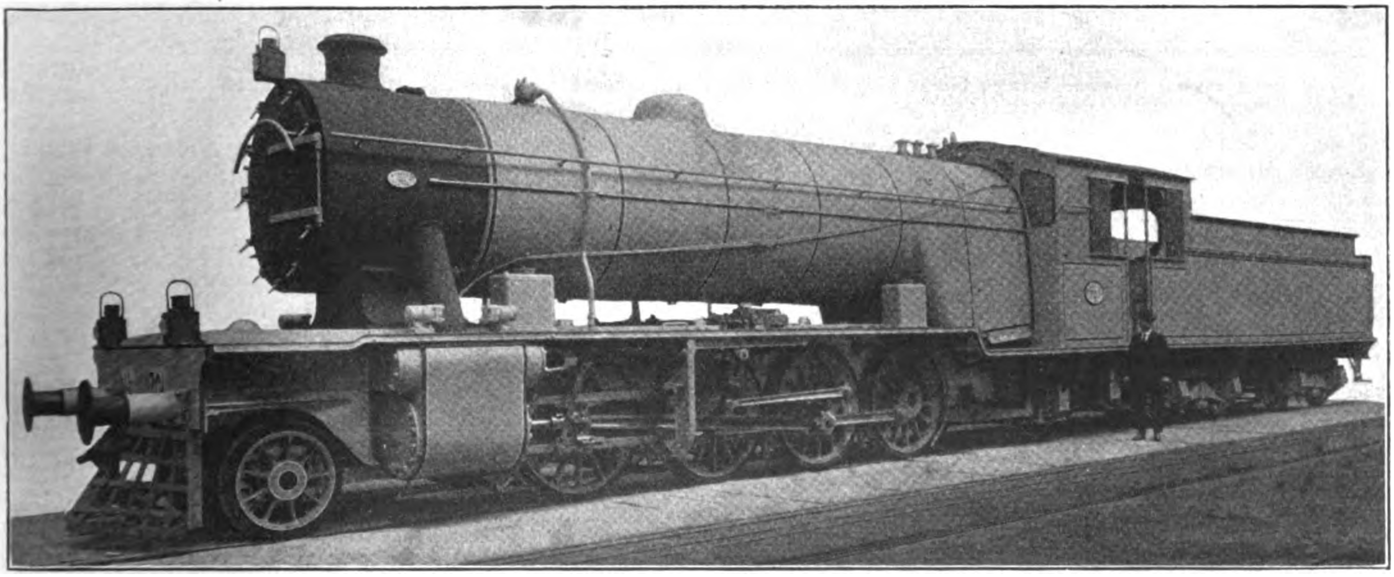
Company's Stirling type header. A large automatic air valve is fitted to the saturated steam side of the header, the function of which is to open when steam is shut off, thus allowing air to be drawn into the elements when drifting. This valve also acts as a vacuum breaker for the cylinders, which are equipped with by-pass valves that will be described later. A wide firebox is provided, giving a grate surface of 48 sq. ft., and the brick arch is supported by arch tubes, four in number. The internal firebox of copper is extended forward into the barrel section, thus forming a combustion chamber. The water space at the foundation ring is three inches at the sides and three inches at the front and back, and the one-inch diameter water space stays are of copper. The crown of the firebox and combustion chamber is supported by direct stays. The stays at the front next the tube sheet are so arranged as to permit of upward expansion. Rocking

Table of dimensions, weights and proportions

Type of Locomotive	4-6-2	2-8-2
Service	Passenger	Freight
Two cylinders, diameter and stroke	23 in. by 28 in.	23 in. by 28 in.
Valve gear, type	Walschaert	Walschaert
Valves, piston type, size	11 in.	11 in.
Weights in working order:		
On drivers	133,000 lb.	161,000 lb.
On front truck	40,000 lb.	17,500 lb.
On trailing truck	38,000 lb.	37,500 lb.
Total engine	211,000 lb.	216,000 lb.
Tender	165,000 lb.	161,000 lb.
Wheel bases:		
Driving	12 ft. 9 in.	15 ft. 9 in.
Total Engine	34 ft. 8 in.	33 ft. 9 in.
Total engine and tender	66 ft. 3½ in.	65 ft. 4½ in.
Wheels, diameter outside tires:		
Driving	74 in.	56½ in.
Front truck	36 in.	36 in.
Trailing truck	43 in.	43 in.
Tender truck	43 in.	43 in.
Journals, diameter and length:		
Driving	8¼ in. by 11½ in.	8¼ in. by 11½ in.
Front truck	6¼ in. by 9 in.	6¼ in. by 9 in.
Trailing truck	6½ in. by 11 in.	6½ in. by 11 in.
Tender truck	6½ in. by 11 in.	6½ in. by 11 in.
Boiler:		
Type	Straight top	Straight top
Steam pressure	160 lb.	180 lb.
Fuel	Bituminous coal	Bituminous coal
Diameter, third course	75 in.	75 in.
Tubes, number and diameter	130-2¼ in.	130-2¼ in.
Flues, number and diameter	30-5¼ in.	30-5¼ in.
Arch tubes, number and diameter	4-3 in.	4-3 in.
Length, between tube sheets	18 ft. 0 in.	18 ft. 0. in.
Grate area	48 sq. ft.	48 sq. ft.
Heating surfaces:		
Firebox, including arch tubes	239 sq. ft.	239 sq. ft.
Tubes	2120 sq. ft.	2120 sq. ft.
Total evaporative	2359 sq. ft.	2359 sq. ft.
Superheating	550 sq. ft.	550 sq. ft.
Combined evaporative and superheating	2909 sq. ft.	2909 sq. ft.
Tender:		
Water capacity, Imperial Gals.	6240	6240
Coal capacity	31,360 lb.	28,000 lb.
General data and ratios:		
Rated tractive force, 85 per cent.	27,200	40,100
Comb. heat. surface ÷ grate area	60.6	60.6
Firebox heat. surface, per cent of comb. heat. surface*	8.22	8.22
Superheat. surface per cent of comb. heat. surface	18.89	18.89
Tractive force x dia. drivers ÷ comb. heat. surface	692	778
Firebox heat. surface ÷ grate area**	4.47	4.47
Factor of Adhesion	4.88	4.01

* Firebox heating surface, including arch tubes.
**Heating surface, less surface of arch tubes.

grate bars are employed with a dumping section at the front end. A top feed arrangement is provided, water being



Large Mikado built for service in India on 5-ft. 6-in. track

supplied by two self-acting, re-starting injectors of reversible pattern. The boilers are protected by three safety valves set to pop at 160 and 180 lb. per sq. in. for the passenger and freight locomotives respectively.

The 23-in. by 28-in. cylinders are in separate castings bolted to the main frames, and between them is fixed a saddle casting on which the smoke box rests. Piston valves operated by Walschaert gear distribute the steam, and reversal is effected by a hand wheel and screw. The piston valves are arranged for inside admission, and outside steam pipes are applied as shown.

Each cylinder is fitted with two by-pass valves of the Hendrie pattern, a detail of which is shown in the drawing. These valves are very simple in construction, and each consists in this instance of a 4⅛-in. diameter valve working in a suitable annular cavity machined in the body casting, and so arranged that its inner end forms a valve seating on a port connecting the valve chest, live steam side, with the steam port. A passage way of 5/16-in. bore connects the outer end of the valve with the steam chest, so that when steam is admitted to the steam chest by the throttle each valve is held closed. When running with the throttle closed any vacuum formed in the steam chest causes the valve to be drawn from its seat, and connection is thus established between the steam chest and the cylinder at each end, irrespective of the position of the main piston valves. In this manner air may be drawn from the steam chests and elements through the air valve placed on the header casting, and as freely expelled. The lubrication of the valves and pistons is effected by a Detroit four-feed sight feed lubricator.

The springs are all of the usual type, placed above the driving boxes. The trailing trucks have boxes of the Cartazzi design working in curved guides. In the case of the Pacifics the trailing truck is equalized with the driving wheels, and on the Mikado the leading truck and first and second drivers form one group, the third and fourth drivers, with the trailing truck, forming another group.

Solid grease lubrication is used for the driving boxes, the system employed being the Franklin, and the lubricant is that supplied by the Galena Signal Oil Company, Ltd.

The automatic vacuum brake acts on the driving and tender wheels only. There are two 24-in. diameter brake cylinders on the engine and two cylinders 21 in. in diameter on the tender. The braking power for the Pacifics is equal to 72.3 per cent of the weight on drivers and for the Mikados is 71.5 per cent. On the tenders the braking power is equal to 97.2 per cent of the light weight.

The principal dimensions and the important proportions are appended in the tabulated statement.

Generally, these new locomotive types follow usual practice on Indian railways, and in appearance are similar to the standard types which have been in service for many years, though they are very much larger and of much greater capacity. It will be evident from a study of the dimensions and proportions that considerable care has been exercised in working out the designs, and it is reasonable to assume that these new locomotives should give an excellent account of themselves in service. The boilers are of considerable size, a most important feature, and their proportions indicate that they should steam freely.

The locomotives were built by Kitson and Company, Airedale Foundry, Leeds. The designs were prepared and the locomotives constructed under the supervision of Rendel, Palmer & Tritton, consulting engineers, Westminster, London.

How the Chicago Great Western controls use of locomotive fuel

RECORDS of coal consumption and engine failures on the Chicago Great Western show that desirable results in these two particulars have been secured within recent months. There was a saving in fuel consumption of 13.5 per cent per thousand gross ton-miles in freight service and 9.9 per cent per passenger car-mile in passenger service during the third quarter of 1924 as compared with the third quarter of 1923. During the same period engine failures were materially reduced. The following are some of the methods used to attain these results: (1) Competition between divisions with cash prizes for the best fuel performance; (2) educational work by means of bulletins, a rotating illuminated sign in the dispatcher's office and study of a book on correct fuel handling methods; (3) careful attention to water conditions and cleanliness of boilers; (4) use of modern locomotive appliances for reducing fuel consumption; (5) holding locomotives under fire as little as possible; (6) careful attention to the grade of coal used; (7) competition between divisions, crews and enginehouse forces regarding engine failure records; (8) critical analysis of all causes of engine failures.

Fuel saving on the Chicago Great Western for the third quarter of 1924 over the third quarter of 1923

	Tons of coal burned on freight locomotives		Tons of coal burned on passenger locomotives		Freight traffic in thousand gross ton-miles		Passenger traffic in passenger car-miles	
	1924	1923	1924	1923	1924	1923	1924	1923
July	31,049	36,213	10,930	12,186	419,245	433,497	1,449,063	1,479,084
August	35,634	36,891	10,862	12,599	494,303	425,681	1,484,444	1,538,858
September	36,539	38,001	11,526	12,266	469,118	427,748	1,482,510	1,406,258
	103,222	111,105	33,318	37,051	1,382,666	1,286,926	4,416,017	4,424,200

	1924	1923	
Lb. coal burned per thousand gross ton miles	149.3086	172.6673	Saving 23.3587 or 13.5 per cent
Lb. coal per passenger car mile	15.089615	16.749242	Saving 1.659627 or 9.9 per cent
Total estimated saving in 1924 freight service	16,148,64 tons		
Total estimated saving in 1924 passenger service	3,664.47 tons		
Grand total saving in 1924	19,813.11 tons at $3.16 a ton = $62,609.43.		

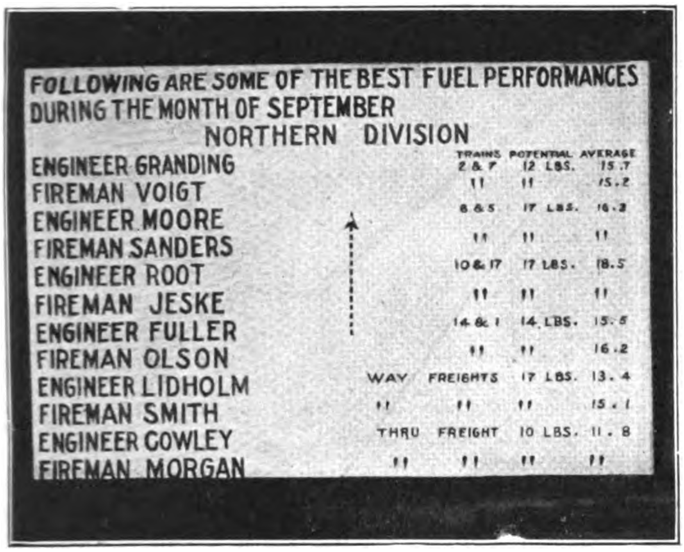
Competition and prizes

A cash prize of $500 is offered every three months for the operating division which makes the best showing in

fuel consumption in freight and passenger service in comparison with the potential consumption for the same period. This potential consumption is computed on a ton-mile basis for freight and on a car-mile basis for passenger service, being 10 per cent less than the actual consumption during the same period in the preceding year. In other words, the potential consumption is a goal or a mark to shoot at. During the third quarter of 1924 a saving of $62,609.43 was made in this service as shown by the attached table.

A cash prize of $200 is offered every three months for the division which makes the best showing in fuel consumption in switching service as compared with a potential consumption per switch engine hour. A saving of about 7 per cent in the amount of fuel burned per switch engine hour was effected in the third quarter of this year.

The results of this competition between divisions and



Rotating sign developed on Chicago Great Western for use in engineman's room; endless linen strip moves slowly in the direction of the arrow

the awarding of prizes have, therefore, been highly satisfactory. The prizes already awarded have been distributed and used largely for benevolent purposes through the brotherhood organizations.

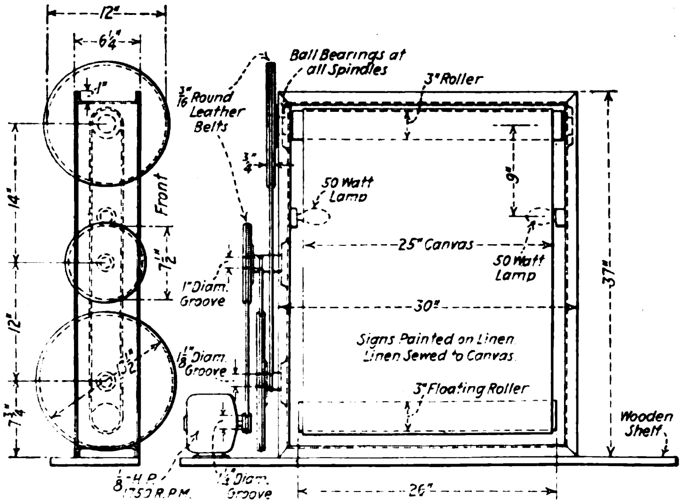
Rotating sign in dispatcher's office

One of the essential requirements in securing effective competition between the divisions is the posting of fuel performance records where they can be seen readily by the crews and others interested. At the enginehouse at Oelwein, Iowa, a rotating sign is used which shows these individual performances and which, on account of its unusual construction, creates a great deal of attention. This rotating sign is located in the enginemen's room on the wall next to the engine dispatcher's window. It consists of a wooden frame, about three feet wide by two feet high, with the performance of the various engine crews painted on an endless canvas-back linen strip which moves continuously from the bottom to the top of the frame. The direction of movement is indicated by the arrow in the illustration. The endless linen strip is driven over suitable rolls by the small electric motor, the rate of revolution being such as to permit easy reading as it moves upward. Two lights back of the wooden frame illuminate the linen strip thoroughly and this with the movement makes it the first thing to catch the eye on entering the room. It attracts attention immediately on opening the door and is frequently surrounded by a considerable group of enginemen and firemen who are anxious to find out what the other fellow is accomplishing. A healthy competition is thus stimulated.

Another factor which should be given partial credit for the fuel performance secured on the Chicago Great Western is the educational work which has been carried on by means of bulletins posted in conspicuous places showing the effects of poor firing and giving specific examples of good practice. Traveling engineers and firemen on each division instruct the crews and offer helpful criticism of their work. A book on the proper use of fuel has also been distributed by the management and this has proved effective in instructing the men in proper methods of firing and the economical use of coal.

Boilers kept clean

Special attention has been given to the treatment of water to eliminate scale so far as possible. Boilers are washed out carefully. On long runs such as the passenger run to Chicago and return, the boilers are washed after every other trip into Oelwein. On the trip that the boiler is not washed the water is changed. Practically all Chicago Great Western freight and passenger locomotives are equipped with superheaters and brick arches. Some of the Mikado and Santa Fe type locomotives have combustion chambers. Thermic syphons are being applied to consolidation locomotives as fast as they come into the shop for new crown sheets. One of the light Mikados has been equipped for purposes of test with a Worthington feed water heater. Good results have been secured with the Superior flue blower applied to a consolidation locomotive running on the Southern division. This effects a large fuel saving, as the locomo-



Details of the driving mechanism and lights for the rotating sign

tive can be run for six or seven trips without knocking the fire. It also makes a great saving in non-effective locomotive hours as the locomotive can be turned in about two hours over the cinder pit.

Every effort is made to have the transportation and the mechanical departments co-operate as closely as possible to avoid holding locomotives under fire in the enginehouse any longer than is necessary. This is checked closely and those responsible for any waste of this kind are severely criticized. All coal received is analyzed and efforts made to secure as uniformly good a grade as possible.

A comparison is made every month of the performance of the various divisions for the previous month as regards

engine failures. This statement shows the individual failures, their causes, the locomotives involved, the places where the failures occurred, amount of delay and the points from which dispatched. It also shows the miles run per engine failure on each division and in total and the per cent of failures to the total number dispatched.

Each failure is entered on a report known as the "Six A. M." report as it occurs. Thorough investigation is made of the persons involved and discipline administered to guilty ones. Broken parts, if any, are sent to the office of the superintendent of motive power and an analysis made to determine the cause of the break. In each case action is taken to attempt to prevent a recurrence of the failure. As a result of these investigations the design of certain locomotive parts may be changed to give more strength or instructions regarding application of the parts revised to correct maintenance methods which are not securing desirable results.

Stationary power plants for railroads

Careful analysis of power requirements facilitates proper selection of mechanical equipment

By Paul R. Duffey

THE modern railroad system has one principal commodity to sell to the public—transportation. To accomplish this economically and profitably is the ultimate aim. The principal agents used to carry on this business when once secured are motive power, rolling stock, tracks, etc., for the maintenance of which adequate facilities must be provided. Such maintenance facilities must depend upon energy in the form of heat and mechanical and electrical power for their successful operation. This naturally brings us to a consideration of the stationary power plant.

It is not the intention of this paper to deal so much with the efficiencies available in the plant, but to bring out the necessity of properly classifying the plants and bringing them up to certain points of standardization as compared to other units in the layout of shops, yards, etc.

From the standpoint of design, installation, operation and maintenance, stationary power plants and their allied facilities, deserve as much thought and consideration as any other important unit.

Classification of power plants

Class 1.—Plants of 1,200 to 2,500 b.hp. and above. On the average system from two to four plants of this size will usually be found located at main shops.

Class 2.—Plants of 800 to 1,200 b.hp. Plants of this capacity will be located at terminals with facilities for receiving and despatching 100 locomotives per 24 hours. Such size terminals usually have facilities for doing considerable car repair work.

Class 3.—Plants of 200 to 800 b.hp. Plants of this capacity are located at the smaller engine terminals, at ore and coal docks, grain elevators, and timber treating plants.

Class 4.—Plants of 100 b.hp. and under. Plants of this size are located at water pumping stations, coach and office heating plants, and for portable service.

We should now group our plants and their allied facilities in such a manner that a close standardization of plants can be established for those covered in Classes 2 and 3. Plants shown in Classes 1 or 4 call for further analysis.

After analyzing present requirements for the four groups of plants, we should add at least 25 per cent reserve to take care of increased requirements for the succeeding ten years after the plant is built.

At this point it is essential that we acquaint ourselves with the requirements of our plant and just what it serves. This leads us to consider the following:

1—THE PRODUCTION OF POWER

Generation of electric power—For turntable motors; coaling station motors; ash pit crane motors; transfer table motors; locomotive hoist and traveling crane motors; electric crane motors; shop motors for driving metal and woodworking tools; electric drills, hammers and fans; battery charging plants; general lighting for shops and yards; special motor-driven compressors and pumps, magnets, etc

Mechanical power—For steam-driven shop engines; steam-driven fan engines; boiler feed pumps; vacuum pumps; boiler wash and fill pumps; water supply service pumps; fire and emergency pumps; steam-driven air compressors supplying air to shop tools, car repair yards, train testing yard, to coach cleaning and painting of locomotives and cars, hoists and jacks, for blowing sand from dryers to storage bins, for lifting water and to operate signal systems and switches.

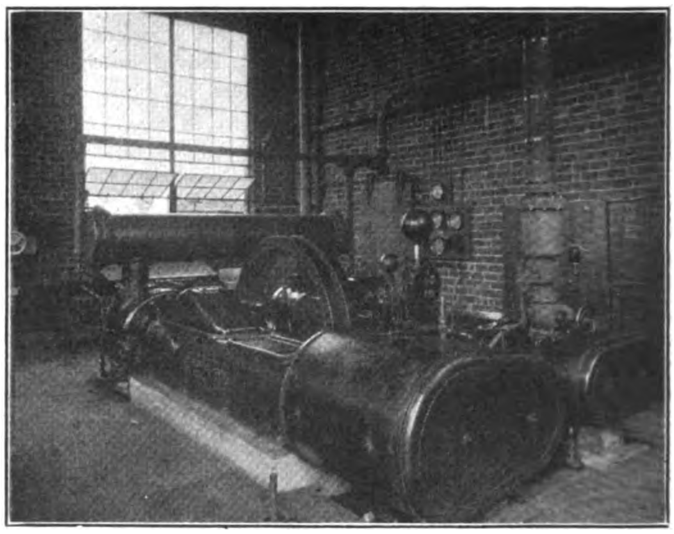
2—STEAM USED FOR ENGINEHOUSE BOILERS

3—STEAM FOR HEATING

Heating required continuously—Oil house and crude oil storage tanks, sand dryers, boiler washing plant, paint shops and dryer rooms, lumber dry kilns, and foundry drying ovens.

Heating required for the winter season—Shops and enginehouse, either by direct or indirect system; offices, storehouses, yard offices, etc.; passenger cars, and thawing devices.

The foregoing items cover the essential classes of service which the stationary plant is called on to serve. In this tabulation are items for which a plant of Class 1 size is required and in some cases a Class 4 plant will serve the purpose.



Air compressor installation featuring large single steam driven unit

Next we must consider the distribution of service and it is well to remember that in working out the distribution we should consider our summer and winter loads. A service distribution sheet should then be compiled to correctly show the charges to be made against the number of departments served by the plant, both on a winter and summer basis.

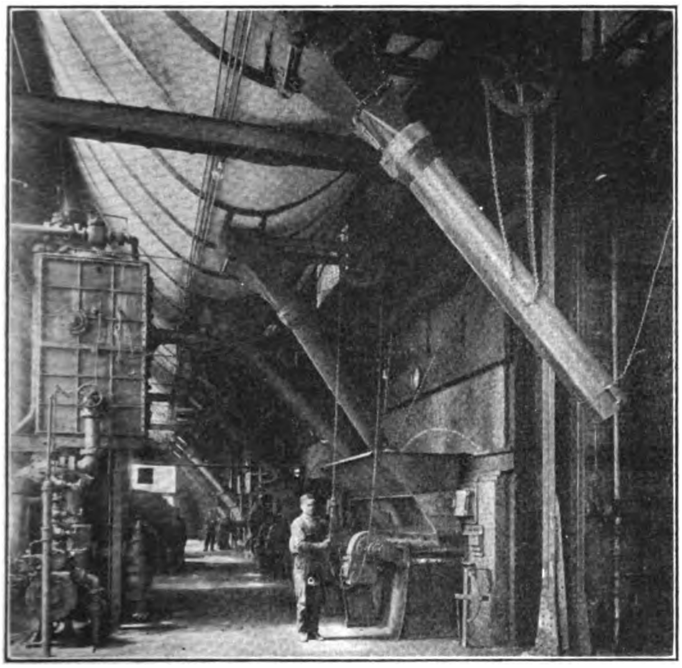
Such distribution sheets assist us in working out the size of the plant necessary to serve our purpose.

Owing to the fact that the majority of our plants range around 1,200 b.hp. and less, we will consider a plant in that class.

Power plant building

Location—The power plant should be located centrally with respect to distribution of steam, electric current, compressed air and water. Consideration should also be given to the handling of fuel to the plant and ash from the plant.

Construction—Hollow tile, reinforced concrete, or brick should be used in the construction of the walls; the roof trusses should be of steel; the roof of fire-proof construction, provided with ample ventilation for the entire length of the plant covered. Ample windows should be provided for natural lighting and ventilation, steel sash are recommended in preference to wood. Doors of ample size should be provided for handling machinery in and out of the plant. Crane runways should be permanently installed in all plants of over 1,000 b.hp.



Boiler plant equipped with vertical water tube boilers, stokers, overhead bunkers, continuous coal and ash conveyor, forced draft fan and feedwater heater

Power plant equipment

Boilers—Plants of the size under consideration are usually provided with either the horizontal return tubular boiler or boilers of the water tube type. When a plant reaches such capacity as to require six return tubular boilers (150 b.hp., capacity per boiler) it is quite justifiable to install water tube boilers of larger capacity instead of having a large number of small units.

Stacks—For plants of the size under consideration we should give attention to the erection of a reinforced concrete, or a radial brick stack. For the small plants (under 1,000 b.hp.) steel stacks are suitable, particularly where return tubular or locomotive type boilers are used. Such stacks should be not less than 40 in. diameter, 80 ft. high, built in sections 20 ft. long, material 1/4 in. thick, guy bands to be set away from the stack by using spacer blocks welded to the bands before they are fastened around the stack. This method will prevent water, fine ash, etc., from settling at this point and causing the stack to rust away. Stacks should be given at least two coats of fire proof paint before erection. Joints should be closely drawn to place before riveting and all rivets should be driven hot.

Coal and Ash Handling Facilities—For the size plant under consideration usually a trestle is built over a coal bin in front of the boilers, the coal being dumped into the bin direct from hopper cars. For handling ashes in this plant a steam jet conveyor is suggested. For more efficient methods of handling coal and ashes a continuous conveyor such as spiral screw, scrapers, pans, pivoted buckets and endless belts are worthy of consideration. In some cases hoists with a car or skip hoist may be found advantageous.

Feed Water Heating and Regulation—The use of a feed water heater is not only desirable but necessary. Feeding cold water to the boiler is not only uneconomical but detrimental to the boiler. The heater selected should be of ample size, and located in a convenient place near the feed pumps. The open type heater is well adapted to use in railroad power plants and as the construction is very simple, it is not difficult or expensive to maintain. Automatic feed water regulation is desirable and a number of regulators are on the market which have proved successful.

Feed Water Pumps—The ideal type of pump for boiler feeding is the multi-stage, centrifugal, turbine driven pump. However, in the size of plant under consideration we usually find duplex pattern steam driven, outside packed plunger type pumps used. In either case we should install pumps in duplicate units. Feed pumps should be installed on firm foundations and raised at least six inches off the floor. All piping to and from the pump should be the full size of openings provided on the pump. At least two feet clearance should be left around the pumps in order that repair work can be done without cramping the workmen in a small space. Feed pumps should be equipped with excess pressure governors and a water relief valve. Force feed lubricators are preferable to hydrostatic lubricators.

Air Compressors—In the selection of air compressors we have a wide range to choose from; steam driven, synchronous motor mounted direct on crank shaft or electric motor belt drive. Whatever equipment is selected should be of ample capacity. Pipe lines should be of substantial size. Air storage capacity should be amply provided and all such storage reservoirs should be provided with safety valves and a conveniently located drain valve. Where such facilities as pipe lines and storage tanks are liable to freeze they should be kept well drained and also provided with alcohol thawing apparatus.

Steam Engines—Due to the fact that the majority of railroad power plants are called upon to supply large quantities of low pressure steam for heating purposes the steam turbine is only used in the larger plants. For plants such as are under consideration the reciprocating type of steam engine is largely used.

The selection of this type of equipment should be carefully looked into and it is advisable to carefully analyze local conditions in each case. Besides the usual types of engines we find the unaflow engine coming into prominence and there is no doubt as to its being economical and worthy of more than passing note.

Power Plant Piping—The design and installation of power plant piping requires more than the amount of thought we sometimes care to give it and we should in no case lose sight of the following items: Size of lines; use of none but the best grades of materials and carefully separate as between low pressure, medium pressure and high pressure work; provide for proper expansion in steam and hot water lines; provide for proper drainage of all steam headers, to be trapped and the condensate returned to heater or boilers direct; all cut-out valves on boilers, engines and pumps should be located where they are accessible for operation and repair; wherever possible avoid placing pipe lines, fittings and valves in trenches, underground and similar unhandy places.

It is suggested in the larger size plants that the use of

welded headers and pipe be resorted to where possible, in order to eliminate joints and fittings. Welded work is in many cases not only cheaper in first cost but by eliminating the threaded joints and bolted fittings and flanges much longer life of pipe can be expected, with resultant reductions in maintenance costs.

Two methods of welded joints are suggested. One is a butt weld. In the second a sleeve or fitting is used which slips on over the pipe and is welded at each end to the pipe. This method is the stronger of the two and eliminates the formation of fins from welding inside the pipe.

All power plant steam lines, hot water lines, and return lines should be insulated with suitable pipe covering and where such lines are exposed to the weather they should further be protected by covering with roofing paper, canvas sewed on and painted or a galvanized iron jacket, the size and importance of the line to govern the method and kind of covering to use. Air lines buried in the ground should be covered first with one good coat of high grade asphalt paint; after this is dry apply a spiral wrapping of 12-ounce canvas secured at convenient intervals with No. 16 soft drawn copper wire; then give two coats of asphalt paint, and allow to dry before placing the pipe in the ground. Fittings should, where possible, be treated in the same manner.

Additional facilities

Boiler Washing and Filling Plant—This facility has developed so rapidly that it is now an indispensable part of our engine terminal equipment and owing to the necessity of successful operation it is usually taken care of by the power plant forces. The plant usually consists of two large wooden or steel tanks, one containing hot water for filling boilers of locomotives and the other tank contains warm water for washing boilers. In addition we have two duplex steam pumps, one used on the filling line and one on the washout line. We also have a separate line for blowing off locomotives under steam into the tank used for washing boilers. A special arrangement is used for separating the sludge of this blow back water in such a manner that mud will go into the sewer, water will go to the washout tank and the steam vapor will pass into the filling tank. Special float valves on the water lines and thermostatic controlled steam valves take care of the automatic features of the plant.

Fire Protection System—In the power plant we usually place the automatic fire alarm telegraph instrument, with a special code of signals to be sounded from the fire whistle when necessary. The fire pumps are also located in the power plant and such equipment should not only be kept in first class condition at all times but it should frequently be tested. Such facilities should not be used for purposes other than what they are intended for.

Steam Heating System—An exhaust steam heating system is one of the most important and economical parts of our stationary power plant and as it is called upon to furnish heat to shop buildings on an average of 212 days per year, it is one of the excuses we have to offer for maintaining steam driven facilities where cheap electric power can be purchased from central station service.

A well designed exhaust steam heating system is justifiable at all medium sized plants and even in the smaller plants in cold localities such a plant must be provided in order to keep the workmen comfortable.

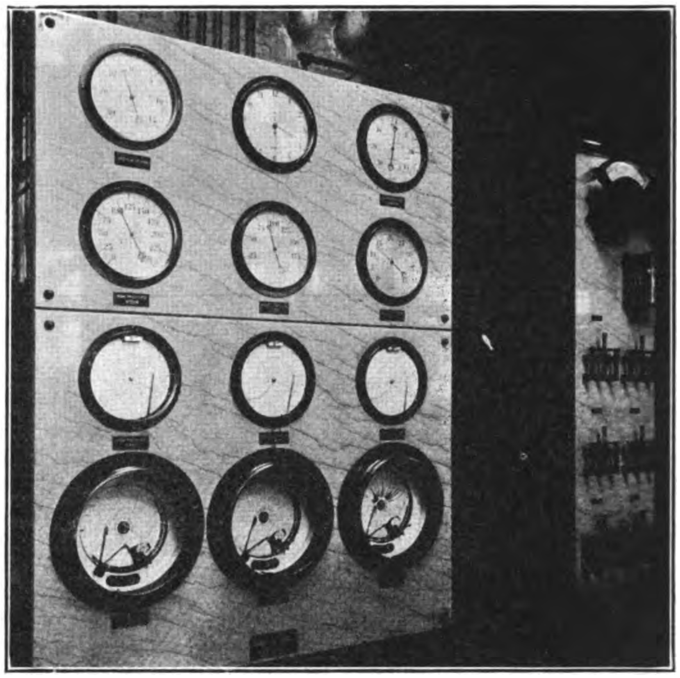
Condensate from the system is usually returned to the feed water heater or boilers by operating the system under vacuum, thus insuring proper circulation and draining of the heating elements at all times.

During the summer or idle period the plant should not be allowed to deteriorate but repairs should be made to all heating elements, valves, traps, vacuum pumps, fans and engines.

Operation and management

To obtain the greatest possible efficiency in power plants is not entirely a matter of design, but a great deal depends on proper operation and management.

In order to operate successfully we must build up an organization composed of a power plant. foreman, whose qualifications should be such as to specially fit him for the responsibilities of the important position he is to fill. The man selected should know power plant operation, how to handle men, how to do and pass on work done in the plant by boilermakers, machinists, masons and electricians. He must know how to indicate engines, set valves and make necessary adjustments; understand modern boiler and engine room instruments and their use in his plant. He should also understand the analysis of accounts entering into power costs. A foreman of this character is necessary to the successful operation of all plants over 1,000 b.hp.



An installation of indicating-recording instruments is a necessity for economical operation

In plants under 1,000 b.hp. the position of power plant foreman can be filled by the first shift engineer, this man to have an assistant engineer to relieve him of the operation of engines in order that he may devote more of his time to the details of efficient operation of the entire plant.

In the larger plants our next step in organization is the shift engineers, who are responsible for the successful operation of the plant.

Stationary firemen should be selected carefully and they should be instructed as to their duties in the boiler plant. Coal and ash handlers are primarily unskilled labor, yet in the larger plants this class of labor is usually promoted to better positions as they occur in the fire room, and for this reason some degree of consideration must be given to the selection of this class of help.

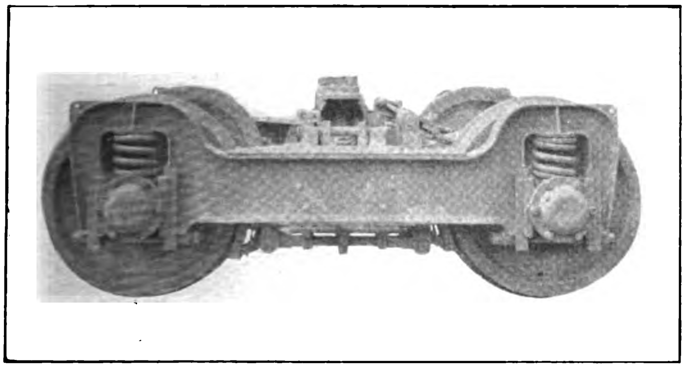
For each district on the railroad there should be at least one man on the staff of the district mechanical officer qualified to follow up all matters pertaining to steam-electric power plants. This supervisor should see that the plants are properly organized, efficiently operated and maintained.

Having built up an efficient operating force it is necessary next to consider the management of this force together with a well defined policy for plant maintenance. No one set of rules can be laid down to fit any two plants without some slight change, and it is not within the scope of this paper to go into details further than to say that the stationary power plant should receive the same consideration as any other unit.

Two-car gasoline motor train

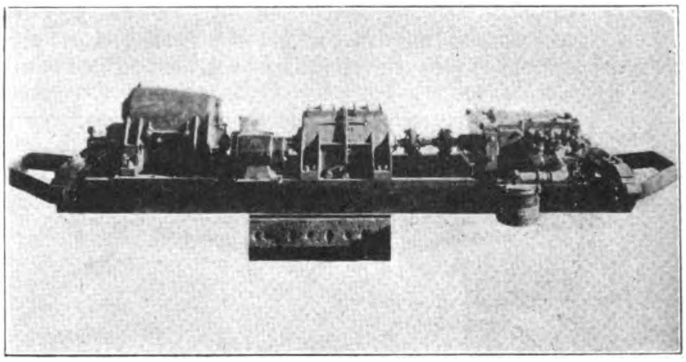
Big Four acquires a combination baggage and mail motor car and 60-passenger trailer for local service on main line

THE Big Four placed in service on Saturday, February 14, between Danville, Ill., and Mount Carmel, on the Cairo division, a two-car gasoline motor driven train, built by the Sykes Company, St. Louis, Mo. Four more trains of the same design are under construction for the Big Four. Two of them will be operated between St. Louis, Mo., and Mattoon, Ill., on the main line, and two between Matoon, Ill., and Indianapolis, Ind., on the main line—all in local service. The outstanding feature of this train is the combination mail and beggage car. This car is the first motor car of its type to have the sanction of the Post Office Department, some of the steam equipment standards of construction of the Department having been modified to meet the conditions of motor train service.



The four-wheel truck of the motor car

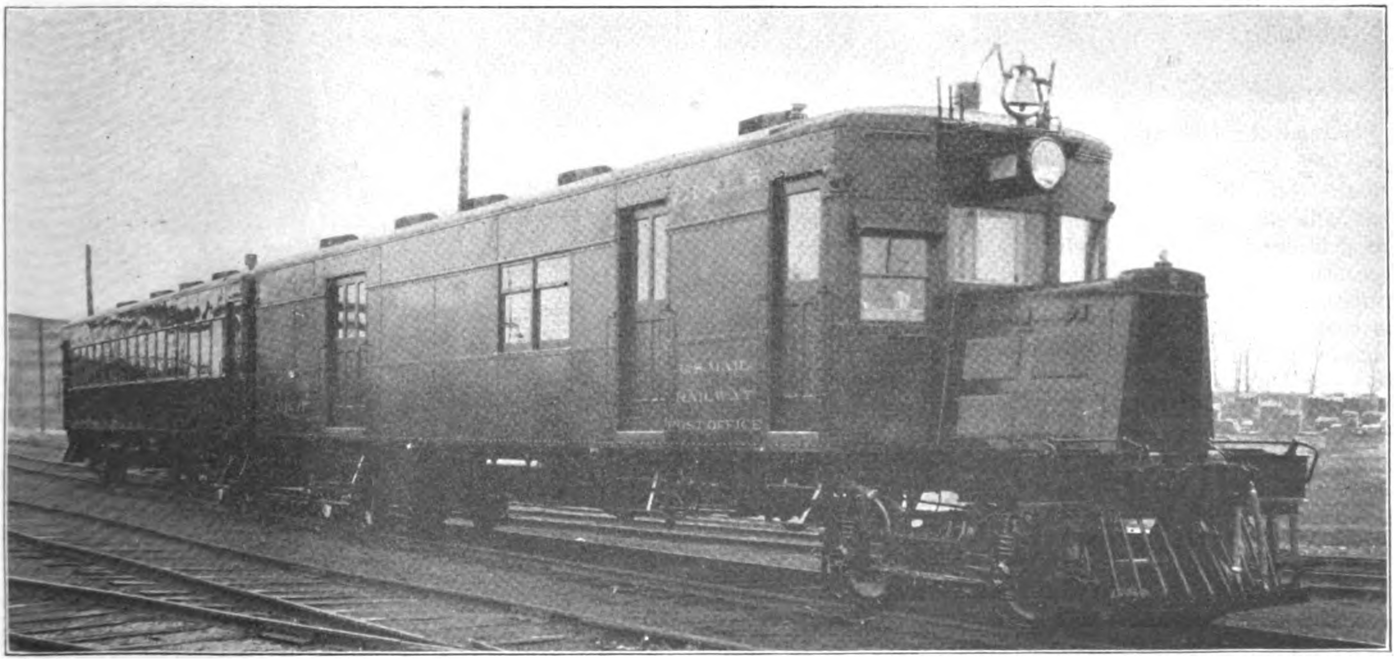
The train consists of a motor coach having a mail compartment, 17 ft. 3 in., long and a baggage compartment 23 ft. 2 in. long, and a trailer coach 51ft. 4¼ in. long, over all, in which seats are provided for 60 passengers. The motor coach is 51 ft. 9⅝ in. long overall, with a body 43 ft. 11 in. in length outside, and 8 ft. 4¼ in. wide at the eaves. The height over all is 12 ft. The trailer coach is 49 ft. 6 in. long over the body and 42 ft. ½ in. long inside of the passenger compartment. The inside widths of the motor and trailer coaches are 7 ft. 10⅛ in. and 7 ft. 11 in. respectively. The height from floor to ceiling of both cars is 7 ft. 7 in. and the elevation of the floor above the top of the rails is 3 ft. 10 in. The distance between truck centers is 37 ft. 2½ in. on the motor car and 33 ft. 6 in. on the trailer. The wheel base of the trucks is 5 ft. 2¾ in. and the cars are adapted to pass around curves of 200 ft. radius.



Transmission subframe assembly showing transmission units and two-cylinder air compressor

The light weight of the motor coach complete is approximately 42,000 lb. and of the trailer coach 29,000 lb. As the trailer provides seats for 60 passengers this is at the rate of 483 lb. dead weight per seated passenger.

The cars are driven by a Sterling six-cylinder gasoline



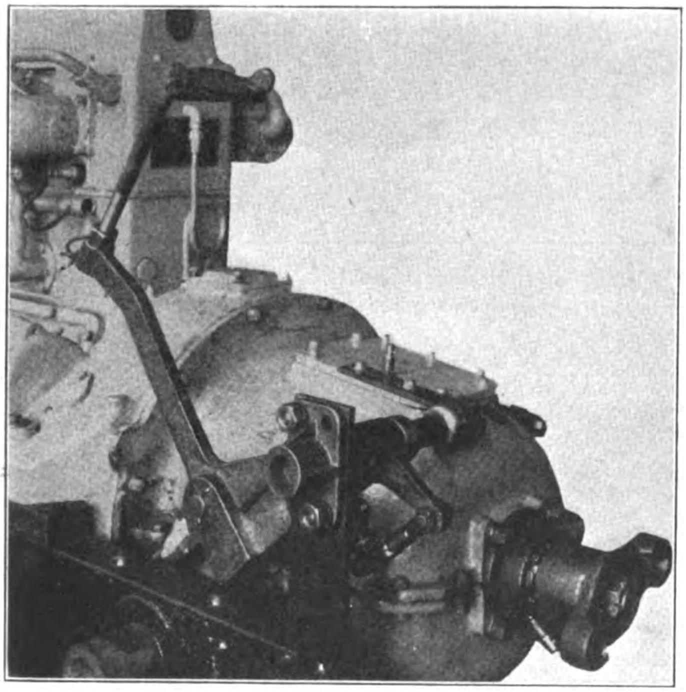
Big Four two-car motor train, built by the Sykes Company, with the motor coach designed as a combination baggage and mail car

motor with cylinders, 5¾ in. bore by 6¾ in. stroke, developing 180 hp. at 1,250 r.p.m. and 245 hp. at 1,750 r.p.m. Electric starting and lighting systems are provided, the generator being directly driven from the engine and of a sufficient capacity to carry all the lights of the train, including the headlight, and to keep the lighting batteries charged to capacity at all times.

A multiple plate, self contained, high capacity clutch is provided, which runs in oil. A special transmission, developed by the Sykes Company, is used. This is so mounted that the speed changing elements may be removed from the coach as a unit on a subframe. The transmission provides for four speed changes ahead, and two in reverse. The low speed gears have a 2-in. face. The third and fourth speed gears are of the herringbone type with 6-in. faces. The speeds provided for are 8.3, 16.7, 33.4 and 44.6 m.p.h. ahead and 7.8 and 10.4 m.p.h. in reverse. The drive is connected by bevel gears on the inside axle of each truck.

The clutch is operated by air

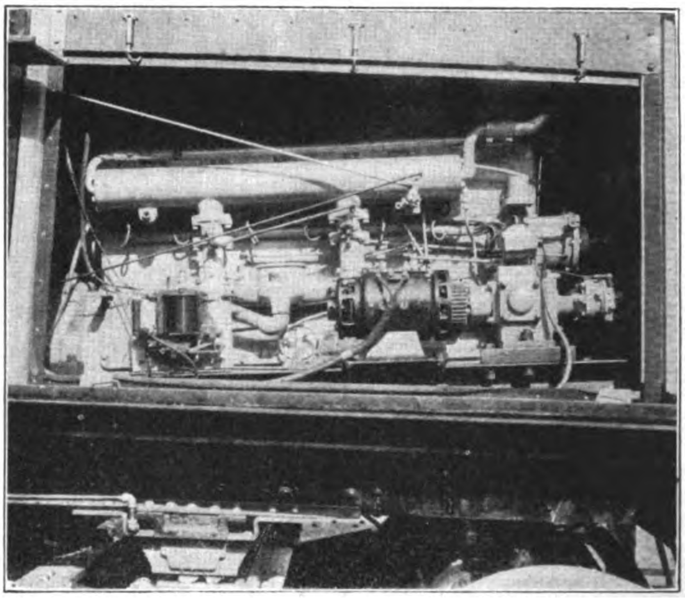
One of the interesting features of the design is an air operated clutch. This development was brought about



Method of mounting the air operated clutch mechanism

by the difficulty of finding a freely operating clutch for mechanically driven cars of large horsepower. A small air cylinder the piston of which is connected to the clutch operating gear so that it assists the foot pressure on the clutch pedal. The first movement of the pedal serves to close the cylinder exhaust valve and open the air admission valve. In releasing the clutch pedal the position of these valves is reversed, and the cylinder pressure exhausted to the atmosphere. The clutch release springs, then function in the usual manner. Another interesting and important feature of design is the use of a subframe suspended by springs from the main frame channels of the motor coach. The transmission units and a two-cylinder air compressor are mounted on this subframe. This method of suspension tends to eliminate gear noises and vibrations from the car body. The entire driving mechanism of the coach may be removed and another unit substituted within two hours time. The power plant itself is mounted in such a manner that it may be removed and replaced within an hour. These features of design are primarily for the purpose of keeping the maintenance cost down to a minimum.

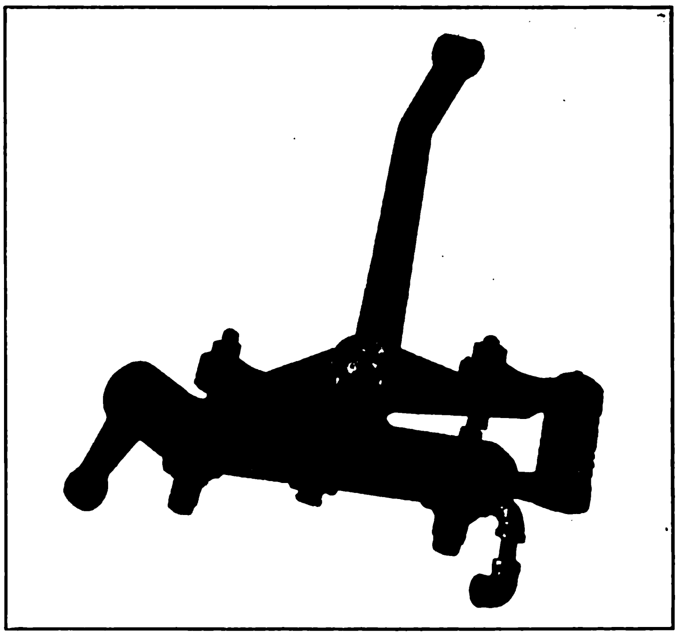
The front and rear trucks are of the standard bolster construction with semi-elliptic leaf springs under the bolster and swinging in a suspended cradle. The wheel



Motor mounted under the hood—the forward bolster is directly under the engine leaving but four feet of overhang

base is 5 ft. 2¼ in. and wheels 30 in. in diameter. The axles are of chrome-nickel steel, heat treated, 3¾ in. in diameter and have 3¾-in. by 7-in. journals fitted with Hyatt roller bearings.

In addition to hand brakes, the cars are equipped with



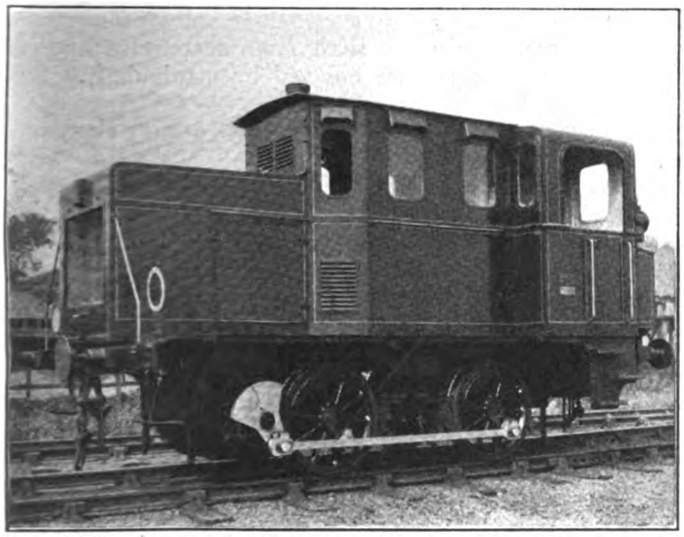
Admission and discharge valves which control the air operated clutch

Westinghouse P. M. and straight air brakes. The air compressor has two cylinders and a capacity of 16 cu. ft. per min. There are two main reservoirs, 16 in. by 48 in. and 10 in. by 24 in. The cars are equipped with A. R. A. automatic couplers at the standard height above the rail.

Hydraulic transmission for Diesel locomotives

Lentz type transmission on switching unit provides three speeds forward and reverse

THE Diesel engine possesses advantages which commend its application to railway locomotives for operation in certain classes of service, such as high thermal efficiency, compact design, cleanliness, ease of operation and particularly the absence of stand-by losses. The internal combustion engine, however, delivers its rated power at a certain speed and it is necessary that some form of transmission be employed which will permit the operation of the engine at a uniform speed while the locomotive works at varying road speeds.



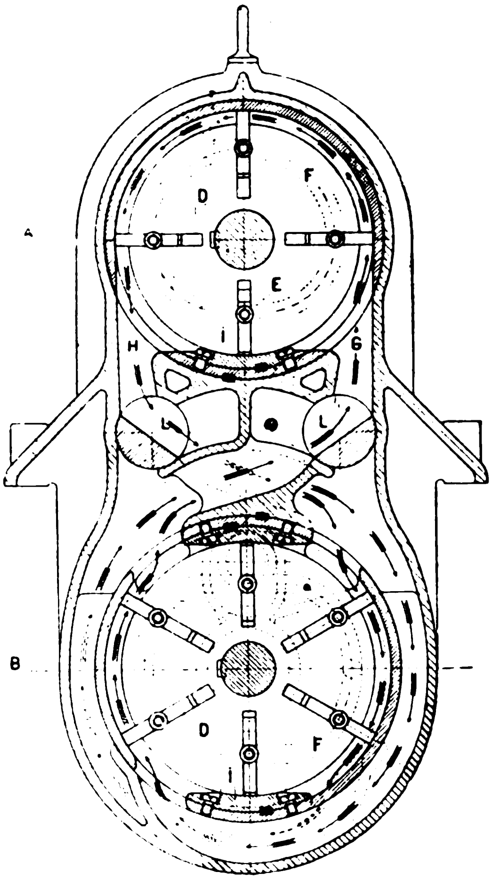
Switching locomotive, with Lentz transmission, driven by a 60-hp. Diesel engine

Of the many forms of mechanical transmission perhaps one of the most interesting is the Lentz hydraulic (oil) transmission which has been incorporated in the design of a switching locomotive, using a Diesel engine, recently tried out in England by the London & North Eastern. The main power plant consists of a six-cylinder, four-cycle, high-speed Diesel engine developing 60 hp. at 350 r.p.m. The hydraulic transmission provides three normal locomotive speeds of 3.1, 6.2 and 9.3 m.p.h.; the corresponding tractive force being 4,000, 2,000 and 1,450 lb., with a potential maximum of 4,850 lb. The total weight of the locomotive in working order is 19 tons.

The axis of the motor crank shaft is longitudinal with the main frames, and this shaft is connected directly with the primary section of the hydraulic gear. The secondary section lies immediately below this, at right angles to it axially, its extremities being fitted with balanced cranks whence the drive is by coupling rods to the driving wheels, the crank throw circle being 19⅝ in. in diameter. The suspension of the driving wheels is by ordinary laminated springs.

The hydraulic gear used on the locomotive illustrated is of a type in which the driving and driven shafts are at right angles but, for the sake of clearly explaining the operating principle of the gear, the sectional drawing shown is of a similar gear having the driving and driven shafts parallel.

The shaft of which A is the center line is that driven by the motor, and has a cylindrical piston rigidly fastened to it. The sides of this piston are closely embraced by walls in the body casting, which also make contact with it below but leave a space above and around for the greater part of its circumference. Within the periphery of this piston are a number of radial slots D, and in these slots are sliding vanes of exact fit which reciprocate in their respective slots and are held by the roller-fitted pins E projecting into the cam-shaped groove F formed in the side walls of the chamber. This groove (or recess) is found upon either side of the rotating piston and is semi-circular above and flattened below the center line, so that the vanes project and make contact with the roof of

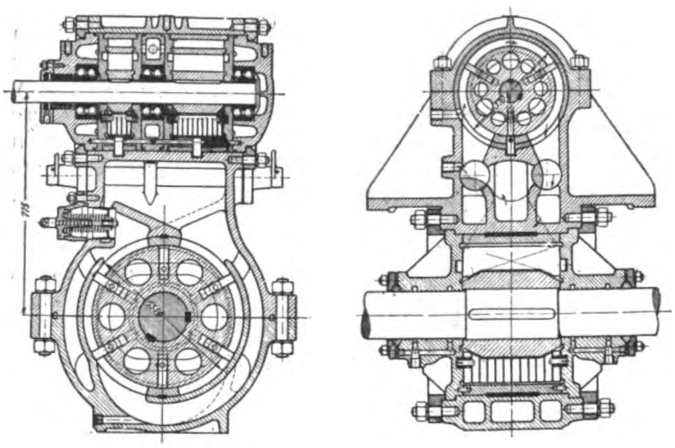


Sectional drawing of Lentz transmission with parallel shafts

the chamber and are withdrawn into the body of the piston at the place where the piston is in contact with the fixed portion of the chamber casting I. It will be seen that the projecting vanes on the rotary piston drive before them the liquid contained between the piston body and the chamber walls towards H in the direction shown by the arrows; simultaneously drawing out the fluid on the

side opposite at *G*. Leakage is avoided by the accurate fit of the vanes, and there are also labyrinth slots (not shown in the drawing) in the surface of the piece *I*, which separates the delivery and suction sides of the containing chamber.

The liquid, which may be almost any kind of clean lubricating oil, flows in the course indicated by the arrows to the lower and opposite side of the chamber where the stream divides, part entering by the upper inlet and the rest through another passage below. There are corresponding vent passages in the casting by means of which the oil escapes and passes back to the suction side of the pump as explained above. The driven rotor or piston is provided with vanes in the same fashion as the driving rotor which are controlled in the same way; but since the pressure is exerted simultaneously upon either side in order to equalize the torque, there are two places where the body of the rotor makes contact with the chamber casting, and consequently the guiding cam grooves have flattened contours in two places, as shown. There is practically no wear on the pump vanes because in the course of their radial movement they are relieved of all pressure, the suction space in the rear of the vane being transformed into a pressure space by the next following vane just before it reaches the end of the pressure stroke. As a result of this, the rollers in their turn have then only the centrifugal force, due to the vane itself, to overcome, and, owing to their lightness, perfect fit and continual immersion in oil, wear from friction may be regarded as negligible.



Lentz gear, with shafts at right angles, such as used on the locomotive described

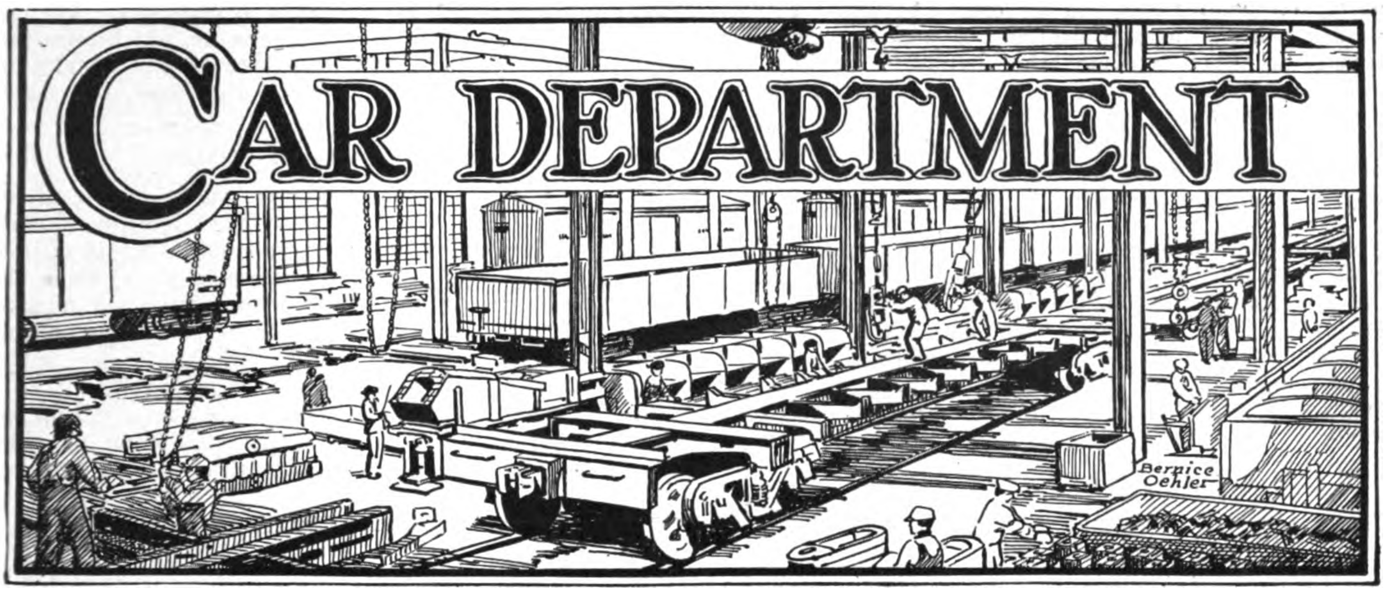
At *L L* are seen two semi-rotary valves, which may be turned to change the direction of the flowing oil stream from one side of the driven piston to the other, and thus alter its direction of rotation.

The foregoing explains the principle by which motion is transferred, from the driving to the driven shaft for either forward or backward running. In order to show how this transmission system acts as a change-speed gear, consider the sectional drawing. It will be seen that the motor driven shaft has two rotors of different widths attached to it, with a separating wall between them. Obviously the smaller piston will drive a lesser quantity of oil before it per revolution than the larger piston, and similarly, by making both pistons work together a still greater quantity is kept in circulation. Meanwhile, the amount of liquid required to displace the driven piston for a given distance is constant, so that by using either the small piston only, the large piston alone, or both large and small pistons in conjunction, three rates of rotation are obtained at the driven shaft from a constant engine speed. These changes are effected by manipulating the rotary valves *L L*.

The disconnection of the driving and driven elements is effected in the simplest fashion by means of a valve built into the center of the casing, which, when closed, divides the pressure chamber of the rotors from the suction chamber of the pumps. It is controlled by a separate lever, and when opened allows the pressure to be neutralized, after which the valves can be moved to any desired position with perfect ease by an arrangement of teeth on the rim of the valve; the pressure is gradually allowed to increase, thus ensuring a perfectly smooth start being effected and no excessive stresses can be generated through careless handling. This valve has the further duty of protecting the transmission by limiting the pressure on the rotor, thus acting as a safety valve, both in forward and reverse directions, and checking any overloads that might develop through too violent a start or a sudden application of the brakes.

The two-piston construction of the driving rotor permits three speeds and reversal. Additional speeds can be obtained by the provision of a third piston, and this is done in some cases, though when more than three speeds are deemed desirable the Lentz system provides a different mechanism than that described.

The shop, office and storehouse of the Boston & Maine at North Billerica, Mass.



Methods of repairing steel cars*

The unit spot system of repairing steel cars is practical and both economical and time saving

By George P. Hoffman

General car foreman, Baltimore & Ohio, Baltimore, Md.

ONE of the most important problems confronting the railroads of this country at present is the repairing and maintenance of steel cars. Each railroad seems to have a different method for making repairs. The greater portion of them are not equipped to properly take care of this important item, and most of this class of work is handled on open repair tracks, without crane facilities. Experience seems to teach that the one method which is completely successful, and efficient for handling this work on open repair tracks is the unit spot system or progressive method.

In order that this system may be carried out, it is necessary to have certain tracks set aside for steel car repairs, and to place the men at different spots on the track, moving the cars down through the tracks, as each operation of the car is completed. This has been developed very successfully by our railroad, organizing the work as shown in the table.

Classification of work and method of designating locations in spot system of car repairs

Color of bulletin board	Symbol	Operation
Red	A	Stripping car for repairs by removing all defective parts that are to be renewed or repaired.
White	B	Repair trucks, underframes, draft gears and attachments.
Blue	C	Fitting and lacing up all parts to place for rivetters, including floors, cross ridge sheets, side hopper, longitudinal hoods, doors, etc.
Green	D	Rivet up parts of car above underframe and apply one coat of paint after quitting time of first shift.
Yellow	E	Apply all safety appliances, hand and adjust doors, repair air brake and hand brake equipment, and applying second coat of paint after quitting time of first shift.
Black	F	Final inspection of cars, tests and adjust brakes, stencil and ship cars.

It is necessary to have all the material to be used at each station, delivered at that point, fabricated, and finished for application, before the men start to work on the cars, so that it will not be necessary for them to move away from their assigned spot for any material. The mechanics who are assigned to the spots perform eight hours' work per day on real mechanic's work, the material being delivered by laborers and helpers, thereby reducing the cost of having mechanics perform work which could be done at a cheaper labor cost.

This system is used in making general repairs, where a car needs renewals of sides and floors, hopper sheets, doors, and other parts of the body. In order that good parts may not be removed and misplaced from cars the work should be checked by a competent car mechanic who should mark up the parts to be removed for replacement, and parts to be removed for repair and replacement. This will insure that the men who are stripping the cars will not destroy a large amount of good usable material.

Rivalry and competitive interests stimulated

It has been found in many places where men are worked under this system, that they will provide themselves with certain shop kinks in order to do their work more efficiently. The men are better satisfied, and will perform a greater amount of work in an eight-hour day than if they were compelled to move their tools from one point to another on repair tracks in order to perform the same operation. A greater efficiency is obtained from the men, for they are continually performing a definite class of work, and become more efficient in its execution each day.

The men at each spot are equipped with the type of tools to perform the particular operation for which they are responsible on each car. This also saves a large amount of tools, as the men on one spot will not require the same tools necessary to perform the operations of other spots.

This system also creates a rivalry among the men who work on the different spots to excel in their work and increase production so that they may lead their fellow-workmen

* From a paper presented at the convention of the International Railway General Foremen's Association, held at Chicago, September 9 to 12, inclusive.

on the competitive spot and the competing unit. In other words, it has a natural tendency to promote competition among the men to produce better results in handling cars through the shop. In order to work the system to the best advantage, of course, it is necessary to have an adequate number of cars passing through each spot daily, which will be gaged by the number of men employed in each unit.

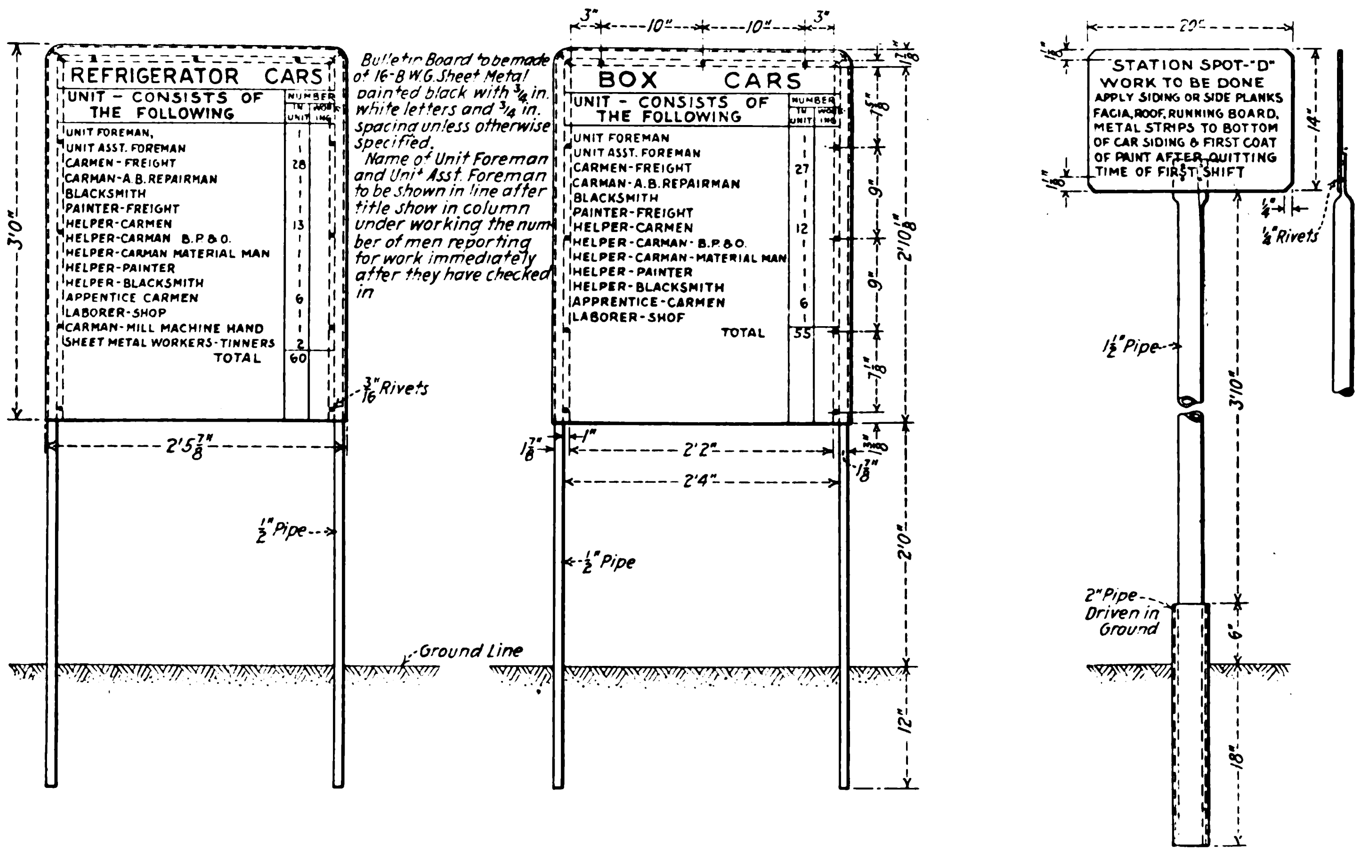
Prompt delivery of material essential

One of the important requirements in carrying out this work is to see that the material is delivered promptly. It has been found that doing this with man power has not produced desired results, and therefore a tractor or an electrically driven truck should be used to deliver the material. They should be kept in continuous operation, to and from material bins and platforms of the various spots. There should be a number of material trailer trucks, to be set off, where the material is to be laid up and the scrap to be small furnaces which are stationery at each spot. The oil is forced through the pipes by air pressure, which saves the cost of handling it through the shops in small tanks or buckets by hand. This will save a great amount of labor and material in any shop.

Dismantling and assembling

Railroads which are equipped with the modern facilities may obtain a greater output and at much less cost if they have the shop supplied with overhead cranes. A shop of this kind should be equipped with a stripping point, where all the deteriorated parts are removed and scrapped, and the material which may be reclaimed, taken to the various presses and straightened out. It is found worthwhile to have sufficient pressure to straighten the steel car parts cold.

After the car has been stripped it should be picked up by the overhead crane and carried to the point where the sills are repaired and riveted up. The trucks should then be



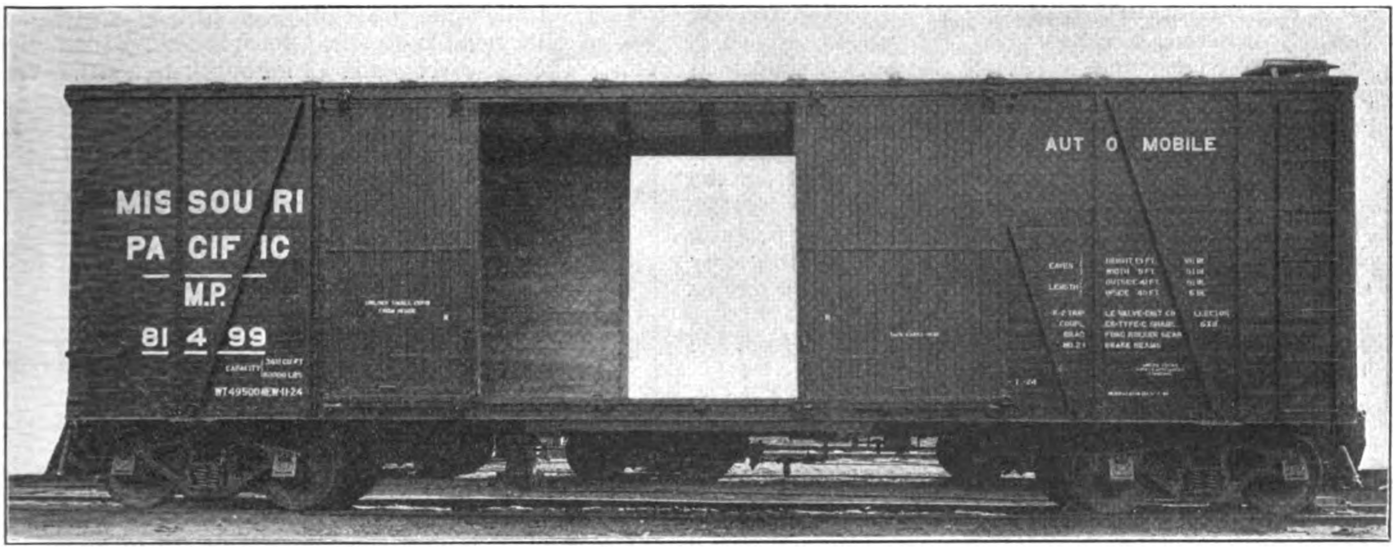
Bulletin boards showing type of cars undergoing repairs placed at ends of the track on which the unit or force is working

hauled away. When loaded, a card is placed in the pocket at the end of the truck, designating to which spot the material is to be delivered. When the operator handling the tractor comes along, he immediately knows by examining the card the destination of the trailer.

The average life of a steel hopper car is estimated at about 15 years, when its superstructure should be rebuilt. This should prolong the life of the car 15 years. It is considered good practice to patch steel cars until the floors and sides have uniformly worn out, after which such parts should be replaced new, and should extend the life of the car about 15 additional years. It should not be considered good practice to allow cars to run which have deteriorated, without substantial patching, which will replenish the lost strength from deterioration. When a car is continued in service in this condition, it is very apt to buckle or collapse, which causes an enormous expense to any railroad in accidents.

On repair tracks where the oil furnace is used, it has been found good practice to pipe the oil from main reservoirs to taken to the last spot, where they should be rebuilt and put in first class condition. The sides of the cars should be fitted and riveted up on a pit riveter and carried to the next spot, and, by overhead crane, delivered to where the sills have been repaired. Then the entire car should be assembled, and carried up to the next spot, where the riveting should be done, then moved up and the trucks placed under the car. It should then be moved to the next spot, where safety appliances should be applied. The car is then ready for painting, and should either be sent to the paint shop or the spot designated for painting.

Another very important item in repairing steel cars is to have the proper material standard to the car applied, and where shops are furnished with this material, they obtain a greater output with less labor cost. The cost of repairs to steel cars will be very high if an attempt is made to manufacture in the shops which have not the facilities for turning out a finished product, to maintain the supply of material to make necessary repairs to cars.

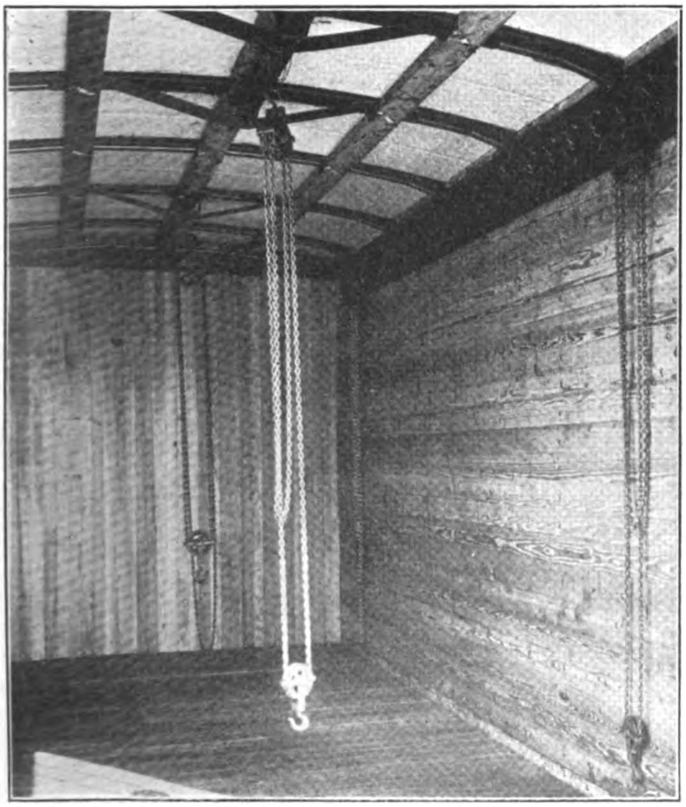


New Missouri Pacific automobile car

Missouri Pacific automobile cars

New design arranged to provide special hoisting facilities—Steel roofs and ends—Large staggered doors

THE steadily increasing movement over the Missouri Pacific of automobiles from eastern and northern factories, and from branch factories and assembling plants at its principal traffic gateways, together with the railroad's policy of providing the most modern equipment for its shippers, resulted in the Missouri Pacific order for 1,000 new 40-ton automobile cars in the latter part of 1924. These cars are now being placed in service. Perhaps their most noteworthy feature is a specially designed hoisting arrangement for loading automobiles within the cars. This arrangement provides both side and center lifting facilities and was devised to meet the most exacting requirements encountered in the shipment of automobiles.



A view of the reinforced T-beam carline sets with hoisting tackle in place at the side and center

The cars are of the steel-frame, single-sheathed type. They are provided with extra thick side sheathing for blocking purposes, staggered doors with 10-ft. clear openings, specially designed Radial all-steel roofs, steel underframes, and Murphy corrugated three-piece steel ends. The cars are 40 ft. 6 in. long, 9 ft. wide and 10 ft. high.

The center hoisting facilities consist of four steel T-beams fastened to reinforced steel carlines of sufficient strength each to carry a load of 2,000 lb. in addition to the roof construction. There are five carlines which are not needed for lifting purposes.

There is one of the T-beam carline combinations on each side of the doorway, with the first of the series set back 3 ft. 1½ in. from the transverse center line of the car. The other two combinations are at each end of the car. To these steel T-beams the automobile manufacturer fastens tongs similar to ice tongs, to which are then attached block and tackle for raising the automobiles.

In addition, there are 36 steel eyes set in the side plate of the car for side lifting. These are arranged in series, four between the first and second T-beam carline combinations nearest the doorway on each side, two between the second and third carlines of these forward sets, and three on each car side between the ends of the car and the innermost hoisting carline.

Such is the arrangement of the hooks and beams that lifting force can be applied with block and tackle from almost every angle or direction and at any place within the car. So far as is known, this method has never been used before.

The extra thickness given to a portion of the side

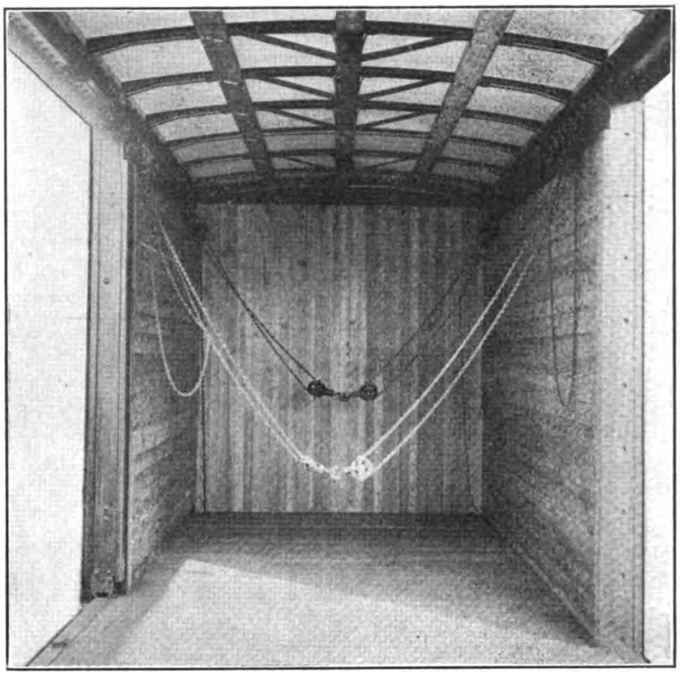
sheathing was devised to provide strong and convenient holding material to which may be nailed, or bolted, blocks for supporting platforms between automobiles loaded on others beneath them. This desired thickness was obtained by applying six tongued and grooved boards, 2 in. thick, with a face of 5¼ in., one above the other, beginning at a height of 3 ft. 3¾ in. from the floor.

The 10-ft. clear door opening, with the stagger feature, is obtained by making the larger side door with a clear opening of 6 ft., or 3 ft. on each side, from the center line of the car, and locating the smaller door, 4 ft. 1⅜ in. wide, on the left side when facing the door from the outside.

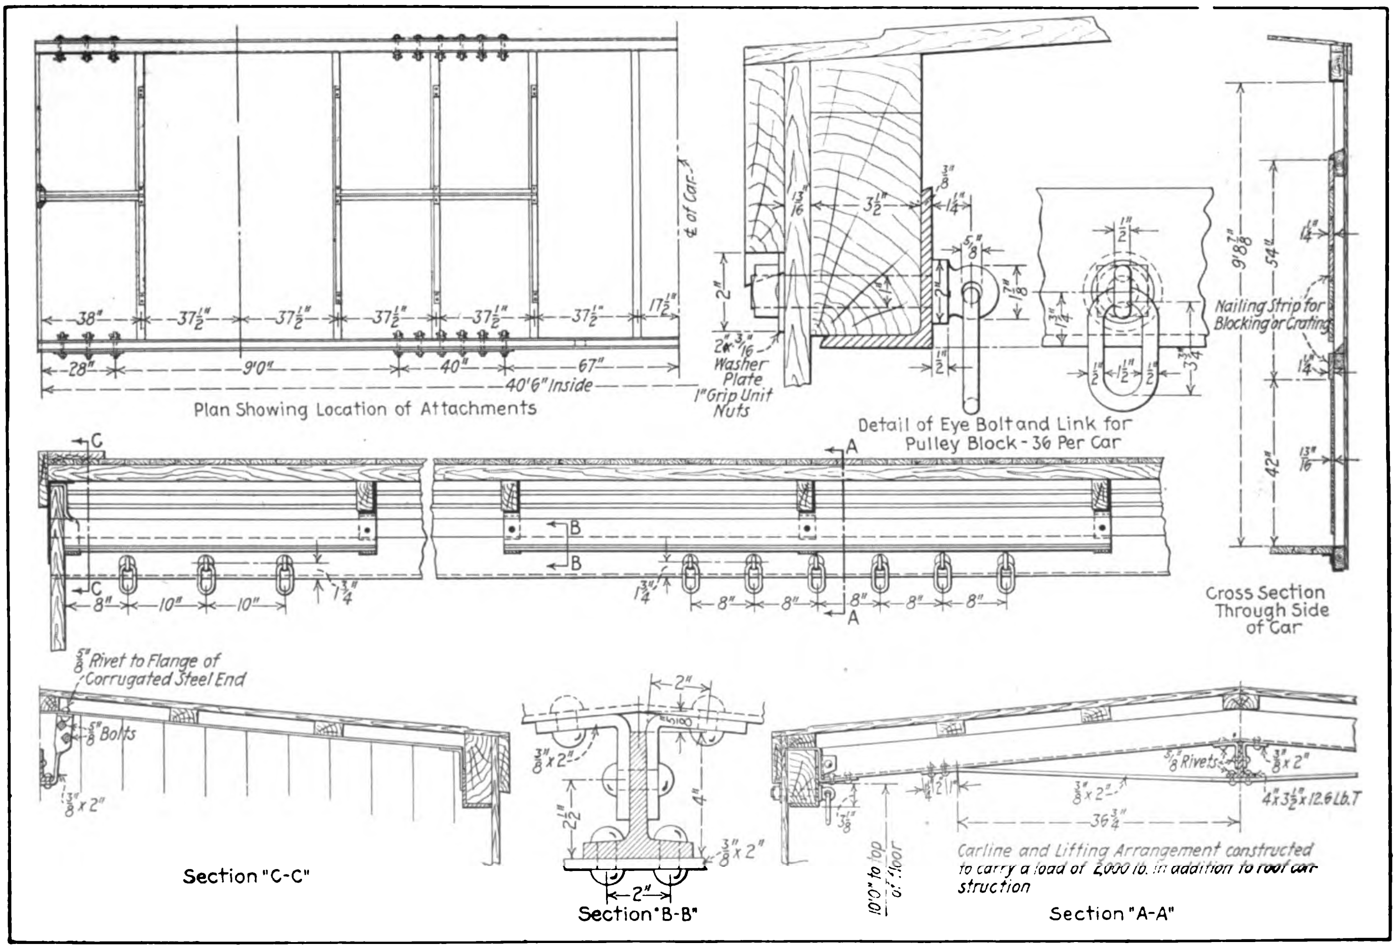
Important construction details

The center sills for these cars consist of two 12-in., 35-lb. channels, spaced 12⅞ in. apart, extending from end sill to end sill with a 20-in. by ⅜-in. top cover plate and a 3½-in. by 3½-in. by ½-in. lower chord angle extending between the bolster filler castings. The specifications call for a cross-sectional area of the center sills of not less than 28 sq. in. The side sills are of Z-bar construction, reinforced at the side doors with a 4-in. by 8.2-lb. Z-bar riveted to the bottom flange and extending 12 in. past the door opening. The body bolster is of box section, having ⅜-in. pressed steel diaphragms flanged 3½ in. all around and placed 11 in. back to back. Top and bottom cover plates extend from side sill to side sill. A diaphragm stiffener of 7/16-in. steel plate is applied at the side bearing.

There are two cross-bearers of 5/16-in. plate flanged 3½-in. all around and reinforced at the top and bottom by 3-in. by 2½-in. by 5/16-in. angles. The cross-bearer center sill fillers are made of ⅜-in. pressed steel flanged 3½ in. all around and extend the full depth of the center sills. The top cover plate, 12 in. by ½ in., extends from side sill to side sill and the bottom cover plate of the same section extends from side to side of the car and is riveted to the side Z-bars.



Tackle in place for side lifting



Arrangement of the lifting attachments in the Missouri Pacific automobile car

A. R. A., Type D, cast steel couplers with 6-in. by 8-in. shanks are used, operation being from the top. The draft gear is of the Bradford rocker type, provided with "G" springs. The cars are equipped with DeRemer-Blatchford side and end ladders and Viloco pressed steel brake steps. The brake equipment consists of Westinghouse Schedule KC-1012 air brakes with double pressure spring type retainers and branch pipe T-bottom outlets. Among the other specialties which are included in the construction are Bettendorf truck side frames with integral boxes and Asco pressed steel lids, Miner rolling rocker side bearings, Chaton fibre dust guards and Schaefer forged three-hole bottom connections and self-locking brake hangers.

Analysis of causes and remedy for hot boxes*

Co-operation in maintenance and the intelligent selection of lubricants are important preventative measures

By M. L. Harger

General foreman, car department, Pittsburgh and Lake Erie, Newell, Pa.

It is well said of those charged with the maintenance of railway rolling stock that there is always a subconscious dread hovering about them of a hot box epidemic breaking loose like a bolt from a clear sky just about the time they think all is going well.

We are all familiar with the usual method of combatting the menace, i.e., tightening up on inspection, whereby more journals are jacked for inspection and more new bearings applied on account of being worn, cracked, or squashed out, so-called conducive elements corrected; more oil is used and more attention given to the treating of the boxes usually resulting in some relief but never completely subduing the hot box, which is conclusive evidence of something basically wrong.

I am in strong accord with the car foreman who stated, "I sincerely believe that with proper and general co-operation in the maintenance of all parts in this connection, that a 50 per cent improvement in results and savings can be made," but after the 50 per cent improvement has been made, you still have some hot boxes. If you follow the same principle to all the "leads" pertaining to the hot box, we should conquer them completely. This is the underlying principle with which I wish to deal in this article.

Eternal vigilance is said by many to be the keynote to successful hot box prevention. By constant vigilance you can keep within certain limits, according to the class of cars and business handled, the full tonnage car being the real trouble, such as those handled in ore, limestone, coal, etc. In such trade where those concerned become a little negligent, it is not uncommon for hot boxes to reach five per cent in the first 100 miles. Careful attention by the inspectors and oilers will bring it down to two per cent, possibly in some cases a little lower.

We often hear the matter referred to as a broad question. It is. But how little the fundamental principle of friction and lubrication is understood by the masses performing the important phases of the different operations to the completed journal under a car. You have only to approach the majority of them, and here again you are back to the foreman who said, "I sincerely believe that with proper and general co-operation in the maintenance of all parts in this connection, that a 50 per cent improvement in results and savings can be made."

After you have corrected all the faults of your yard practice of inspection and treatment which calls for eternal vigilance, you cannot overcome in the transportation yard faulty babbitt, faulty oil, faulty waste, faulty journal turning, etc. These are the underlying faults against which the car repair foreman, his inspectors and oilers, no matter how proficient, are powerless. The average inspector is familiar with the ordinary items usually attributed as being conducive to hot boxes, such as packing that is out of adjustment or glazed, waste grab, dirt, flat wheels, side bearing clearance, broken and compressed truck springs and missing dust guards. After correcting all items known as being conducive to hot boxes, he is at the end of his resources, and his responsibility ceases at this point.

The important items to consider are: the babbitt lining of the bearing, wedge, perfect workmanship and practice in turning journals, good oil and waste.

Reclaimed bearings potential source of trouble

The practice of carrying economy too far in reclaiming journal bearings is the cause of innumerable hot boxes, beyond the control of yard inspection forces.

I will not attempt in this article to draw any conclusions on how far it is safe to go in developing a cheap alloy for lining bearings. Such a paper would be lengthy in itself. The fact is, we have thousands of bearings in circulation, lined with poor alloy which is as detrimental to the service as bad money in circulation. And the greater fault lies with the railroad company that will take an alloy that has caused a hot box, melt it, and reline another bearing with it to cause more trouble, or perhaps melt it with a good alloy and depreciate the value of the whole batch.

The practice of relining journal bearings with so-called babbitt metal reclaimed from all sources without first ascertaining by analysis what it is composed of, is mechanically unsound. It should be analyzed, and where it does not come within set limits, make it so by the addition of the necessary elements to make the standard alloy; then and then only, is the babbitt as good as new.

The practice of having the relining done by men abso-

*A paper submitted in the competition on hot box prevention which closed March 1, 1924.

lutely ignorant of metallurgy, at least within the limits of the metal they are handling, is bad. Such ignorance is the cause of many hot boxes where all other elements were 100 per cent.

While I do not wish at this time to go into details of bearing alloys, I will say I am of the opinion that lining bearings with plain lead and antimony is bad practice, because with little variation of antimony, you obtain a poor alloy. If too little is added, the alloy will become plastic and will readily squash out like dough under a rolling pin. If too much is added, it will crack readily and break away from the shell, and above all, with the slightest failure of the oil, the journal and bearing will abrade each other more readily than other alloys, and when once it grips the journal its destruction is very rapid. This causes a dangerous condition in transit, as such bearings will not respond to temporary treatment intended to carry the car to a terminal, thus necessitating setting the car out at once or taking grave chances on hauling it to a terminal.

Care in selection of oil and waste is important

Proper oil and waste for lubricating journals is of major importance to abolish the hot box, and the same principle applies to oil and waste as to bearing alloy. By far too many accept without question the thought that any kind of alloy termed babbitt is all right or that any form of oil will answer the purpose.

As the use of reclaimed babbitt of unknown content is bad practice, and mechanically unsound, so is the use of reclaimed oil of unknown viscosity, gravity and content.

Many hot boxes are caused by foreign substances in reclaimed oil which will gather along the edge of the bearing until it acts as a "wiper" or works its way into the bearing, forming a carbon coating, absolutely void of any friction absorbing quality, resulting in the gradual heating of the journal. Such heated journals, if caught in time, can be flooded with good oil and if the paste has not formed a hard coating, it is safe to proceed, or the bearing can be cleaned, oiled and replaced. This is the slow developing hot box, very common to the car man, and is the kind of hot box that, if it occurs to a journal in transit having a good babbitt lining on the bearing, can be nursed for quite a long distance by the train crews without much difficulty, and will in time cool down under proper treatment and give no further trouble. The same ignorance usually prevails around the oil reclaiming plant as that associated with reclaiming babbitt and relining bearings, whereby, questionable oil is put in circulation, just as sure of causing trouble as the bad babbitt. The theory of lubrication and the theory of friction and chemical properties of oil is unknown to the average dope reclaiming plant.

The reclaiming of oil is a necessary conservation of the oil supply as well as an economy to the railroads. But in order to make it a real economy, it must be done right.

Oil should not be reclaimed in a back yard plant of every division by inexperienced men, but at a well equipped central point, supervised by a competent chemist, thoroughly versed in petroleum and the friction the oil is to absorb, as well as the conditions under which it must absorb it. Not a drop of oil, new or old, should be used until it has satisfactorily met laboratory requirements.

Such a plant means an initial outlay of money, but it will soon pay for itself and then pay larger dividends in operating savings than any other efficiency movement on the system, assuring a wonderful reduction in hot boxes and lubrication at a surprisingly low figure.

Closely allied with the oil is the waste, which should be handled the same as the oil and completely renovated, preferably at the same central point as the oil. Old waste should never be used until completely renovated and restored to the same specifications as new waste for dope, having the maximum amount of resiliency consistent with the correct proportion of capillary power. Many hot boxes owe their origin to dead waste which lacks enough resiliency to hold the oil in contact with the journal. The inspector or oiler finding a box where the dope lacks resiliency will pack the dope around the journal as solid as possible, but a few jolts of the car and the action of the journal will pack the dope away from the journal for its lubrication until treated at the next terminal, if it happens to run that far without developing a hot box.

Dope should not be prepared at the reclaiming plant for shipment to car shops in barrels or other containers, but properly reclaimed oil and waste should be shipped the same as new oil and waste to the local point and there made up into dope by an experienced man, according to the demands at that point.

Improper wedges increase bearing pressure

The journal wedge is of major importance in the abolishing of hot boxes, because the wedge is an equalizer of the weight to be carried on the journal. The wedge is well taken care of by the use of A. R. A. standard wedge, and where all the provisions surrounding the A. R. A. wedge are right equal distribution of weight is assured. Where they are not, which is quite often the case, the bearing surface is reduced and the weight per square inch increased to a point above 800 lb. which is bound to develop a hot box, because, while some oil will maintain a lubricating film under 1,200 lb. pressure, the average oil will not. Therefore, too much attention cannot be given the bearing surface of the journal box and the wedge, which if worn very much will give undesirable service and become the source of trouble.

The broaching of relined bearings, if mechanically performed, is good practice, especially where the bearing is to be applied to a loaded car of full tonnage, because here you have a condition subjecting the lubricant to its utmost, where it must lubricate under pressure exceeding in most cases 800 lb. per sq. in., and where the bearing has been broached it has a good smooth surface and increased bearing surface for a start. Seventy-five per cent better service is recorded as the result of broached bearings under loaded cars, which is conclusive evidence aside from the theoretical argument. The broaching of second-hand bearings causes many hot boxes due to proper inspection not being made, whereby cracked lining and otherwise defective alloy is put in service.

Poor journal turning a contributing factor

Not the least of hot box trouble can be traced to faulty journal turning, and is a matter which must be watched with as much diligence as yard and shop practices. The practice of taking a rough cut from a journal and rolling it does not, at its best, give a 100 per cent job, and where care is not taken to make the best possible cut a satisfactory result in operation will not be obtained. The tool should never be adjusted in the middle of the cut, and if exceptional care is not taken with the roller, the journal will have a series of waves; the bearing will bear only on the crest of the waves, causing increased pressure, or the bearing will seat in the waves and the lining be destroyed by the lateral motion.

I believe that the day is not far off when the A. R. A. will incorporate into the rules for billing foreign car owners, such provisions as will assure the application of bearings lined with a babbitt metal of known good content, oil of known viscosity and gravity, free of all foreign substance, and good clean, live waste of proper resiliency and capillary power, in order to justify billing.

In closing, there is one reliable method of combating the hot box, and many of the other difficulties in railroad operation. That is knowledge—knowledge of existing facts at the time of their existence, not a month or more later.

This of course is recognized by many of our railroads and practiced to some extent by many, but in most cases in a disorganized haphazard fashion. On many roads the old-fashioned theory of keeping everybody in ignorance is still in vogue. Nothing can be gained by, or is more harmful than, dissimilation of conditions. Meet any condition full in the face, meet a fact with a fact, conquer or be conquered. Armed with the mechanical theory, full knowledge of all existing facts, you can overcome an epidemic of any kind.

In order for a foreman to have these weapons he must chart his operations, know at a glance when they are good, and be able to see at a glance the first indication of something going wrong; immediate investigation will correct the matter before an epidemic starts. The foreman cannot keep his chart up to the minute without the co-operation of the divisional officer over him, who should keep him well supplied with the information he cannot gather locally. On the hot box question he should be furnished promptly with the initial and number of every car having journal failure leaving his point, together with inspection pass marks, and the opinion of the foreman under whose jurisdiction the repairs were made.

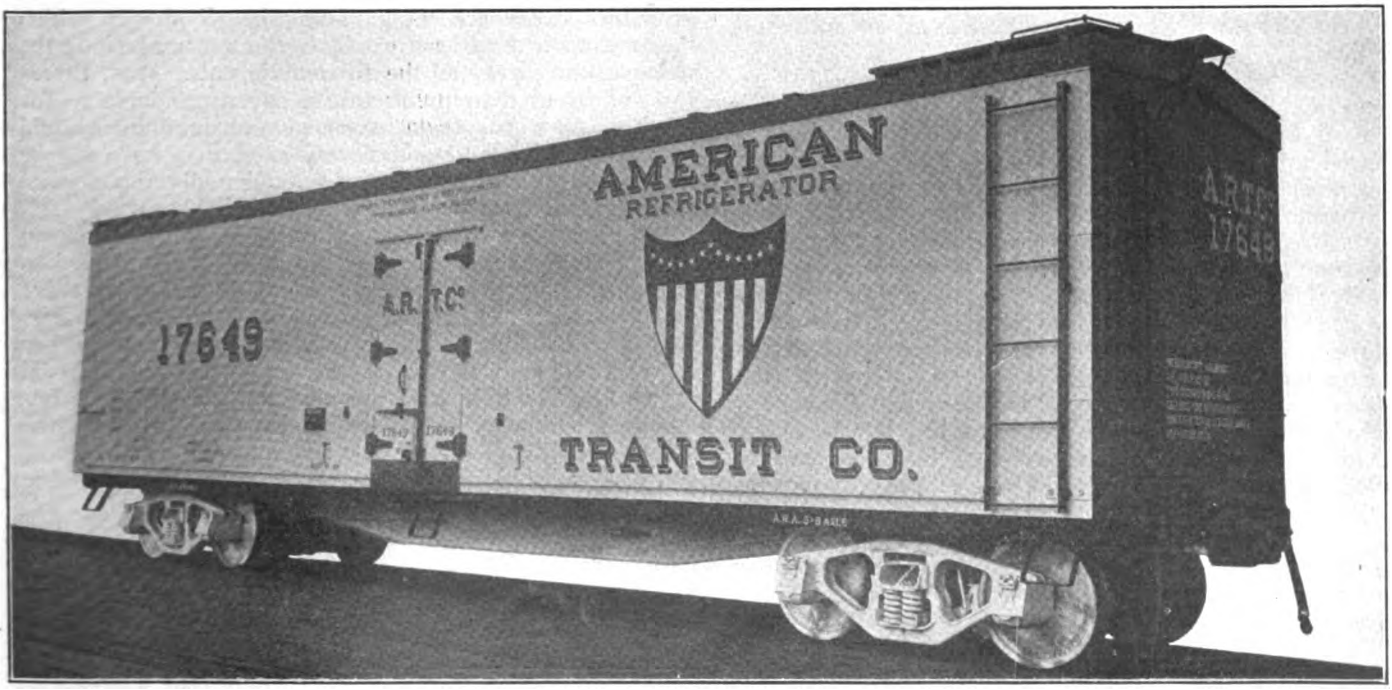
Every department should have its intelligence department, which should gather all facts, analyze all failures, have experts to cover certain fields of operation, to school the inexperienced and correct the faults, furnish the foreman promptly with information pertaining to failures in certain lines; just as the laboratory is essential to the manufacturer of steel, so is the intelligence department essential for successful operation of the railroads. Without the laboratory and chemist, the steel manufacturer would be ruined by the bad steel manufactured before he corrected the fault. Without the intelligence departments the railroads will have epidemics and failures of various kinds which they will not understand. Take your choice.

American Refrigerator Transit buys new equipment

Modern features of design are incorporated in large order of new refrigerator cars

LAST September, the American Refrigerator Transit Company, a private refrigerator car line owned jointly by the Missouri Pacific and the Wabash, divided an order for 2,000 refrigerator cars among the American Car & Foundry Company, the Mt. Vernon Car Manufacturing Company and the General American Car Company and the work of constructing these cars is now practically completed. They embody the most serviceable features developed over a long period of years.

The cars, built with steel underframes, are 39 ft. 9 in. long; weigh 58,000 lb., and have a capacity of 80,000 lb. They are equipped with the basket type ice bunkers having a capacity of 10,500 lb., and insulated bulkheads. These ice baskets are made of heavy galvanized wire



The new A. R. T. refrigerator car

netting and are suspended in the bunkers in such a way as to allow about two inches of space between the netting and the walls of the car on all four sides. This gives a free circulation of the air, allowing it to come in contact with the ice on all four sides and causing much more rapid refrigeration than could be obtained otherwise. The insulated bulkheads result in a better circulation of cold air through the car. Each bulkhead is insulated so as to allow no infiltration of air except at the top and bottom, there being an opening of about 12 in. at both places. The warm air entering at the top of the bunker comes in contact with the ice and passes out at the bottom opening. On account of the limited open space at the bottom of the bunker, the cold air of its own pressure is carried all the way to the center of the car, circulating freely under the floor racks and touching all parts of the load.

The floor racks in question are hinged to the side walls so that they may be raised to permit a thorough cleaning of the car floor. The use of these floor racks gives a more thorough circulation of the cold air under the load as well as a protection from excessively low temperatures by keeping the commodity off the floor proper. They also allow the warm air, where cars are moving in heater service, to circulate under the load.

The cars are equipped with No. 22 gage metal roofs of the Murphy X L A type. The underframe is of the fish-belly type and the trucks have cast steel side frames and cast steel bolsters. The roof insulation consists of 2½ in. of Hairinsul, the floors 2 in. of Hairinsul in addition to the double flooring, and the air space and the side and end walls consist of 1½ in. of Hairinsul and two layers of Celotex, each being ½ in. thick.

Special attention given to insulation

Between the stringers is placed a false floor on which is laid two inches of insulation. A ⅞-in. tongue and grooved floor is laid on the stringers and over this is spread a layer of waterproofing asphalt, the regular 1¾-in. flooring being placed on top. Waterproofing material is also poured between the framing on the sides and ends to prevent water seeping through. This waterproofing material meets a rigid specification so that it will stand up under extreme heat or cold. In addition to waterproofing the floor, the insulation in the walls is covered with a layer of waterproofing paper in order that it may be kept dry and retain its efficiency as an insulating medium.

Celotex, which is comparatively new in the field of refrigerator car insulation, is made from the pulp of sugar cane, thoroughly ground and the fibres interlaced and pressed into boards ½ in. thick and of any desired size. It is much lighter than lumber and its insulating value is approximately three times as great. In these cars, Celotex has replaced the sheathing, both inside and outside of the framing, reducing the weight of the car approximately 4,000 lb. Celotex also adds to the rigidity of the car body because it is applied in large sections the full height of the car, so that its diagonal strength is much greater than that of lumber.

Ten of these cars are being insulated with Dry Zero, a product of the Johns-Manville Company, which is comparatively new in the refrigerator car field. This material has already been applied in a few cases but the application in these cars is different from any previously made. In the past, it has been applied entirely in bulk, packed between the framing, but in this lot of cars it is applied in blanket form in the side and end walls. A blanket of the material two inches in thickness and sewed between layers of burlap is applied on the outside of the framing between the sheathing and car siding. In the roof and floor, four inches of Dry Zero is compressed approximately 40 per cent, being packed between the floors and between ceiling and roof.

Fifty of the new American Refrigerator Transit cars will be equipped for passenger train service and will be known as express refrigerator cars. They will be 50 ft. in length, equipped with heating and lighting systems, metal bulkheads, etc. The other cars will be placed in regular refrigerator car service.

Economies effected by insulating train steam pipes*

By William N. Allman

General Railroad Department, Johns-Manville, Inc., New York

ECONOMY in operation and conservation of fuel has been the subject of considerable discussion during the past few years in locomotive operation and at the present time it is a matter of paramount importance. The conservation of fuel should, therefore, receive careful attention and investigation. There has not been much data presented on the subject insofar as train steam pipes are concerned, and in a large number of cases the railroads have treated this most important subject lightly. In the operation of passenger train equipment there is considerable exposure in the train line; for a ten-car train there would be approximately 500 sq. ft. of exposed surface. If this surface is not adequately insulated there would be a large loss of heat units.

In meeting the necessity for effectively insulating these pipes against loss of heat, the question arises as to the proper material that shall be used, and what is of even greater importance is the thickness of material that shall be employed to secure the greatest economy. There are a great many types of commercial pipe covering on the market at the present time and it is, therefore, necessary to select wisely the proper insulation in order to obtain the results desired. These types may be generally classified under three headings, namely, the laminated, moulded and cellular type.

It should be borne in mind that the efficiency of all insulators varies according to the size of pipe to which they are applied, and according to the temperature of the steam in the pipes and the surrounding air. It is, therefore, apparent that in selecting a covering adaptable for this service, construction, efficiency and durability should be considered. It should be observed that it would be subjected to continuous vibration and under this service every type of covering would not be suitable.

Efficiency is a very important factor, for the reason that the lines which are to be insulated are subjected to extreme changes of temperature and, furthermore, there is a great increase in loss of heat due to the air velocity on the pipes. The efficiency of pipe covering is the per cent saved by insulating a pipe with a certain material of what would be lost if the pipe were left bare or uninsulated. This per cent is obtained by subtracting the heat loss of the insulated pipe from that of the bare pipe and dividing the difference by the heat loss from the bare pipe. Expressed as a formula it would be as follows:

$$E = \frac{A - B}{A}$$

where:
E = Efficiency
A = Heat loss through bare pipe
B = Heat loss through insulated pipe

*Paper presented before the Manhattan Air Brake Club, New York, on December 18, 1924.

The heat losses may therefore be compared directly as follows:

Bare pipes ....100 per cent
Efficiency ....per cent saving
100 per cent — per cent efficiency = loss through insulation expressed as a percentage of bare pipes.

For example, an insulation having an efficiency of 86 per cent allows a loss of only 14 per cent of the loss from bare pipes.

As an example of the increase in heat losses from bare and insulated pipes due to wind velocity, the following will show approximately what is encountered:

Wind velocity, miles per hr.	Percentage of heat loss for bare pipe in still air	Percentage of heat loss for insulation 1 in. thick
5	155	21.0
10	260	26.0
15	335	28.2
20	397	29.6
25	450	30.6
30	493	31.2
40	562	32.1
50	610	32.7
60	648	32.9

The above table indicates what effect velocity will have on losses and, on bare pipes, it will be noted this mounts up very rapidly. The table as prepared is for a very high-grade of pipe covering. For other materials the losses would be greater in about the same proportion that their rated losses are greater. These values are necessarily only approximate but give an idea of what these particular losses amount to.

Three types of insulation discussed

Not all pipe coverings can be termed good insulation, some being efficient at low pressures, but very inefficient at higher pressures. Some coverings are fairly efficient when first applied but soon deteriorate and do not maintain their efficiency, while others maintain their initial efficiency indefinitely. The underlying principle of efficient insulation is confined to dead air cells, and perhaps one of the best forms of pipe covering is that of the laminated type, which consists of a number of layers of felt composed of asbestos fiber and particles of finely ground spongy material, this combination forming an extremely cellular felt. These layers of felt, being built up in laminated form, confine a large volume of minute dead air cells between the layers, and the general construction makes it a highly efficient covering and one that is most durable as well as maintaining its efficiency indefinitely.

Speaking in general terms of insulation, the next best form, perhaps, is the moulded type of insulation, which is a light, highly efficient insulation. In this type of covering there is also a large number of microscopically small dead air cells. These cells cause the air to become stagnant, and thus a very poor conductor, thereby increasing the efficiency. This particuar form of pipe covering, however, is not as adaptable to service on train pipes as is the laminated form, because of the constant vibration already referred to soon has a tendency to disintegrate the covering.

The next best classification would be that of the cellular type. In order to give an approximate idea of the saving which would be obtained from the various types of pipe insulation on a comparative basis on covering of a known efficiency, I will designate for the sake of convenience three types, known as A, B and C, all 1 in. thick.

A—Laminated form.
B—Cellular type, corrugations running around the pipe, not parallel with pipe.
C—Layer form with indentations in layers.

The efficiency of these coverings for a 2-in. pipe and for the temperature difference dealt with hereafter, are as follows:

A—85.84 per cent.
B—82.00 per cent.
C—78.60 per cent.

For our investigation we will consider a 10-car train, each car having 80 ft. of 2-in. pipe, which is equivalent to 500 sq. ft. of radiating surface. Train line pressure 50 lb., outside temperature 20 deg. F. above zero. The calculated results would run as follows:

Loss in B.t.u. per hour, per sq. ft. bare pipe	1,070
Total radiating surface, sq. ft.	500
Total loss in B.t.u. per hour	535,000
Hours of service per day	16
Total loss in B.t.u. per day	8,560,000
Temperature of steam in train line at 50-lb. pressure	334.3 deg.
Outside temperature	20.0 deg.
Temperature difference	314.3 deg.

Assuming coal to have a thermal content of 10,000 B.t.u. which is very conservative, this would be equivalent to 856 lb. of coal per day loss, or at $4 per ton we would have $1.71 loss per day from bare pipes.

The saving per day effected by using the three types of covering which have been described would be as follows:

Type of covering	Efficiency	Saving per day
A	85.84 per cent	$1.47
B	82.00 per cent	1.40
C	78.60 per cent	1.35

The initial cost of the covering would soon pay for itself and the saving of wasted heat units and ultimate dollars and cents would soon amount to a considerable item. The temperature of steam in a train line of 334.3 deg. F., as covered in the above analysis, is obtained from the following formula:

Temperature of steam (saturated) at boiler pressure of 200 lb. per sq. in.	338 deg. F.
Total heat in saturated steam at 200 lb. per sq. in.	1,199.2 B.t.u.
Total heat in saturated steam at 50 lb. per sq. in.	1,178.5 B.t.u.
Difference	20.7 B.t.u.

Since the change through the reducing valve has been a constant heat change, that is, no work done and no heat gained or lost, the heat in steam at 50 lb. per sq. in. above normal saturation content must be in the form of superheat. Therefore:

$$H_t = S\,(T_s - T_n)$$

Where:

H_t—Total heat above saturation heat content
S—Specific heat of superheated steam
T_s—Highest temperature of superheat
T_n—Normal temperature of steam at pressure given

Therefore:

$$H_t = 20.7 \qquad S = .57$$

Substituting:

$$20.7 = .57\ (T_s - T_n)$$

$$\text{or } (T_s - T_n) = \frac{20.7}{.57} = 36.3$$

$$T_n = 298.0$$

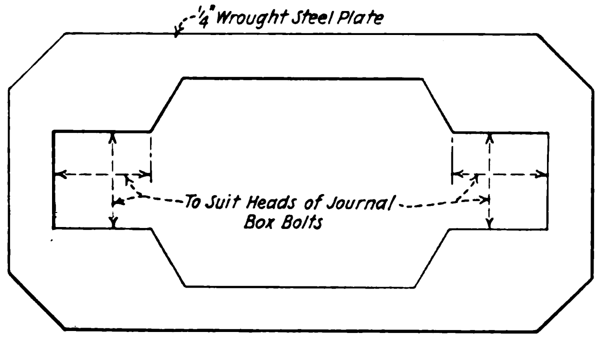
$$\text{or } T_s = 298.0 + 36.3 = 334.3$$

The above conditions and analysis may be considered normal, and results would vary with temperature conditions. For example, in certain sections of the country during the winter the temperature would be much lower than that considered above, also, as the velocity of train increases the loss is greater and as the foregoing is based entirely on still air conditions, the saving would be even greater and more so by using the best insulation, or that having the highest efficiency.

A handy device for the truck repair man

A SIMPLE device for holding the heads of journal box bolts while removing or tightening the nuts, is shown in the sketch. It is made from ¼-in. steel plate. The outside edge and center opening can be readily formed with a cutting torch. The holes for the bolt heads should be

cut square and provide a reasonably close fit to hold the bolt securely. The car repair man places the plate on the top arch bar so that the heads of the journal box bolts fit



A device which eliminates an extra wrench and holds both journal box bolts while the nuts are being removed

into the slots. The nuts can then be applied or removed without any liability of the bolts turning.

Decisions of the Arbitration Committee

(The Arbitration Committee of the A.R.A. Mechanical Division is called upon to render decisions on a large number of questions and controversies which are submitted from time to time. As these matters are of interest not only to railroad officers but also to car inspectors and others, the Railway Mechanical Engineer will print abstracts of decisions as rendered.)

Second application of journal bearings on different roads comprising the same system

On December 15, 1922, the Oregon Short Line applied a journal bearing to C. B. & Q. car No. 132,798 at journal box location L-4. The charge was reported on the billing repair card which was included in the audit bill of the car owners. On December 25, 1922, the Union Pacific applied a journal bearing to the same car at the same journal box location and the charge made on the billing repair card was included in the audit bill to the C. B. & Q.

On December 9, 1922, the Oregon-Washington Railroad & Navigation Company applied a journal bearing to C. B. & Q. car No. 98,944 and included the cost of repairs in their audit bill using a Union Pacific billing repair card. On December 12, 1922, the Oregon Short Line applied a journal bearing to the same car at the same journal box location and the charge was reported on the billing repair card which was included in the audit bill. The charge for a prior application on the Oregon Short Line, November 22, 1922, to the same car, same journal box location, was included in their audit bill on a Union Pacific billing repair card.

Claims presented by the C. B. & Q. to the Union Pacific for cancellation of one or more of the charges was declined by the Union Pacific on the grounds that such applications of journal bearings were made by separate railroad companies, and, therefore, Rule 99 did not apply to these cases. Insofar as Interchange Rules are concerned, the Union Pacific is comprised of four subsidiary companies which should be considered as individual railroads.

It was contended by the Union Pacific that the four subsidiary lines commonly known collectively as the Union Pacific System are separate units, under the laws of the United States, and therefore, also under the Interchange Rules of the A.R.A. The Union Pacific substantiated this statement by giving eight reasons why the four units should be considered as separate railroads.

The C. B. & Q. contended that so far as Rule 99 was concerned, the several units of the Union Pacific System should be considered as comprising one and the same road and not as individual foreign roads. Therefore, when a foreign car has a journal bearing applied and charged for on two or more of the units of the Union Pacific, such charges should be subject to the provisions set forth in the rules.

The Arbitration Committee in rendering a decision in this case, stated that: "In view of the status of the four roads in question with regard to their relation to the Union Pacific System as explained by the Union Pacific, they are properly considered as separate roads in application of Rule 99. Therefore, the contention of the C. B. & Q. is not sustained."—*Case No. 1319, Union Pacific vs. C. B. & Q.*

Responsibility for damaged car offered in interchange

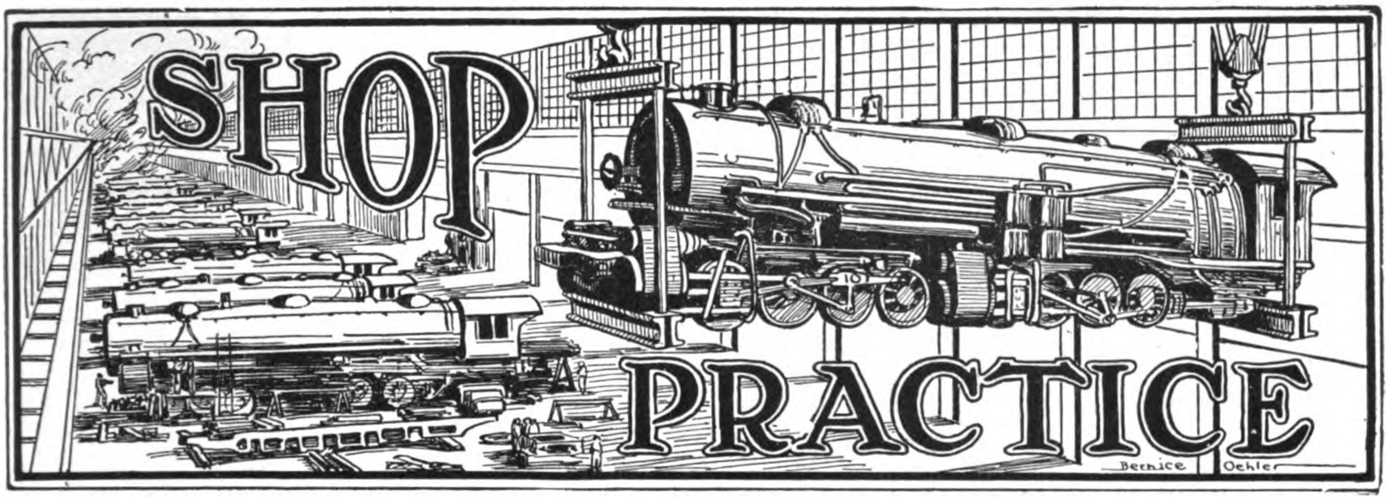
Pierce Oil Corporation tank car No. 2393 was wrecked in derailment at Randolph, S. D., and damaged to such an extent that it was necessary to load it on a flat car for movement to the Minneapolis shops of the Minneapolis & St. Louis for repairs, and on March 22, 1922, the owners were advised of its release for service. The car was moved home to Sand Springs, Okla., via Minneapolis & St. Louis to Wabash at Albia, to M.-K.-T. at Kansas City, to Sand Springs Railway at Home Junction for delivery to the owner. On April 11, the day after delivery, a joint inspection was made, on the basis of which the car owner contended that a number of defects had been left unrepaired and that in some cases wrong material had been applied. The Minneapolis & St. Louis stated that there may have been a possibility of other roads which handled the car from the time it left its Minneapolis shops until delivery to the owner contributing to damage en route. It also stated that defect cards for wrong repairs as claimed had been furnished, but refused to furnish cards for the other items, being of the opinion that it was not responsible, in view of the fact that the tank was put in good condition before leaving the shops and had passed inspection points without exceptions.

The Arbitration Committee, in a decision rendered February 15, 1924, decided that, with the evidence presented, the car owner's recourse is against the delivering line in accordance with the first paragraphs of Rules 2 and 4.—*Case No. 1318, Pierce Oil Corporation vs. Minneapolis & St. Louis.*

Responsibility for car damaged in switching

The Michigan Central humped a cut of six cars in the Niles, Michigan yards, February 15, 1923, damaging Midland Valley box car No. 4047 to the estimated extent of $1,000. The Michigan Central claimed that the car was not derailed, cornered, side swiped or otherwise damaged as outlined in Rule 32, but on the other hand failed in ordinary handling owing to the general worn out condition. The car owner claimed that the damage to this car was due to the causes set forth in paragraph *D* of Rule 32 and was the handling line's responsibility.

The Arbitration Committee rendered the following decision: "The car was not subjected to any unfair conditions and, according to Rule 32, the car owner is responsible."—*Case No. 1321, Midland Valley vs. Michigan Central.*



British methods of setting locomotive valves

By F. Norman
London, England

THE operation of setting locomotive valves is one in which the need for accuracy will be self-evident to those interested in this subject. The purpose of this article is to describe the practice of setting valves, adopted by a large locomotive works in England. The fact must first be appreciated that any divergence of lead of the valve, relative to the cylinder ports, from that laid down by the designer, may result in a measure of inefficient working, due to losses of steam, etc.

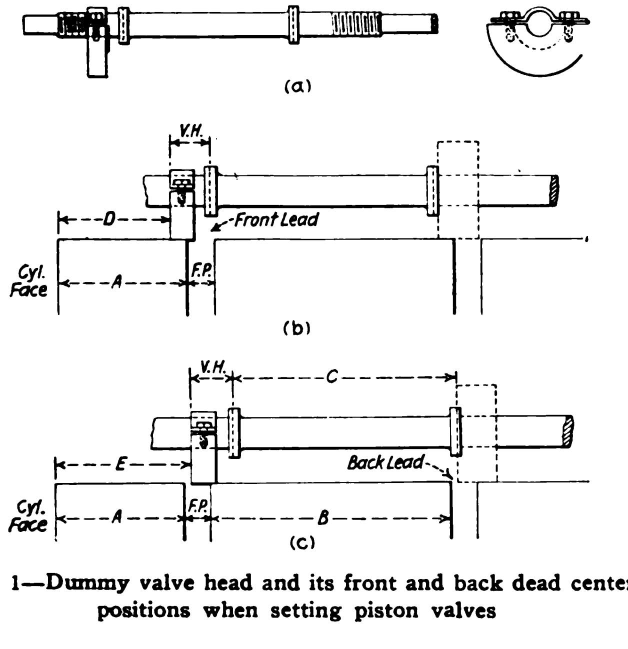


Fig. 1—Dummy valve head and its front and back dead center positions when setting piston valves

Method of setting piston valves with internal admission

The responsibility of setting the valves on all locomotives is in the hands of a mechanic known as the valve setter. He performs his duties at any stage of the erection of the locomotive as most convenient to the progress of the work through the shops. His first step, after the cylinders have been erected with the valve liners pressed in, consists of measuring, by means of a vernier, the position of the ports relative to the front face of the cylinder. These dimensions form the basis of all the valve setting calculations, both when the locomotive is first erected and at any later time when it may be returned to the shops for repairs. A permanent record is kept of these figures for each locomotive. It is well to state that these dimensions almost invariably differ, owing to slight inaccuracies in machining, from those laid down by the designer.

It will be appreciated that, with piston valves a much closer setting is possible than is the case with slide valves for the reason that each valve head is independent of the other and can be adjusted to govern the admission of steam at its respective end of the cylinder. A dummy valve head as shown at *A* in Fig. 1 is used when setting the valves. This is mounted on the valve spindle, the collars of which are left ¼-in. wider than required to allow for the necessary adjustments. Another method adopted in some works is to make the collars according to the dimensions called for by the drawings and then use thin steel washers between the heads and the collars. The objection to this practice is the possibility of the washers either being lost or wrongly assembled, when the locomotive is overhauled, which will alter the leads.

The dummy head is made 1 in. shorter than the valve head. It is placed on the valve spindle, inserted in the cylinder, and the whole coupled up to the valve motion. The engine is placed on the front dead center and then the head is adjusted to its correct position relative to the front cylinder face. Following this, the spindle is removed from the cylinder and put between lathe centers. The collar is then faced up so that a 1-in. setting block will pass between the collar and the dummy head. This will insure that the valve head will be in its correct position when assembled on the valve spindle.

Sketch *B*, Fig. 1, shows the position the valve spindle

and the dummy head should occupy when the engine is on the front dead center. Referring again to sketch *B*, it will be seen that:

$D = A + FP - (FL + \text{standard valve head})$ when,
D = distance of dummy head from front of cylinder.

Take for an example the measurements on a locomotive which show that:

$A = 7.998$ in.; $FP = 1.747$ in.; $FL = .125$ in.; $WH = 2.5$ in.
$D = 7.998 + 1.747 - (.125 + 2.5)$
$D = 7.120$ in.

When the locomotive is on the back dead center:
$E = A + FP + B + BL - (C + VH)$

Assuming for the moment that the dummy head has been adjusted with the engine on the front dead center to bring the valve head to its desired position, then since the distance *B* between the two ports is fixed, it follows that *C* must also vary in proportion. For example, if *B* is found, after measuring, to be .005 in. wider than as designed, the dimension of *C* should be increased a like amount, for otherwise, the back lead will be increased or decreased accordingly. Thus on the same engine where:

$B = 10.505$ in. as against the designed 10.500
$BL = .250$ in.
$C = 14$ in. according to design
$E = 7.998 + 1.747 + 15.505 + .250 - (14.005 + 2.500)$
$E = 8.995$ in.

It may probably be found by the valve setter that after having adjusted his dummy head with the engine on the front dead center, when he places his engine on the rear dead center and takes his measurement, a discrepancy will be found between the actual and the calculated figures. It is then his object to minimize this difference by dividing the distance between the two centers. Emphasis is laid on the fact that when the front collar on the valve spindle is faced up, the back collar must also be machined to give the correct distance between the two heads. This automatically ensures that the back lead shall be correct.

Fig. 2—Table for setting valves on a locomotive equipped with the Walscheart gear

To eliminate the necessity of making a calculation for each locomotive, a table, as shown in Fig. 2, was compiled, giving at a glance *D* and *E* for all probable variations of *A* and the front port measurements.

Setting the D-type valve

When setting the flat D-type valve a somewhat different procedure is followed. In this case the admission of steam into both ends of the cylinder is controlled by one valve. Sketch *A*, Fig. 3, shows the position on the front and back dead centers respectively. From sketch *A* it will be seen that the distance of the valve from the front cylinder face $= A + FL$. In a similar manner

$D = A + B - (BL + \text{total width of valve})$.

As an example, on a certain engine the dimensions for one cylinder were:

$A = 13$.; $B = 8\frac{3}{4}$ in.; $FL = \frac{1}{4}$ in.; $BL = \frac{1}{8}$ in.
Total width of valve $= 10\frac{3}{4}$ in.
Therefore:
$D = A + FL = 13 + \frac{1}{4} = 13.250$ in.
And also:
$D = A + B - (BL + \text{width of valve})$
$D = 13 + 8\frac{3}{4} - (\frac{1}{8} + 10\frac{3}{4})$
$D = 10.875$ in.

A table was compiled as shown in Fig. 4 similar to that for piston valves, in which it will be observed that due provision is made for adjustment of the back figures in accordance with any variation of the width of the valve

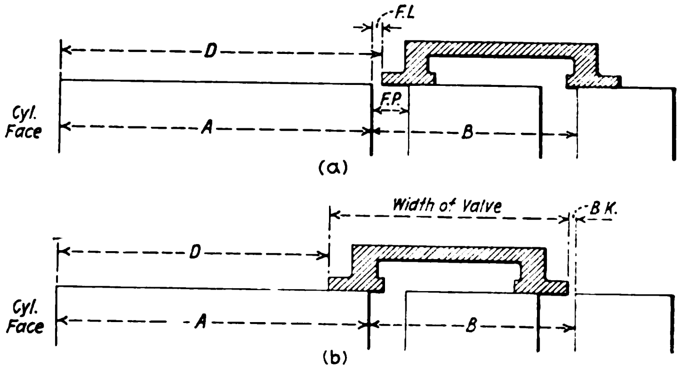

Fig. 3—Front and back dead center positions when setting flat slide valves

from the standard. Thus, for an engine of this class, the actual measurements were found to be:

$A = 12.999$ in.; $B = 8.747$ in.; width of valve 10.753 in.

By using the table we find:

Front figure = 13.249 in.
Back figure = 10.868 in.

In the event of it being found that the measurements taken, when the locomotive is on a particular center in the forward gear, vary to any appreciable extent from those taken on the same center but in the reverse gear, adjustment is made by altering the eccentric blades on the Stephenson gear, and the expansion link on the Walschaert gear. In order to reduce the forward gear lead on the Walschaert valve motion, the expansion link carrier is lowered by reducing the thickness of the liners at the bottom and of course substituting a thicker one at the top. A stock of liners is kept, increasing in thickness by 1/32 in. In order to reduce the forward lead, in case of the Stephenson gear, the eccentric blade of the forward eccentric is shortened.

Table for Valve Setting - Class W Engines with Stephenson Valves

Standard Dimensions A-13", B-8.750, Front Lead ¼", Back Lead ⅛", Width of Valve 10.750"

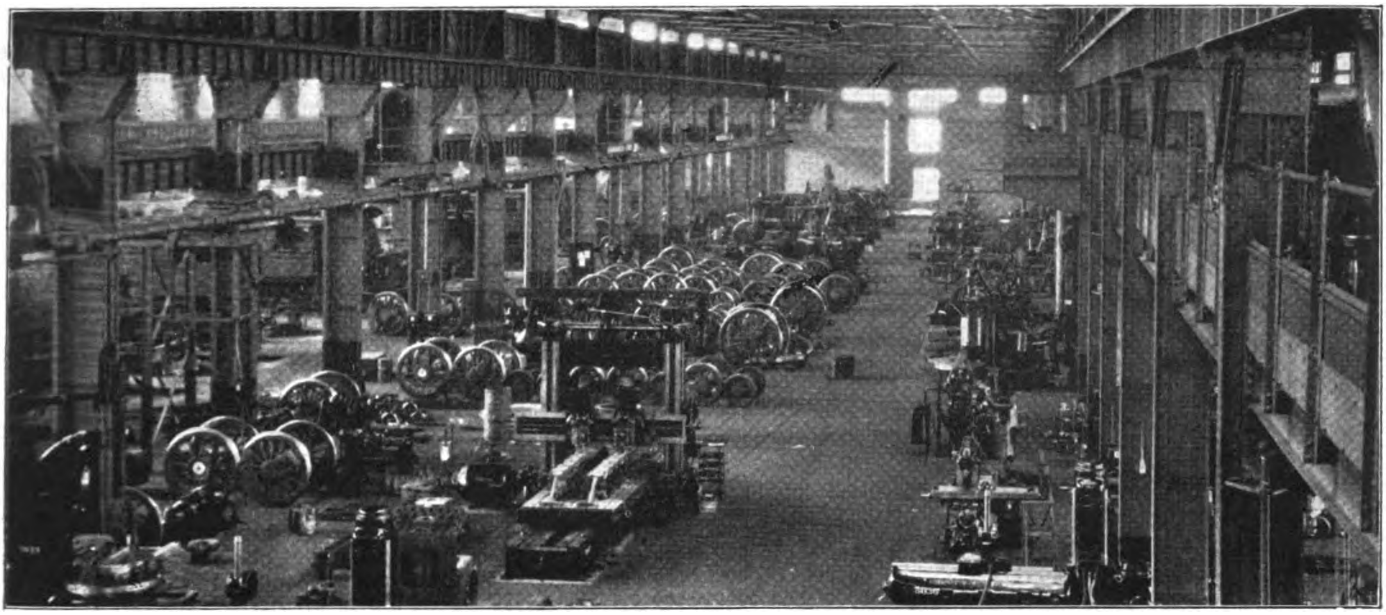
Fig. 4—Table for setting valves on a locomotive equipped with the Stephenson gear

---

THE SHOP CRAFT EMPLOYEES on the Chicago & North Western have taken a referendum vote on the question whether the co-operative plan introduced on the Baltimore & Ohio and later adopted on the Canadian National shall be put into effect on the North Western. Although the result has not been announced it is expected that the men will favor the plan, since the railway employees' department of the American Federation of Labor strongly advised its adoption. If the adoption of the plan is approved, Capt. O. S. Beyer, Jr., consulting engineer for the unions, who supervised the introduction of the plan on the Baltimore & Ohio and the Canadian National, will make a study of the North Western shops to determine at which point to start the program.

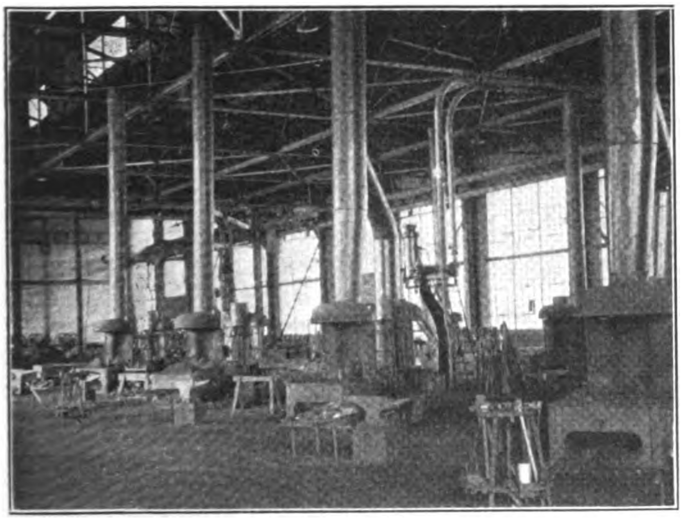


Interior view of the Finley locomotive shops of the Southern Railway, North Birmingham, Ala.

Southern builds modern equipped locomotive shops

Excellent results are being obtained through a system of cost control and inspection

WORK on the first locomotive repaired at the Finley shops of the Southern at North Birmingham, Ala., was completed on October 15, 1924. This locomotive, a Pacific type, was sent into the shops for class three repairs on October 1, 1924, making a total of 13 eight-hour working days between the "day in" and the "day out." The total amount of labor and material expended on this locomotive was 40 per cent less than the cost to perform the same work in the old Alabama Great Southern shops at Birmingham, which formerly handled the classified repairs of the Alabama Great Southern, now a part of the Southern System, and the Birmingham division of the Southern.



Interior view of the blacksmith shop

The repair work of these two divisions was consolidated at Birmingham in 1922. This placed on these shops the burden of maintaining 219 locomotives which eventually required that approximately 20 per cent of the classified repairs be turned over to the shops of other divisions. The working force employed at Birmingham by the mechanical department at that time totaled over 1,500 men. This included the forces employed in both the locomotive and car departments.

New installation has decreased costs

With the new installation at Finley, the mechanical department was able to reduce the working forces in both the locomotive and car departments to 1,138 men, with a staff of 31 foremen and supervisors and 11 clerks, which includes the day and night forces of the two engine houses. In addition, the locomotives of the Memphis and Mobile divisions, the New Orleans & Northeastern Railroad and the New Orleans Terminal Company, now included in the Southern System, are dependent on the Finley shops for classified repairs, making a total of 466 locomotives.

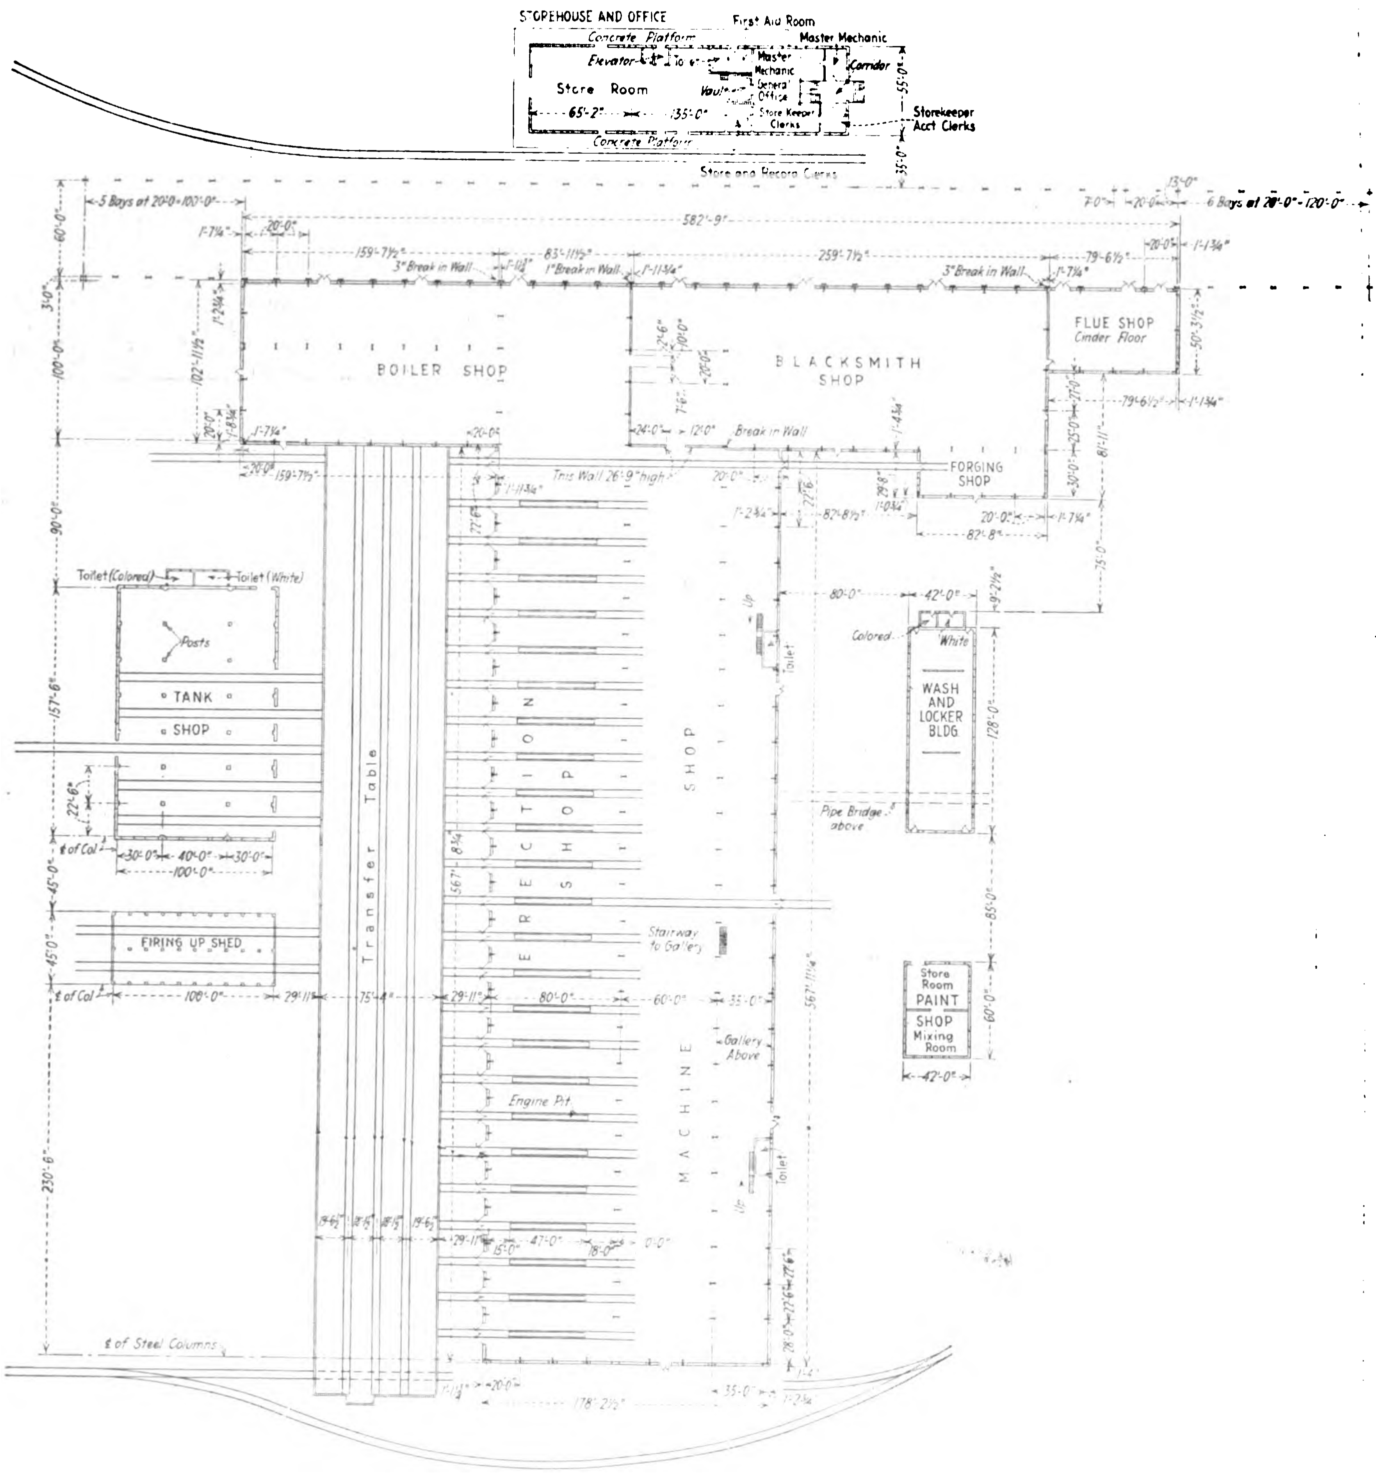
The Finley installation, named after W. W. Finley, president of the Southern from 1906 to 1913, includes both a locomotive and car repair shop. The locomotive repair unit consists essentially of a T-shaped structure in which are housed a 24-pit erecting shop, and machine, boiler, smith, flue and forging shops. Each shop is laid out for its efficient operation as an individual unit as well as in its relationship to each other. As shown in the floor plan of the locomotive repair unit, the boiler, blacksmith,

forge and flue shops are located in the horizontal arm, while the erecting and machine shops are located in the vertical arm of the "T."

The section containing the erecting and machine shops is 178 ft. wide by 568 ft. long. The erecting shop is of the transverse type with a width of 80 ft. and a clear height of 47 ft. to the roof trusses. The locomotive pits, 24 in number, are 47 ft. long. Each pit-track extends 10 ft. into the machine shop area on one side and to a 75-ft. 4-in., electrically operated transfer table on the other. The pit-tracks are 22 ft. 6 in. from center to center.

The machine shop consists of two bays 60 ft. and 35 ft. wide, respectively. The 35 ft. bay is arranged with a gallery floor running the entire length. This floor has landing extensions built out into the crane bay in order that the cranes may be used for handling materials and parts to this floor. The gallery is used for the electrical department, air room, manufacturing tool room, and the tin and jacket shops. The heavy machine tool equipment is located on the main floor. Both the erecting and machine shops have flooring of wood block laid on concrete.

The boiler shop occupies approximately one-half of the section forming the horizontal arm of the "T." The fabricating department of the shop is 100 ft. wide by 240 ft. long, the erecting floor being 80 ft. by 100 ft. The



Floor plan of the Finley locomotive shops at North Birmingham, Ala.

boiler shop is divided into two bays of 40 ft. and 60 ft. each, the latter bay being equipped with a 20-ton overhead crane.

The blacksmith shop occupies the remaining portion of the horizontal arm of the "T." It is 100 ft. wide by 260 ft. long. Two additions at one end of this shop, house a 50-ft. by 80-ft. flue shop and a 30-ft. by 80-ft. section is utilized for the forging machines. The forge shop is served by a track passing along the outside of the blacksmith shop, through the machine and erecting shops and across the transfer table.

Shop buildings are well lighted

All of the shops are well lighted. A large exposure of steel sash is used in all the side walls and in skylights, monitors and clerestories. Electric illumination is provided by the installation of overhead reflectors with 500-watt lamps spaced approximately 25 ft. apart.

Wash and locker facilities have been provided for in a 42-ft. by 128-ft. brick building located near the machine and forge shops. Toilet facilities have been provided for within the shops, the main installation being on two intermediate or mezzanine floors located in the machine shop, between the main and gallery floors, as shown in the drawing on page 168.

The location of the various shops has been planned with a possible need for future expansion. Sufficient space has been left to permit another erecting and machine shop to be built on the opposite side of the transfer table. For this reason the construction of the tank shop and the firing up shed now on the opposite side of the transfer table is of a temporary nature. Both buildings are constructed of timber, the former having five tracks, of which one is a through track, and the latter having two tracks. They are respectively 100 ft. by 157 ft. 7 in. and 100 ft. by 45 ft. in dimensions.

The storehouse and office building—Assembly room for instruction classes is provided

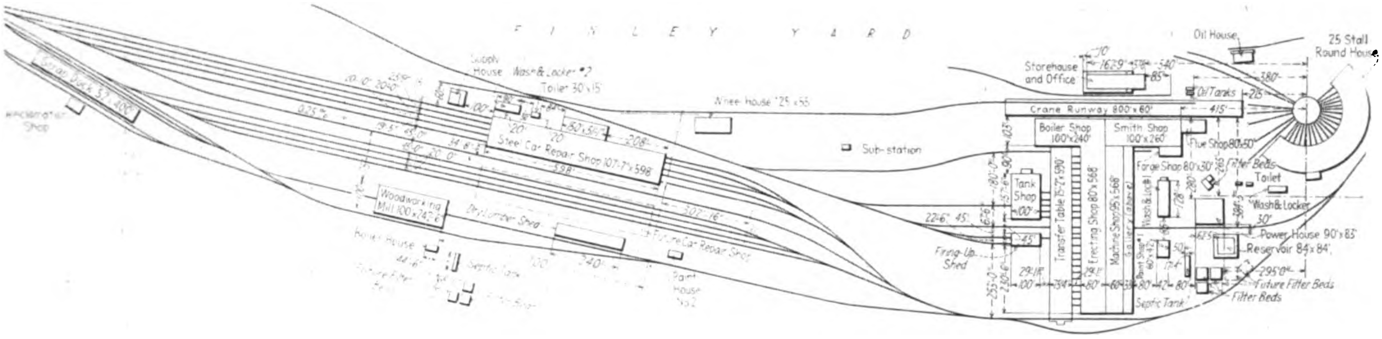
The combined storehouse and office building is a two-story structure of pleasing appearance. One end is devoted to the offices of the master mechanic and division storekeeper and the other to the storeroom. It is of concrete and brick construction with concrete platforms extending across one end and for about three-fourths the length of the building on each side. It is 210 ft. long by 55 ft. wide, the office section occupying approximately one-third of the total length of the first floor and approximately one-fourth of the second.

A large assembly room is also located on the second floor of the office building which provides excellent accommodations for staff meetings, instruction classes and a meeting place for the various shop committees.

A well equipped first aid room, in charge of a trained nurse, is located on the first floor between the offices of the master mechanic and the storeroom.

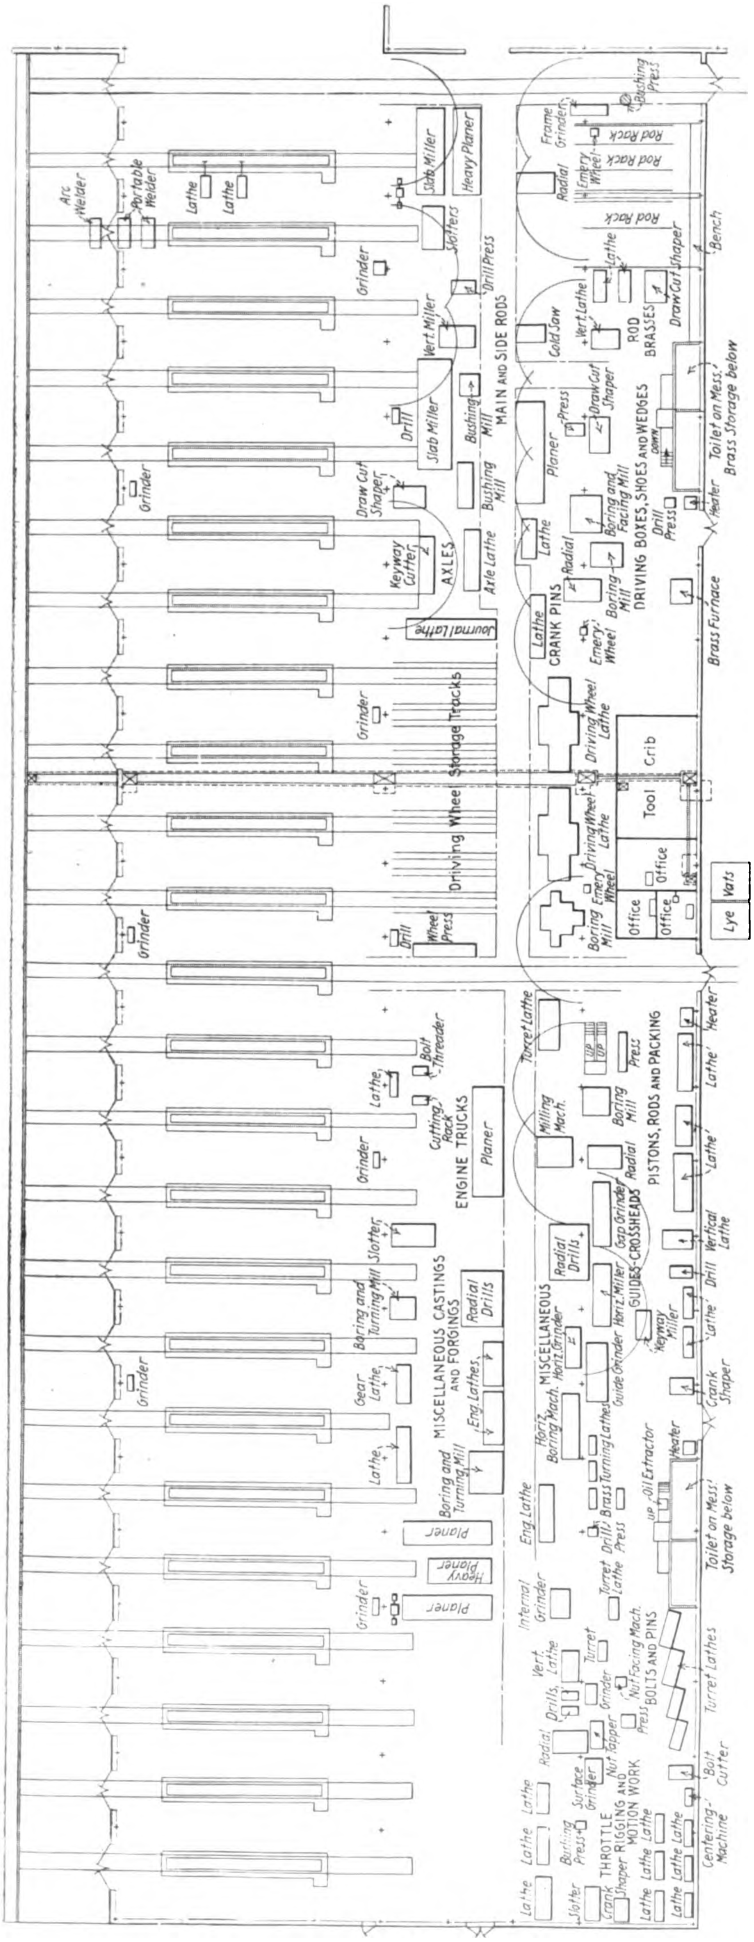
The space between this building and the locomotive shops is utilized for a casting yard. It is served by a 20-ton crane, one runway of which is carried on the walls of the shop buildings. This craneway is now 800 ft. long but it is planned to extend it so that it will also serve the wheel shop of the car repair unit.

The power house equipment consists of three 420-hp. boilers with stokers and forced draft. Overhead coal bunkers are provided which feed directly to the stokers. Two sets of hoisting equipment have been installed, one for elevating the coal to the bunkers and one for carrying up the ashes from the basement to an overhead bin, which in turn, provides some storage and gravity loading

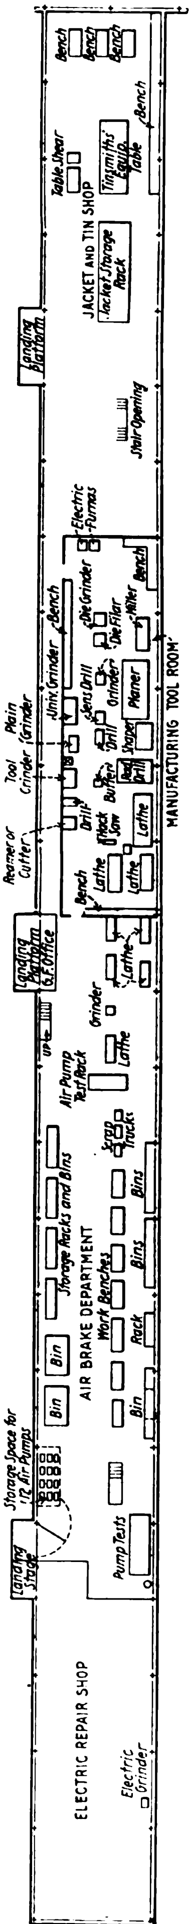


General plan of the Finley locomotive and car shops, North Birmingham, Ala.

An aeroplane view of the locomotive shops, showing the relative location of the engine house to the machine shop

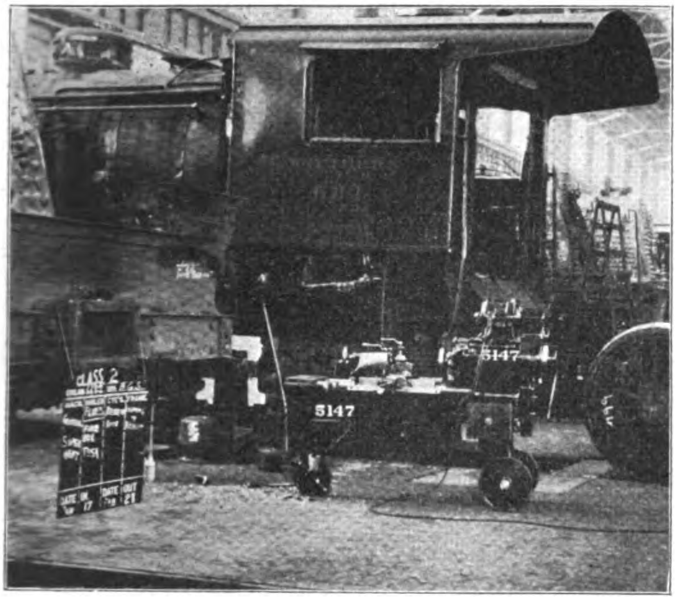


Floor plan of the machine and erecting shops, showing the machine tool layout



Machine tool and equipment layout of the air brake department, manufacturing tool room and tin shop

into the cars. The air compressor units consist of a 2,500-cu. ft. steam driven unit and a 1,500-cu. ft. motor driven unit. Exhaust steam is utilized in unit heaters which are placed along the walls and along the interior lines of the columns of the various shop buildings. A



A bulletin board showing the principal jobs to be done is hung on each locomotive

turbine generator of 300 kw. capacity has been installed in the power house for use in case of emergencies.

Excellent crane service is provided

One of the features of this installation is the excellent crane service that has been provided for all departments. partitioning wall between the two. Jib cranes have been installed to serve machines that are used for heavy material. A transfer table is provided for the transfer of engines to the erecting shop pits and the firing up shed. The same table also serves the tank shop. The boiler shops and the blacksmith shops are equipped with a full complement of heavy and light overhead cranes for the handling of boilers, hot forgings and heavy parts.

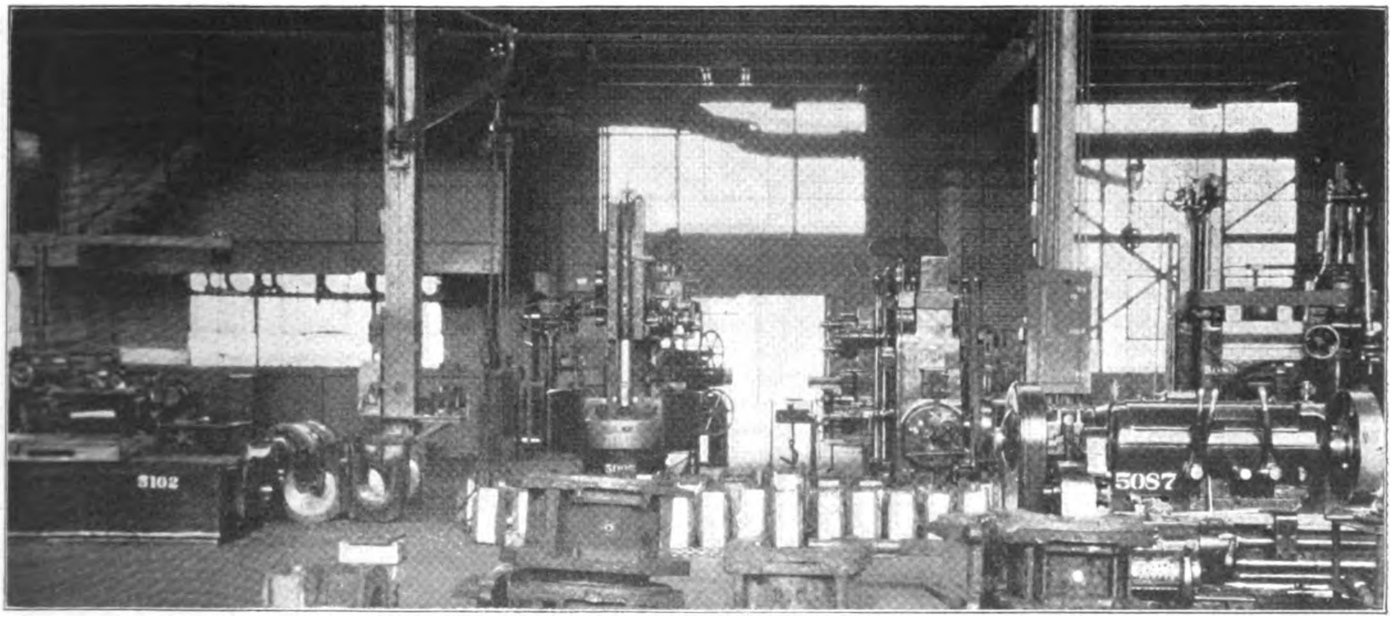
System of handling work in the erecting and machine shops

Only classified repairs are handled in the erecting shop. As soon as a locomotive is brought in for repairs, the wheels are removed and placed on the wheel storage tracks which are located in the center of the wheel shop. Each erecting gang does its own stripping and routes the various parts to the proper departments where they are inspected for repairs or scrapping. The brake and spring rigging are annealed upon arrival at the blacksmith shop and then inspected by the foreman. Valve motion parts, rods, crossheads, guides, etc., are removed by the stripping gang, sent to the lye vat for cleaning and are then routed to the various departments in the machine shop.

A work report of work to be done on each locomotive is sent to the general machine shop foreman by the erecting shop foreman. This report is then analyzed and the necessary instructions are transmitted to each sub-department head, by the general machine shop foreman.

A regular system of shop scheduling has not as yet been installed. However, a careful check is kept on the progress of the work in each department to see that the results correspond to the outgoing date of the locomotives. All material sent to the machine shop for repairs is carefully checked by the head of each department and inspected for limits and standards.

The work of unwheeling and transferring the boilers and cabs to the boiler shop is handled by the overhead



Interior view of the driving box department

The erecting shop is served by one 150-ton crane with a span of 77 ft. and two 15-ton overhead cranes with a span of 75 ft. which can be operated the entire length of the unit and into the boiler shop. The 15-ton traveling cranes of 56-ft. span are also provided for the machine shop which can also be operated the full length of the unit and into the blacksmith shop through an opening left in the cranes. A rack, which is shown in one of the illustrations, has been provided for front end covers. This rack is of sufficient strength to permit its being moved when loaded to capacity by a crane to any place desired. A high platform truck is used in the work of removing super-heater units.

Portable engine lathes are used for fitting frame bolts

in the erecting shop. Bolts are drawn from stock, cut to length and are delivered to the bolt department where they are centered on a centering machine. They are then turned to a fit on the small portable engine lathe and then threaded. Considerable attention is paid to the accuracy of these fits and with the lathe located close to the locomotive, it is thought that more satisfactory individual fits can be made, rather than by manufacturing the bolts in quantity to certain standards and then reaming the holes to fit the bolts.

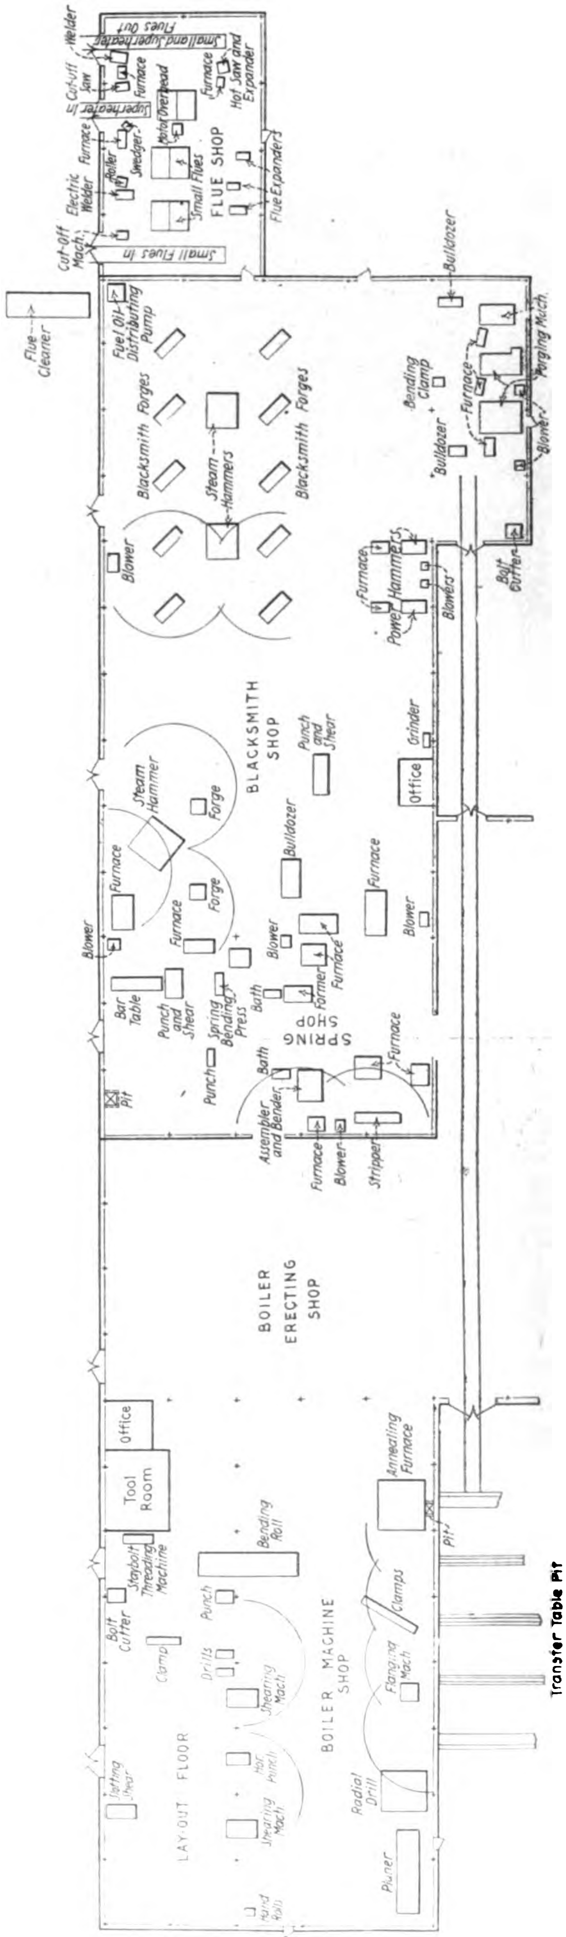
A feature of the supervision of both the erecting and machine shops is the bulletin board placed on each locomotive undergoing repairs. This bulletin board, one of which is shown in an illustration, has space provided for entering the important items of repairs that are being made on the locomotive. The class of repairs is shown at the top of the board. Directly underneath is shown the number of the locomotive and the division to which it is assigned. Four columns for listing the repairs to the machinery, boiler, cylinders and frame are ruled vertically and sufficient space is left at the bottom to show the incoming and outgoing dates. These boards are hung on the end of each locomotive towards the machine bay. The information on these boards enables the master mechanic and his assistants to check immediately the progress of the work on each locomotive and in cases where unsatisfactory progress is shown, to take prompt measures towards improving the situation.

Progress reports are made at weekly staff meetings

A meeting of the supervisory forces is held on Friday of each week. Each department head submits a report of the progress of the work for each locomotive that is being performed in his department. Each foreman, knowing the progress of the work going through the various other departments, can then adjust the work under his supervision so that there will be no delay in the outgoing date of the locomotive from the erecting shop. The success of this system is shown by the fact that there have been comparatively few variations from the outgoing dates originally set since the Finley shops have been placed in operation.

Daily report of labor and material expenses is made to the master mechanic

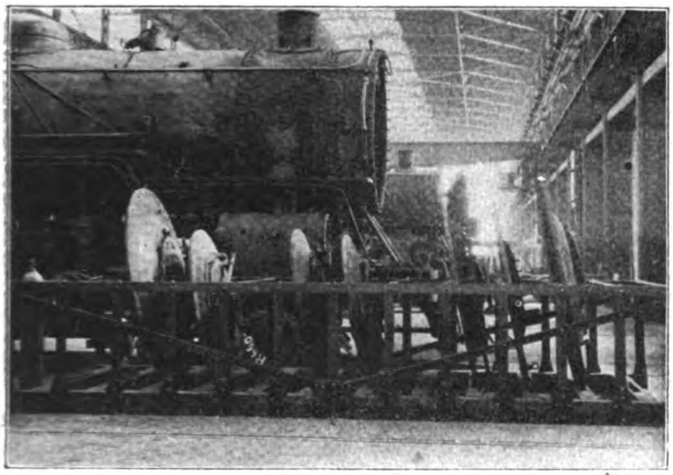
Frequent inspection trips are made through the shop each day by the master mechanic. These inspections enable him to make a note of any unsatisfactory condition and to take proper steps towards its elimination. These inspections are supplemented by a system of labor and material expense control. As soon as a locomotive is brought into the erecting shop for repairs, a record is kept of labor and material expenditures for each day. All work performed in the various departments of the machine, boiler, smith and flue shops is charged direct to the locomotive. Data for these costs is collected by each department foreman from the time cards of the men and requisitions that have been filled by the stores department. These expenses are compiled for each day by a clerk in the master mechanic's office who enters the day's total along with the grand total of labor and material expenditures, on each locomotive to-date, on a chart which is laid on the master mechanic's desk each morning. This chart is ruled with columns for each locomotive in the shops. At the extreme left is a column listing the days of the month, each date being assigned to a separate line sufficiently wide to accommodate both the daily and grand total figures. A column at the right of the column showing actual labor and material expenditures shows the allowance made by the stores department for scrap. The actual expense for repairing each locomotive is obtained



Machine tool and equipment layout of the boiler, blacksmith, forge and flue shops

by subtracting the amount shown in the left-hand column from the amount shown in the right-hand column and this figure is entered in a third column.

No account is taken of shop expense or overhead items as the object of this report is to give the master mechanic a basis upon which to estimate the efficiency and progress of shop production. In other words, the principal value of the figures shown in the report is obtained by comparison with previous expenditures for similar class repairs.



A rack for front end covers designed to be moved by crane

When necessary, the master mechanic is also able to determine quickly the total cost of each day's operation. General overhead charges are kept on a separate record to which the master mechanic can refer at any time. Although considerable emphasis is laid on keeping production costs down, quality of workmanship is not sacrificed in the least. Careful inspection of all work by the department foremen, supplemented by frequent inspections by the master mechanic and general machine shop foreman insures a high standard of workmanship.

Castings and heavy materials are stored in a yard provided with overhead crane service—Platforms for the storage of material are being built in this yard

Machine tools are motor driven

Practically all the equipment used in these shops is electrically operated, alternating current being supplied for the machine tools, yard cranes and transfer table. Direct current is used for the cranes in the locomotive shops. The power, which is purchased locally, is alternating current and is stepped down and used where needed. The current is used also to drive two 150-kw. motor-generator sets for the supply of direct current.

The shop is very largely equipped with the latest design of machine tools and shop equipment. A few machine tools of more recent design were moved from the Alabama Great Southern shops. The large machine tools designed to work on heavy parts are located where they can be served by the 15-ton cranes. The smaller machine tools and work benches are placed beneath the gallery floor and jib cranes have been installed at various strategic points to assist in the handling of material.

The rod department is located at the end of the machine shop next to the blacksmith shop. This location makes it comparatively easy to route the rods directly from the smith shop for finishing without back-tracking or interfering with the work of other departments. Rods are completely finished and bushed in this department from whence they are routed directly to the locomotives in the erecting shop. Racks are provided that hold the rods, to which bushings are being fitted, at a convenient height for calipering and trial fitting.

The repair units for driving boxes, shoes and wedges, crank pins and axles are located in close proximity to each other. Each unit is complete in itself and the various machine tools and shop equipment are located so as to facilitate the work of each department. The axle lathes are located where they can be served advantageously by the 15-ton cranes from and to the adjacent wheel department. The driving box and shoe and wedge departments extend beneath the gallery floor. Driving boxes are bored and faced in the same operation on a Sellers vertical boring mill. This job from floor to floor has been performed in 9 min. Eccentric grooves are cut for holding the brass liners to the driving box face. These grooves are cut 2½ in. wide at the top and are then narrowed down to 2 in. at the bottom. By the use of this method it is unnecessary to drill holes in the face.

Shoes and wedges are gaged end to end on the platen of a planer. A jig that will hold four tools is now being built so that both the inside and outside surfaces can be finished at the same time.

Two large driving wheel lathes are located at the ends

of the wheel storage track. All of the machine tools in the wheel department are grouped around the wheel storage track so that they may be readily served by the 15-ton cranes. As the machine shop is also required to handle the work of the enginehouse, provisions have been made in the wheel department to turn unmounted tires. A jig has been devised for holding the tire to the face plate, as shown in Fig. 1. This device is of heavy construction and is secured by means of bolts, the heads of which are inserted in the grooves of the face plate. The clamp *B* which pivots on the pin *D* is tightened against the tire by means of the wedge *A*. The tire is held securely by the clamp against the shoulder *E*. The average time for turning engine truck wheels is 20 min.

The piston rod, guide and crosshead, throttle rigging and motion work departments are arranged in order of work from the wheel department to the end of the shop. Provision has been made to handle miscellaneous castings

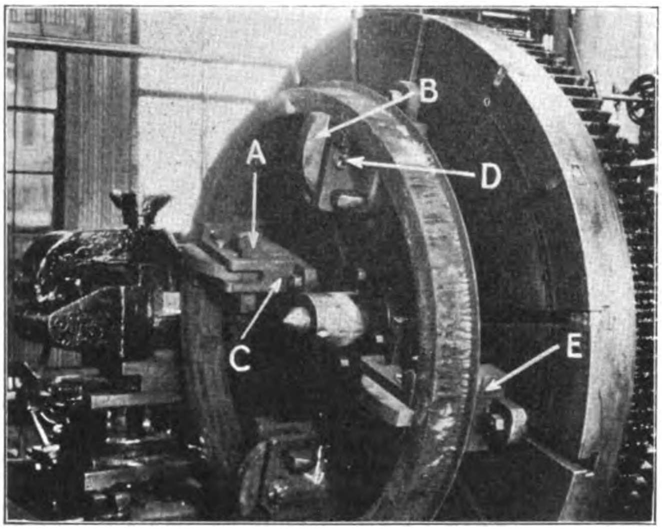


Fig. 1—Jig for holding unmounted tires on the face plate of a wheel lathe

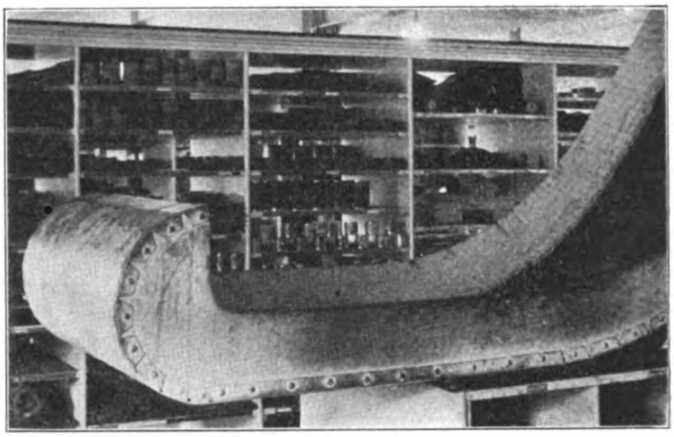
and forgings on a separate group of machine tools. Valve packing rings are finished by chucking them in a 16-in. lathe. Piston rods are ground on an 18-in. by 30-in. by 96-in. Morton cylindrical grinder. A 4-in. Diamond face grinder is used for finishing guide bars, etc. All motion work pins, crosshead pins and knuckle pins are rough turned from the bar and then threaded.

The toolroom is divided into two sections. The repair or manufacturing section is located on the gallery floor while the disbursing toolroom is located directly beneath on the floor of the machine shop. Communication is provided between the two units by a dumbwaiter type of small hand elevator.

Disbursements are made by means of the check system. Tools requiring repairs or grinding are placed in the dumbwaiter by the disbursing unit attendant and hoisted to the manufacturing unit above. Reconditioned tools are



Articles stocked on the second floor of the storehouse are sent to the delivery window by a chute

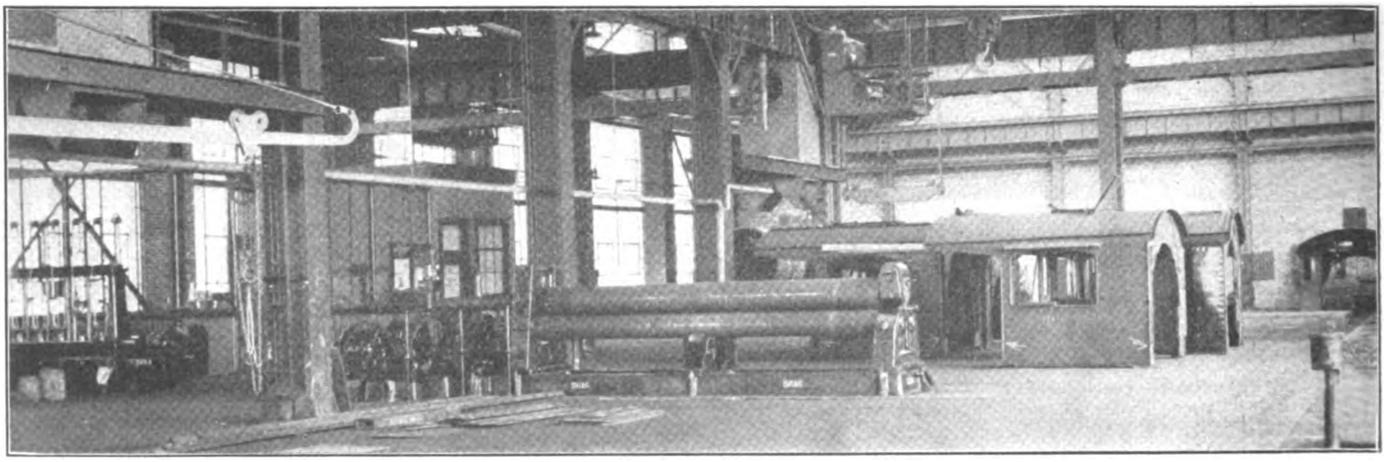
transferred to the disbursing unit below by the same method.

Boiler and flue shop work

The location of the boiler shop with respect to the erecting shop makes it comparatively easy to lift the boiler from the frame and move it to the boiler shop by crane.

Cab repairs are also made in the boiler shop. Boiler sheets are flanged cold on a ¾-in. McCabe pneumatic flanging machine. In this shop, which is well equipped to take care of heavy boiler repairs, is a 48-in. reinforced shearing machine, a Southwark horizontal bending roll, a six-spindle staybolt threading machine, a 16-ft. plate edge planer, a 6-ft. Ridgeway radial drill, and six 2-in. double Acme bolt cutters, all of which are new machines.

The flue shop is located at the opposite end of the horizontal arm of the "T" from the boiler shop. It is well equipped and organized to handle work on a production basis. Flues are handled from the erecting shop to the flue shop by means of a carrier built somewhat in the form of a large basket, which can be picked up by crane. The carrier is placed on a truck and taken by rail directly to the flue shop. Two different gangs are employed, one on tubes and the other on flues, the arrangement of the



Interior view of the boiler shop

machinery being such that all movements are in a straight line as much as possible, thereby eliminating excessive handling. All tubes and flues are tested after being welded.

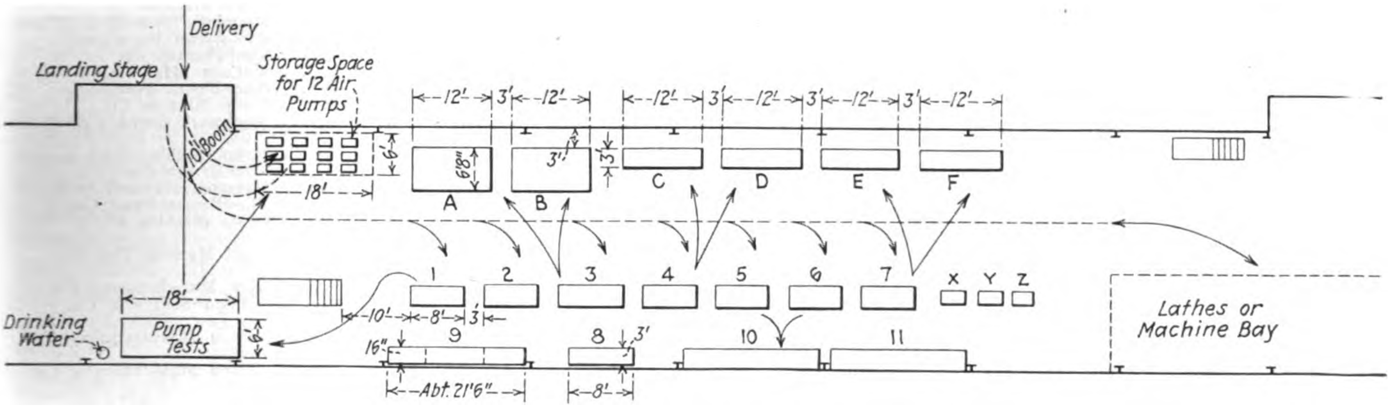
The blacksmith shop

The blacksmith department, located between the boiler and flue shops, is well arranged for efficient performance. Two 1,500-lb. single frame steam hammers are located in the center aisle between two lines of forges. A 3,400-lb. hammer for handling rods and heavy forgings is also provided. An 18-in. double-end punch and shear, and a reverse bulldozer is also included in the new equipment.

The forge shop is located in a bay which is served by a track running through the machine shop. Many locomotive forgings are made in the blacksmith shop of scrap material, such as tender drawbars, binders, equalizers and other parts requiring this kind of material. Radial staybolts used in the boiler shop are upset on special machine tools and dies. The new equipment in the forge shop includes a 3½-in. Ajax heavy-duty twin geared forging machine and a 1⅞-in forging machine.

The air brake department

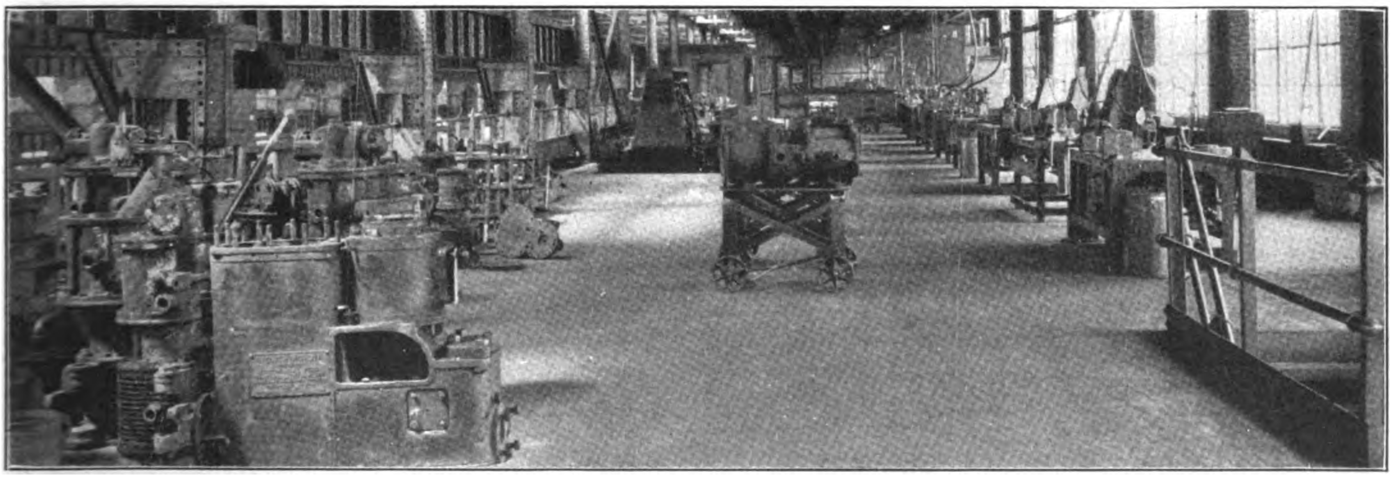
A feature of the shop operation is the organization of the work in the air brake department. This department is located on the gallery floor of the machine shop. Material is delivered by one of the machine shop cranes to a landing stage which projects out into the machine shop bay. The various parts are routed, as indicated by the dotted liens shown in the floor plan of the air brake department. Benches equipped with tools and facilities for repairing air pumps, power reverse gears, injectors and lubricators, cab cocks, feed valves and governors, miscellaneous air brake parts, and valve stems and piston packing are arranged along the outside wall in the order named. Suitable storage bins arranged along the gallery rail have been provided for storing the various parts handled in the department. Scrap brass, steel and cast iron are deposited in separate three-wheeled trucks.



Drawing showing a proposed routing of work through the air brake department

1—Air pump bench.
2—Power reverse bench.
3—Injector and lubricator bench.
4—Cab cocks.
5—Feed valve and governor bench.
6—Miscellaneous air brake bench.
7—Valve stem and piston packing bench.
8—Triple decked storage rack for gages on top deck, safety valve on middle deck, and whistles on lower deck.
9, 10 and 11—U-shape material bin.
A and B—Storage bins for injectors and lubricators.
C and D—Storage bins for cab cocks.
E and F—Storage bins for valve stem and piston packing.
X—3-wheel truck for brass scrap.
Y—3-wheel truck for steel scrap.
Z—3-wheel truck for cast-iron scrap.

Portable benches or wagons for air pumps and feedwater heaters, a number of which are shown in the interior view of the air brake department, have been provided. Holes are punched in the top to suit the different sizes of air pumps and feedwater heaters so that the work can be bolted securely to the wagon. By using this wagon the pump or heater undergoing repairs can be moved from bench to lathe, or vice versa, according to the needs of the mechanic.



The air brake room is located on the gallery floor of the machine shop—Portable benches have been provided for air pumps and feed-water heaters

The stores department

The organization of the stores department is closely in-

List of New Machine Tools Installed in the Finley Locomotive Shops of the Southern Railway, North Birmingham, Ala.

No.	Description	Manufacturer or jobber
1	Chaser grinder	P. H. McArdle Equipment Co.
1	Sundstrand internal radius length and surface grinder	Manning, Maxwell & Moore.
1	Lucas cold saw	Carbon Steel Co.
1	16 ft. Plate edge planer	Consolidated Machine Tool Corporation of America.
1	Tool grinder with Morton clamp center emery wheel	William Sellers & Co.
1	30 in. by 14 in. Quick change gear lathe	Cincinnati Lathe & Tool Co.
1	18 in. by 10 in. Quick change gear lathe	Cincinnati Lathe & Tool Co.
1	Jackson duplex typeless die linker	Walcott Lathe Co.
2	Motor driven wet tool grinder	Safety Emery Wheel Co.
1	3 in. Drill grinder	William Sellers & Co.
1	Springfield Mfg. Co. frame grinder	D. Nast Machine Co.
2	3 in. by 36 in. turret lathes cross feed	Jones & Lawson Machine Co.
1	6 ft. Ridgeway radial drill	Niles-Bement-Pond Co.
1	3,400-lb. Single frame steam hammer	Niles-Bement-Pond Co.
1	Double head axle lathe	Niles-Bement-Pond Co.
1	36 in.-44 in. Side head boring mill	Niles-Bement-Pond Co.
2	1,500-lb. single frame steam hammer	Niles-Bement-Pond Co.
1	44 in. Vertical boring and turning mill	Niles-Bement-Pond Co.
1	53 in. Boring and turning mill	Niles-Bement-Pond Co.
1	Universal collar hexagon turret lathe	Warner & Swasey Co.
6	2 in. Double Acme bolt cutter	Niles-Bement-Pond Co.
1	4½ in. Four-spindle Acme nut tapper	Niles-Bement-Pond Co.
1	48 in. Putnam car wheel borer	Manning, Maxwell & Moore.
2	18 in. Dresses universal monitor lathe	Manning, Maxwell & Moore.
1	20 in. Mechanics back geared compress drill press	C. A. Thumb.
1	28 in. Mechanics Rockford back geared compress drill press	C. A. Thumb.
1	18 in. by 10 in. Heavy engine lathe	Cisco Machine Tool Co.
1	48 in. Reinforced shearing machine	Cleveland Punch & Shear.
1	18 ft. by 8 ft. Bayer & Emmes heavy duty lathe	Manning, Maxwell & Moore.
1	90 in. Driving wheel lathe	Niles-Bement-Pond Co.
1	16 in. by 36 in. Pratt-Whitney Model B tool room lathe	Niles-Bement-Pond Co.
1	12 in. by 30 in. Pratt-Whitney Model B tool room lathe	Niles-Bement-Pond Co.
1	18 in. by 30 in. by 96 in. Grinding machine	Norton Company.
1	18 in. by 8 ft. Heavy duty geared head engine lathe	American Machine Co.
1	Car wheel lathe	Niles-Bement-Pond Co.
1	Reverse bulldoser	Williams, White & Co.
1	84 in. Diamond heavy bar grinder	Manning, Maxwell & Moore.
1	Victor nut facing machine	Manning, Maxwell & Moore.
1	18 in. Double end punch and sheer	New Doty Manufacturing Co.
1	42 in. by 14 ft. Reversing drive planer	Niles-Bement-Pond Co.
1	30 in. Vishold vertical boring and turning mill	Wind Machine Co.
2	24 in. Bement slotter	Niles-Bement-Pond Co.
1	500-lb. Bradley upright helve hammer	Niles-Bement-Pond Co.
2	500-lb. Bradley upright helve hammer	Niles-Bement-Pond Co.
2	36 in. by 16 ft. LeBlond engine lathe	Niles-Bement-Pond Co.

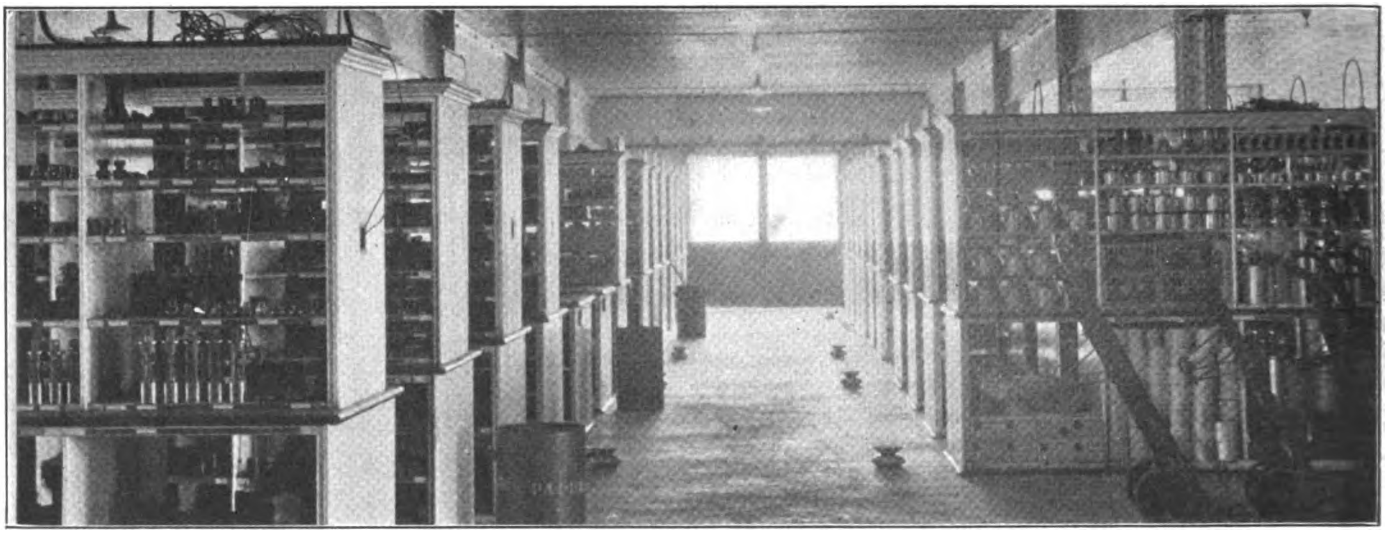
terlocked with that of the mechanical department in the management of the Finley shops. In order to prevent overstocking and ordering of material that is not being used, a careful check is made of all material on hand by the stores department. Daily reports are made to the stores department by the mechanical department as to what material will be needed in the future and the approximate date.

It is planned to install a delivery system, operated by attendants who will wear red caps, on a 15-min. schedule. The object of the red caps is to easily distinguish the men charged with the responsibility of delivering and collecting material, from the other workmen. Many instances occur when it is desired to expedite a requisition and considerable time can be saved by not having to hunt for a delivery man. Stations will be established in each department provided with a hook for requisitions and bins for the collection of scrap.

Fuel oil is stored in a large tank located near the oil house. Deliveries are made by pipe lines to various stations in the shop. An inventory is taken every 30 days and the amount used is charged to the mechanical department.

At present time requisitions for material from the storeroom are filled at a delivery window opening onto the platform on the side of the stores building next to the boiler-



The store room is equipped with open shelves—The unit piling system is employed

shop. The interior arrangement of shelves, racks and bins is well planned and the unit system of piling is used for practically all material. Articles on requisitions for material stored on the second floor are delivered to the attendant at the delivery window by means of a chute. An elevator, with a direct entrance from the outside platform, is also provided for the conveyance of trucks and heavy material to and from the second floor. A cage for storing tools and other valuable material is located on the second floor. Only one key to the door of this cage is issued at a time and it is given to one man who is held responsible for all material contained therein.

Results accomplished since starting operation

Mention should be made of the exceptional results that have been accomplished in the Finley shops as compared to the old system of handling repairs in the shops of the Alabama Great Southern. As previously mentioned the first locomotive undergoing class three repairs at Finley was turned out of the shops in 13 eight-hour working days at a total reduction in cost of labor and material of approximately 40 per cent over the cost to do the same work in the old shops. At the present time class three repairs average 18 days, a reduction in time over the old record of from 45 per cent to 50 per cent and a reduction of labor and material expense of 43 per cent. The cost of applying a new firebox, including general repairs to machinery, has been reduced by 33½ per cent to 40 per cent. Similar reductions have also been accomplished in practically all classes of repairs.

No small share of the credit can be given to the excellent spirit of co-operation and interest that has been shown by the men and the supervisory forces. This spirit is due largely to the efforts of C. E. Keever, master mechanic, Finley shops, and H. W. Miller, vice-president, who personally placed the shops in operation on October 1, 1924, at which time there were 12 locomotives awaiting repairs. The new shops were planned under Mr. Miller's general direction, the machine tool and mechanical department details being worked out under the direction of R. L. Ettenger, mechanical assistant to the vice-president.

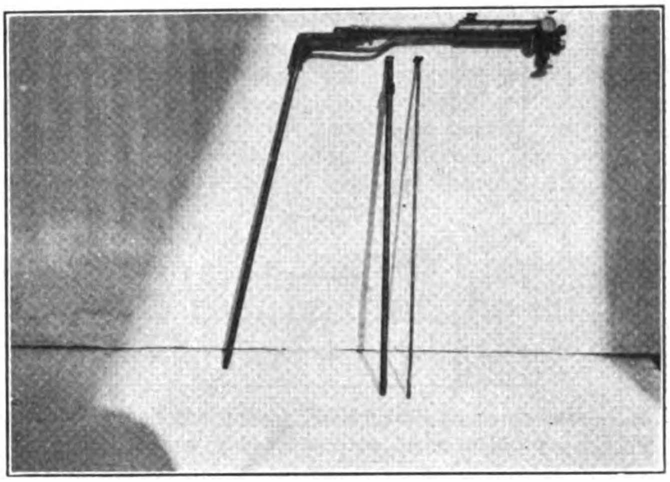
Saving time with an acetylene cutting torch

By David Pearson

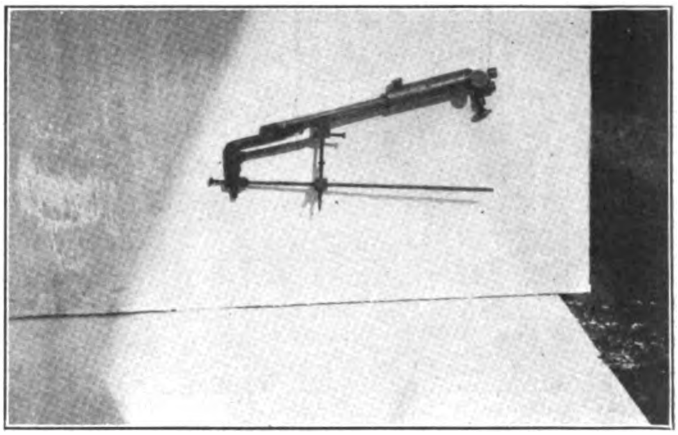
Welder foreman, Atchison, Topeka & Santa Fe, San Bernardino, Cal.

CUTTING circles with a hand acetylene cutting torch is a tedious, crude operation at the best. The operator experiences great difficulty in keeping his hand steady enough to produce an even cut. Fig. 1 shows a simple arrangement whereby these objectionable features are greatly reduced thus effecting a considerable saving in time and labor. The device consists of a radius bar one end of which is fixed to the torch tip. There slides along this bar a pivot bar one end of which fits over and slides along the acetylene pipe of the torch. Suitable adjustments are provided to take care of the various radii.



Extended cutting tip for getting into inaccessible places

The acetylene operator is often confronted with the problem of trying to reach inaccessible places with the cutting torch. Fig. 2 shows an extension tip for reaching such places. It is made from a piece of copper tubing and a rod. One end of the tubing is threaded and fitted with a nipple which is screwed in where the cutting tip normally goes. The rod fits inside of the tubing. These extensions have been used to lengths of 10 and 20 ft. The device can be readily used in connection with boiler repair work.



Attachment for cutting circles with an acetylene torch

Tool for machining ball rings on a lathe

Ball rings shaped like the one shown in Fig. 1 are sometimes used in connection with piston rod packing, valve stem packing, and at other places on steam locomotives. The shape of the rings presents no particular difficulty in machining operations when they are made in such quantities as to justify tooling up a machine suitable for the job. But when they are finished on an engine lathe and shaped to a template, the results are not always satisfactory. Changing the parting tool and forming tool requires careful adjustment each time a change is made. This method involves repeated trial cuts and settings, with attendant loss of time.

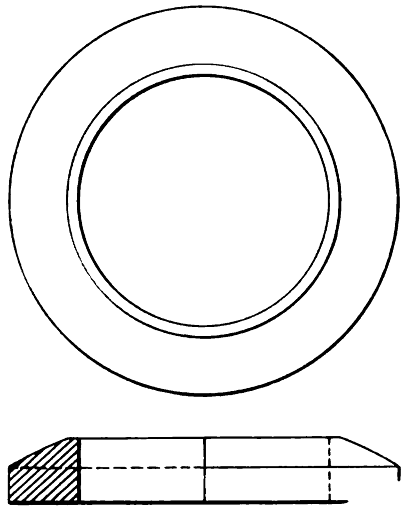


Fig. 1—Ball rings, as shown here, present a difficult machining problem when not produced in quantity

The tool shown in Fig. 2 is made by chucking or clamping to the face plate of a lathe a piece of tool steel of suitable section and by boring the radius *A*. Care must be taken in setting the piece to place it in such position as to have the radius extend beyond the diameter of the rings to be machined. After the radius *A* is completed the work is reset and the radius *B* is machined, as shown in Fig. 2, half through the thickness of the piece, reversing the operation on the opposite end. This brings the cutting edges of the opposite ends along the center line, insuring the contour of the finished work to be of suitable radius.

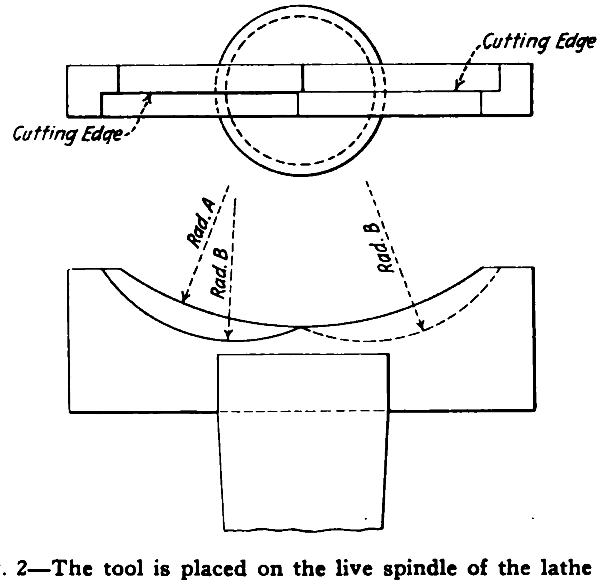

Fig. 2—The tool is placed on the live spindle of the lathe and adjustments can be made by moving the tail stock

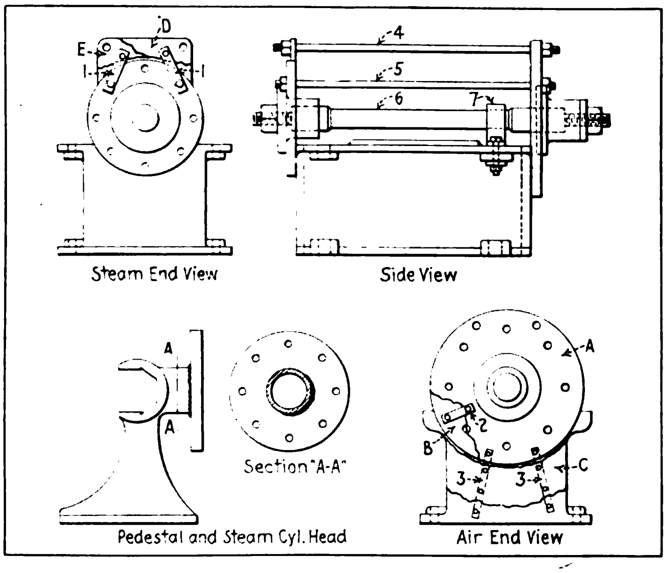
The shank is slotted endwise to receive the cutter. If it is desired to use different cutters in the same shank they may be positioned by the use of a centering dowel. The shank is turned to fit the tail stock spindle.

In using a forming tool of this kind, any variation in the alignment of the tail stock spindle with the live spindle will interfere with an equal distribution of the cut on the opposite ends of the tool. In placing the tool on the spindle it is well to set the cutter at an angle of about 45 deg. from the horizontal. In this way a slight side movement of the tail stock will furnish sufficient adjustment to center the tool and to overcome interference due to unequal spindle heights.

Oxy-acetylene welding of cast iron with brass

By V. T. Kropidlowski

A small, Ingersoll Sargent 10-in. by 10-in. by 10-in. straight line air compressor was broken almost beyond repairs, presumably due to a piston rod nut becoming loose and falling down in the clearance space. A number of parts were broken away entirely. The air cylinder head integral with the main frame was broken from the frame in two pieces as shown in the illustration at *A* and *B*. A piece *C* broke out from the end of the frame. Two pieces, *E* and *D*, were broken from the steam cylinder end of the same frame. The other steam cylinder head, integral with the pedestal, was cracked, and the center was knocked out of the other air cylinder head.



Method of holding broken pieces together when making a brass weld on cast iron

As it was imperative that the compressor should be repaired as quickly as possible, the broken parts were set up in their relative positions and held in place by bolting them with strips of iron such as designated by 1, 2 and 3 in the drawing. A mandrel, 6, was turned up in a lathe so that its ends fitted snugly in the stuffing boxes of the two cylinder heads. The ends of the mandrel were

threaded to take 1¼ in. nuts which held the heads rigidly in place against expansion and contraction during the process of welding. A strap, 7, with a prop underneath the mandrel was bolted to the frame near the air end to hold the mandrel parallel with the guides. In addition, rods 4 and 5 were used.

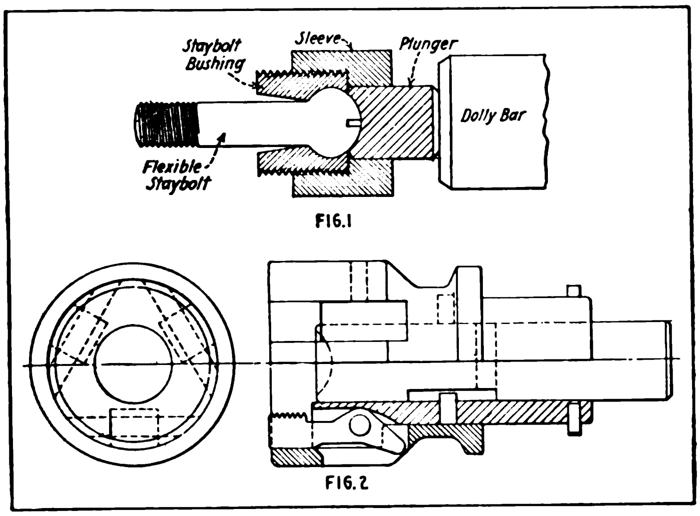
The oxy-acytelene method of welding was used, the welding material being brass. The compressor was of cast iron and if iron filler had been used the work would have had to be heated to redness, causing the casting to crack in the thinner sections at the time of cooling. In using brass as a filler, it was only necessary to heat the work slightly. There is a further factor of safety in using brass because it possesses a quality of flexibility which prevents cracks in the welds by reducing the strains set up by contraction when cooling. The casting was preheated by a gas burner, made from a ¾-in. pipe having ⅛-in. holes drilled in it similar to those in the hoops used in heating driving wheel tires.

When the job was done the casting was practically perfect in alinement. The air cylinder head *A*, was a scant 1/32 in. out vertically, which could have been easily dressed by hand, had it not been that it was readily faced in a 53-in. boring mill. The cylinder head integral with the pedestal was repaired by grooving around the crack and filling in with the acetylene torch using brass as a filler. The front air cylinder head which had the center knocked out was repaired by boring the center and threading it. A brass plug was then made, screwed in and welded in place.

The whole job cost $385 including a general overhauling which was not due to the accident. The job was completed within a month.

An improved dolly bar for holding on flexible staybolts

IT has long been known that the old method of holding on flexible staybolts for driving was slow and inefficient. A number of devices have been developed with a view to eliminating some of the drawbacks. Many of



Old and new devices for backing up flexible staybolts

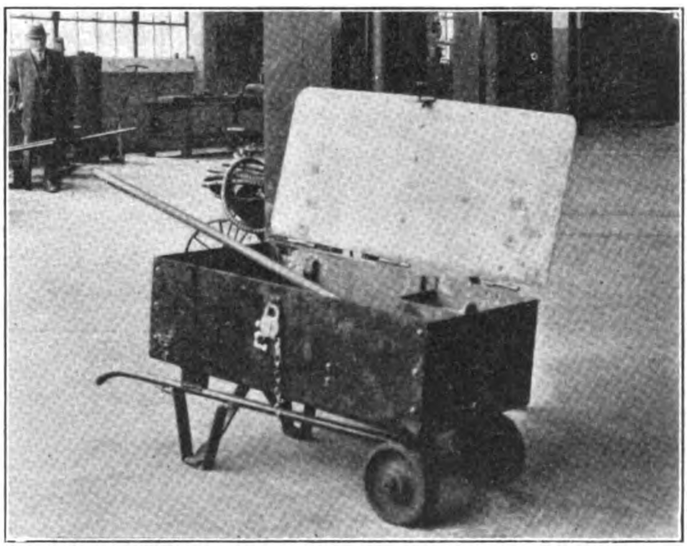
these have been found exceedingly helpful and in the list can be included the one described below which was developed at the Boston & Maine shops, Billerica, Mass. In the old method, as shown in Fig. 1, it is necessary to screw on the bushing sleeve for directing the plunger and for holding it in place. After the driving operation, time is required to remove it and fit it to another bushing. In driving a complete installation of bolts a great deal of valuable time is thus wasted in an operation that might be eliminated.

In the case of the new holder-on, as shown in Fig. 2, the operation can be done instantly. The opening sleeve which slides on the body of the device, when drawn back moves the cams actuating the three threaded gripping dogs and allows the holder-on to be easily slipped into place on the bushing. When the sleeve is moved back to its normal position these dogs grip the bushing threads securely and the operation can go forward. The plunger, which also moves in the body of the tool, is backed up by the dolly bar exactly as in the case of the old type holder-on.

To remove the device from the bushing after the driving operation is completed, it is only necessary to draw back on the control sleeve and the grips are instantly released. The device can of course be made of any practicable size—the one shown in Fig. 2 being designed to fit 1¾-in. flexible staybolt bushings having 12 threads per inch.

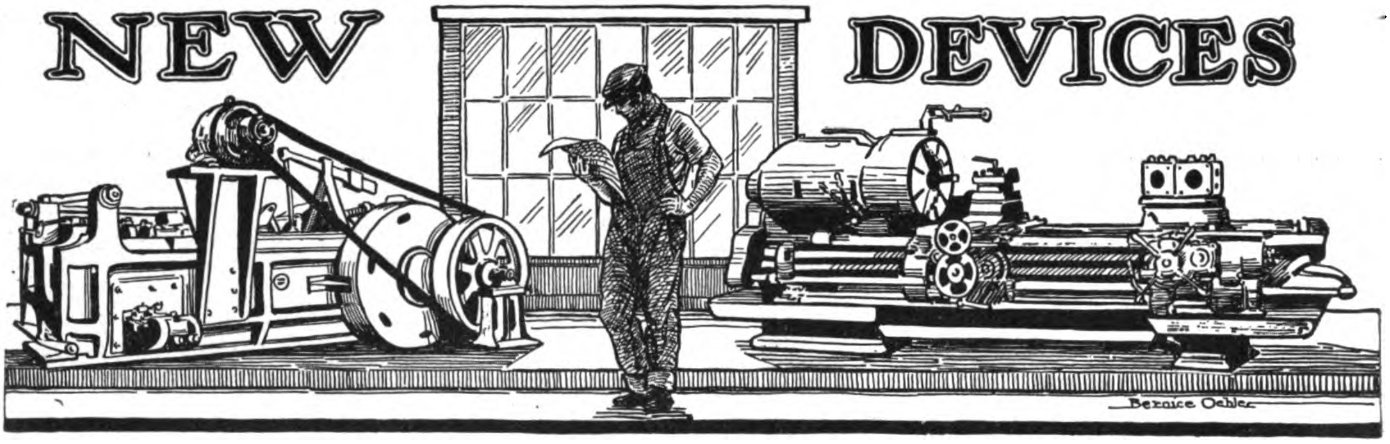
Portable tool box for the engine-house mechanic

PORTABLE tool boxes of the type shown in the illustration are used in the engine houses of the New York Central at its Selkirk terminal near Albany, New York. It is constructed of light sheet metal with a raising lid, which is provided with a hasp. Several small compartments for small tools are placed near the top so that the entire bottom of the box is left clear for the larger and heavier tools. The truck frame is constructed of two



A tool box which insures the enginehouse mechanic that his tools will be available when needed

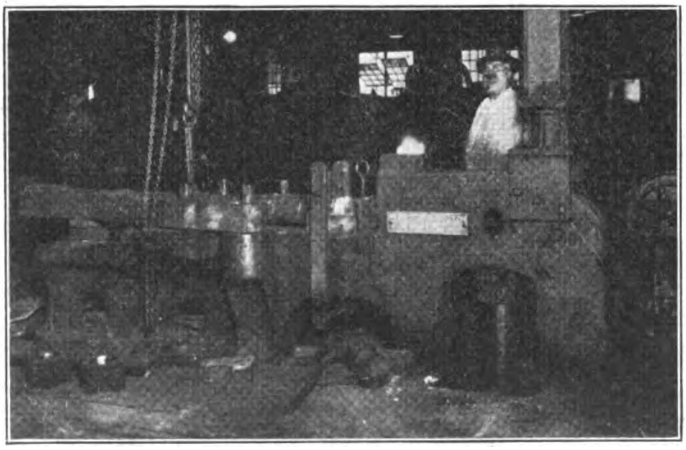
lengths of extra heavy 1-in. pipe, which are extended so as to form the handles, and 1¼-in. by ¼-in. rolled steel bar. It has proved to be very convenient in enginehouse work. Each mechanic has his own tool box which is identified by a number stenciled on the side. Individual padlocks may be used to lock the box when it is not in use and the mechanic is always assured of having a full complement of tools when needed.



Adjusting machine for the blacksmith shop

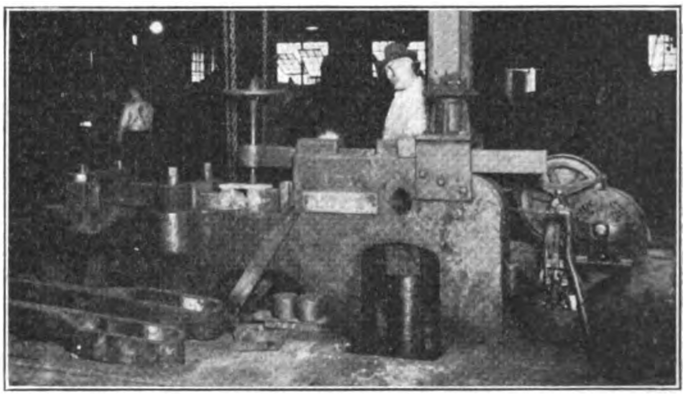
LENGTHENING, shortening and straightening by hand the various parts of the running and valve motion gear of a locomotive has always been considered a slow and inaccurate method of doing this work. The Walter Stock Adjusting Machine Company, Toledo, Ohio, have placed on the market an adjusting machine which has apparently solved this problem. It is made in four types all of which are identical in design, the only difference being the kind of power used for operating them. The type recommended for most railway shops is the one equipped with an electric motor driven hydraulic pump. This type is not dependent on any other equipment except electric power which is generally available and seldom out of service for any length of time. It is also always ready to operate without first starting up some other power unit such as the pumps on a hydraulic accumulator.

The construction of the machine is very simple, consisting of a frame, two toggle links, a ram, a filler, wedge and sliding block, four eccentric gripping cams, a clamping bar complete and two binding links. The two toggle links and the ram are joined together. The end of the rear link rests in a recess provided in the frame and is held in position with a pin. When the machine is in operation no pressure is exerted on any of the pins joining the links and the ram. Provision is made in the frame for the reception of the filler block, the sliding block, the two eccentric gripping cams and the wedge block.



Shortening an axle in the Walter Stock adjusting machine

When using the machine for shortening operations, the work can be held by either the forward or rear cams. If the rear cams are used, the sliding block is prevented from moving by placing the wedge block in one of the recesses of the frame provided for this purpose. When the pressure is first applied there may be some little slipping of the piece before the cams will grip it. Should the ram reach the end of its stroke before the operation is completed, the pressure should be released, and the space filled up with pieces of suitable dimensions, and the process repeated until the necessary adjustment is made. One end of the work is held by the cams, the other end is in contact with the ram, and the heated portion is between the two. As the pressure is applied the ram, pushing against the end of the work, upsets the part in the heated area.

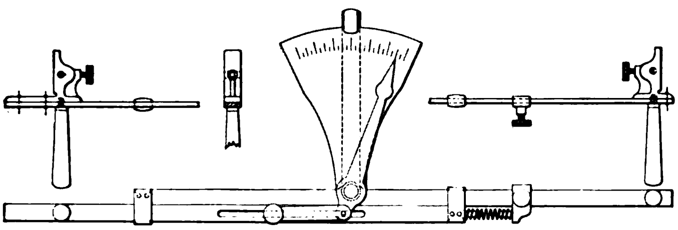


Motor driven adjusting machine closing up the jaws of a pedestal binder

When a piece is being lengthened it is held by two pairs of cams, with the heated portion between. The wedge block is removed and the space between the ram and the filler block as well as the space between the filler block and the sliding block is made up with false pieces. Pieces of scrap channel, side-rods or main rods cut in various lengths make the best filling-in pieces as they are light and more easily handled. Care should be taken to see that there is space allowed for the ram to extend to the limit of its stroke without touching the end of the part to be lengthened. It can be readily seen that with all space between the ram and the sliding block filled up, making a direct connection between these parts, any extension of the ram will move the sliding block. The part to be lengthened has one end held by the cams in the

frame, and the other end held by the cams in the sliding block with the heated portion between. As the sliding block is pushed, the piece will be stretched and lengthened.

For ordinary straightening jobs, it is necessary to place the wedge block behind the sliding block, to prevent it from moving. The work is placed cross-wise in the machine and the space between is made up so that the filler block will reach the work. As the ram moves forward the work is pressed against the sliding block and straightened. For straightening main and side rods it is advisable to have two heavy bars of steel about 4½ in. by 8½ in. by 40 in. machined all over, which are placed cross-wise in the machine. A badly bent and twisted main or side rod can be heated in a furnace and placed between these bars and made perfectly straight without a twist. There will be no hammer or die marks, and no thin spots.



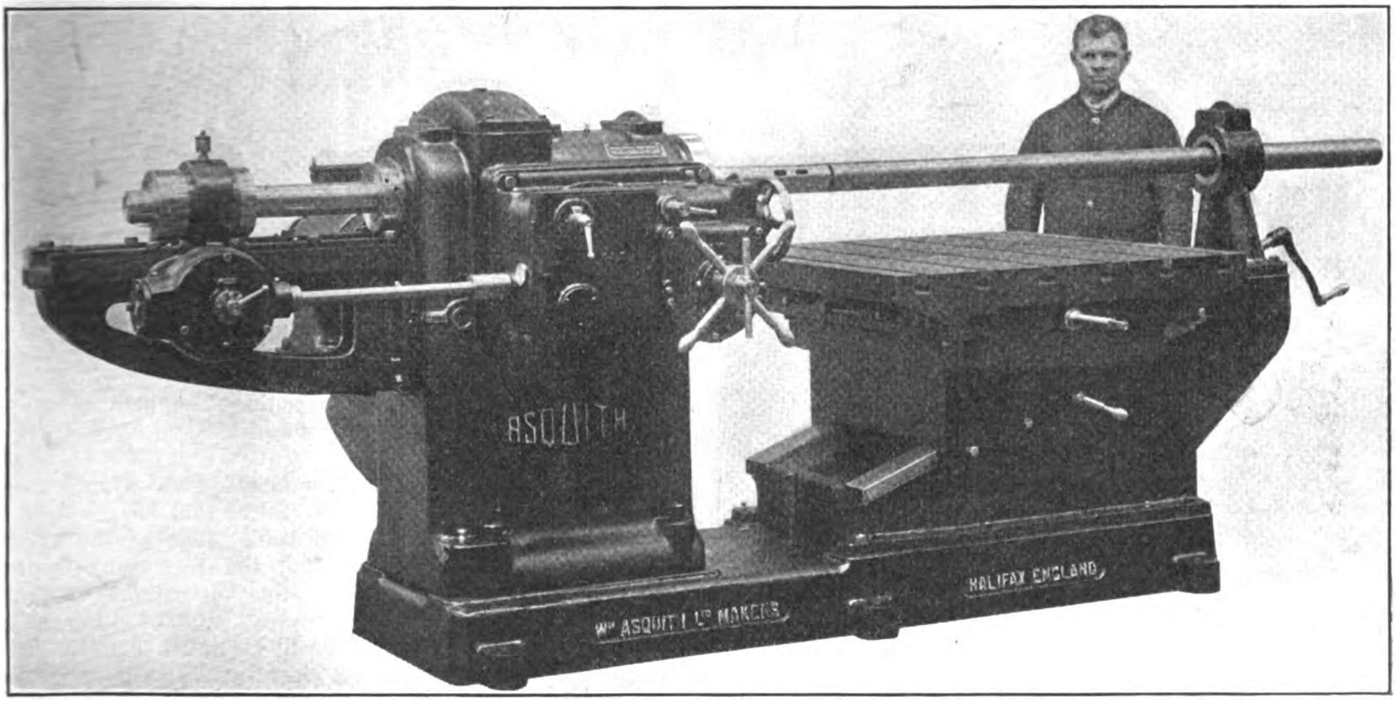
A gage with the machine which provides a means of making accurate adjustments when used on pedestal binders, side rods, drawbars, etc.

The gage with which each machine is furnished is an important feature of its equipment as it provides a means of making very accurate adjustments. When using the gage on pedestal binders, side rods, draw bars, etc., it is not necessary for the blacksmith to make the customary "hot and cold" marks. The lugs on each end of the gage are designed to slip into the jaws of the binder and a spring insures constant pressure against the binder jaws. As the machine pushes the jaws of the binder together it causes a hand to move across the dial, which is graduated at a six to one ratio which means that the graduations on the dial, which are 3/32 in., show that the work has been shortened 1/64 in.

Horizontal boring machine for journal box bearings

A SPECIALLY designed machine for the economical boring of journal box bearings has recently been developed by Wm. Asquith, Ltd., Halifax, Eng. The boxes are mounted on a strong work table which is provided with suitable T-slots. It is adjustable by hand motion on an angular slide, in order to enable the machine to handle boxes of varying heights. The boring bar, which carries the cutters, is cottered into the No. 5 Morse taper end of the spindle, and is removed through the steady rest after the cutters have been removed.

The spindle is of high carbon steel, accurately ground between dead centers, to be truly cylindrical. It is subject to no rotary wear, but simply slides in a large, accurately ground sleeve or socket. The spindle has a variable self-acting feed motion, fine hand feed motion, and a quick adjustment by hand, through rack and pinion. The sleeve which carries the spindle is of ample diameter for its purpose and has conical bearings at the front and rear. These bearings are accurately ground and are adjustable for wear, so as to maintain the correct alinement of the spindle with the steady rest bearing. The spindle feeds are obtained by means of a change feed



Asquith boring machine provided with a table adjustable on an angular slide by hand motion

gear box, the control to which is conveniently arranged.

The steady rest for the boring bar is firmly secured to the end of the angular table slide. The boring bars also are not subject to rotary wear, as they slide through a steady bushing and rotate in a large conical bushing in order to allow for taking up wear.

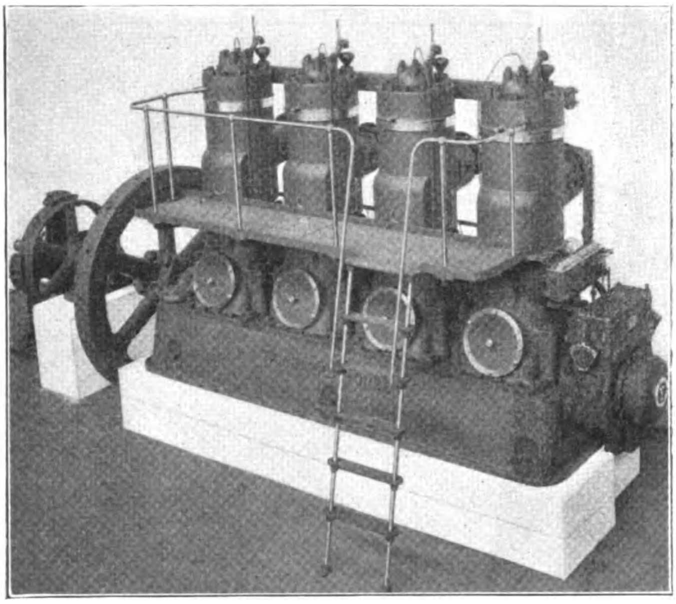
The machine is arranged for self-contained motor drive, the 5-hp. motor being mounted on a suitable bracket at the rear of the machine. Where d.c. current is available, the motor recommended is of the variable speed type with a speed of approximately 400 to 1,200 r.p.m.; where a.c. current only is available, the motor can be of the constant speed type, driving through a three speed gear box.

The complete machine is mounted on a strong foundation plate which is well ribbed to obviate deflection. The arrangement of the machine illustrated is such, that two boxes may be handled at one setting, being arranged in line with each other. It is possible, however, to handle four boxes at one setting by the adoption of the duplex form of the same type of machine. This duplex form is generally similar to the machine above described, except for the twin spindles, the two steady rests and the relatively larger dimensions. In this case the arrangement is such that each spindle deals with two boxes in line.

Changes in Fairbanks-Morse Diesel engine

ONE of the reasons for the increasing interest in the application of Diesel engines to a wide variety of railway power problems, such as the furnishing of power, light and pumping service, is in the increased dependability of these prime movers due to the constant mechanical improvement of the designs. Normal progress has indicated that an engine which would start without the aid of auxiliary ignition devices was an advantage and an improved design incorporating this feature has been brought out by Fairbanks, Morse & Co., Chicago.

No changes have been made in the general type of engine as the two cycle principle has been adhered to and the combustion scheme is based on solid injection of fuel as in the former Type "Y" engine. The engine operates under a compression of 500 lb. and the increased heat due to this compression fires the fuel without the aid of a torch when starting.

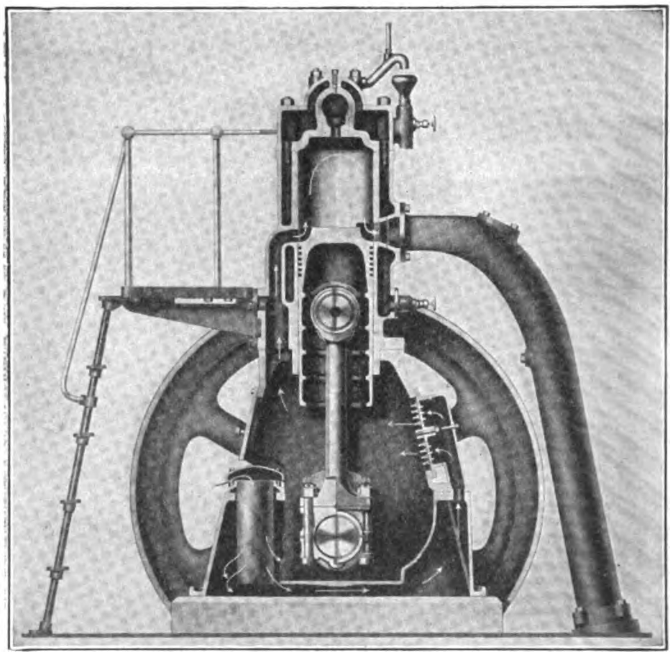


General view of new Fairbanks-Morse 200-hp. Type Y Diesel engine

Piping has been eliminated or enclosed, the control simplified, and what few adjustments there are, have been made more accessible without sacrificing simplicity of construction and reliability of operation.

At the present time the engine is built in ratings of 37½ and 50 hp. for the single cylinder unit; 75 and 100 hp. in two cylinders; 150 hp. in three cylinders; 200 hp. in four cylinders; and 300 hp. in six cylinders.

The primary consideration has been to develop an engine of the greatest reliability with low maintenance costs, maximum accessibility and one which is simple to operate. Fuel economy was also carefully considered, although no sacrifices were made in ultimate performance to secure the lowest possible test consumption of fuel.



Transverse section through the engine—The path of scavenging air indicated

The tests which have been conducted show a fuel consumption of 0.42 lb. of 18,000 B.t.u. fuel oil per brake horsepower-hour at full rated load. One of the characteristics of the engine is that the fuel consumption curve is practically a straight line on ratings varying from 75 to 120 per cent load.

From the sectional view it will be noted that the fuel is sprayed into a combustion chamber. This part of the design is quite similar to the former design except that certain improvements have been made in the shape of the chamber and in the neck leading to the cylinder. One advantage of this combustion chamber is that the air, on the compression stroke, rushes through the neck of the chamber and meets the atomized spray from the injection nozzle. The turbulence caused by this meeting of the air and fuel aids in preparing the fuel for complete combustion and also holds the charge in suspension. Owing to this thorough preparation of the fuel the final

burning is accomplished without an initial rise in pressure, resulting in true Diesel indicator cards. This system also eliminates the need for high injection pressure or a complicated injection nozzle of a type where the oil is sprayed through extremely fine holes.

When the piston reaches the end of its stroke, the temperature of the fuel charge in the auxiliary combustion chamber is raised to the ignition point and combustion begins. The hot gases then expand through the neck of the chamber and combustion is completed in the cylinder. In this way complete combustion is obtained as shown by the clear exhaust, from light load to over-load conditions. Moreover, the combustion does not cause any rise in pressure above the compression pressure, and the expansion is, therefore, similar to that of steam.

The fuel injection system is of the same general design as used in the former engine with the exception that the pumps are grouped on a pump deck and enclosed in a case which serves as the fuel oil reservoir. The change in the design has provided a more compact arrangement since it eliminates suction piping. By having the fuel pumps submerged the possibility of their becoming air bound is prevented. This fuel injection system, governor and the complete control of the engine centers in a unit mounted at the right end of the engine as shown in the general view.

Starting is accomplished by means of compressed air, the air being stored by an auxiliary power compressor in steel tanks of sufficient capacity for several starts. The pressure used for starting is approximately 200 lb.

Another important point in Diesel engine design is in the arrangements which are provided to eject the burned gases at the end of the expansion stroke. One of the improvements which has been made in the new design is that this scavenging air is transferred from the crank case to the cylinder through a passage outside the water jacket, thereby eliminating the necessity for air ports in the pistons and allowing the cylinder to be completely water-jacketed for its entire length. Reference to the sectional view will give an idea of how the scavenging air circulates through the base and to the cylinder. Before the opening of the air inlet or scavenging ports, which occurs shortly after the opening of the exhaust ports, the exhaust pressure drops to virtually atmospheric pressure. The air which has been compressed to a low pressure in the crank case, enters the cylinder when the scavenging ports are uncovered and is deflected by the piston to the upper portion of the cylinder, clearing out the remaining burned gases and charging the cylinder with fresh air. This scavenging air is supplied by the piston and crank case acting as a pump. On the upstroke of the piston, air is drawn through a screen and automatic air valve, into the crank case and is compressed on the working or downstroke.

Cooling water is introduced into the jacket of the head at both a top and bottom connection with the result that the whole jacket has a practically uniform temperature. The ridges of the cylinder ports are also cored for water passages and are thus kept at a uniform temperature. At the cooling water outlet, at the top of the cylinder head a spout is provided that discharges into a water header. This arrangement gives a visual check on the water circulation. Where the cooling water supply is limited and a re-circulation system is necessary, a closed connection from the cylinder head is used. In either case thermometers are provided for checking the cooling water temperature.

In the new design, several changes have been made in the lubricating system. The new system is entirely automatic, consisting of a double lubricating oil pump and an outside filter. The lubricating pump supplies oil to the mechanical lubricator, governor case, and main bearing wells. The governor case and main bearing wells are inter-connected and the oil is maintained at a constant level in them by the lubricating pump.

Used oil drains from the crank case to the oil sump and is pumped from this sump to the filter. The filter is entirely separate from the engine and is an efficient two-compartment type of large size, permitting the slow settling and filtering of the oil. Clean oil only is pumped from this filter back into the engine. One of the rather unique features of the lubricating system is the entire absence of oil caps, grease caps or oil holes. An oil can is unnecessary.

A welding flux suitable for iron, steel and bronze

WELDING flux plays an important part in making a homogeneous weld free from impurities. The chemists and metallurgists of the Chemical Treatment Company, New York, had these requirements in mind when they selected the ingredients of the welding flux known under the trade name of Welfex. The raw materials are passed through several progressive stages of manufacture for the purpose of securing a thoroughly uniform product.

The manufacturers claim for it several properties desirable for an effective welding flux. Its use gives a strong, soft and ductile weld or patch which can be machined, faced or drilled without chatter or change of speed and it can be readily used with all high temperature welding methods. The slag produced not only protects but absorbs the impurities from the exposed surface of the hot metal. It also prevents serious changes of silicon or carbon content in the metal. Welfex is a desulphurizer, the affinity of its slag being greater than that of the fused or molten metal.

When using the flux, one end of the welding rod is heated with the torch flame and when brought to a cherry red is dipped in the flux which will fuse and form a coating over the rod. The heat of the torch will then cause the flux to flow from the rod to the weld. The end of the rod and the welding area should be kept well covered with this coating of slag.

If the welding is to be done on heavy or massive work, additional flux should be provided by direct supply to the surface of the weld. Care should be exercised in having the flux form a fluid slag, of sufficient quantity to float over and completely cover the metal under fusion. This is essential, as the important service rendered by a fluxing slag is to dissolve metallic oxides, and shield the molten metal from oxidization.

The higher the temperature of the molten metal, the greater its affinity for oxygen. The quantity of flux to be added is regulated by the welding conditions. It should be used liberally rather than sparingly. This question must depend upon the judgment of the welder. If the flow of the welding metal is sluggish, additional flux will increase fluidity. Care should be used, however, to avoid excessive fluidity which would create a greater tendency for too rapid chilling of the welded metal.

Disk bearings for railway cars

THE Wollmar Engineering Corporation, New York is introducing a disk bearing for use on railway cars which is said to have all the advantages of ball and roller bearings with additional carrying capacity. The construction of these bearings, which are known as NKA disk bearings, is shown in Fig. 1. It will be noted in the drawing *Y* that the rolling surface of the disks has a radius of curvature larger than the diameter. The disks run in race grooves which are so dimensioned that practically the entire width of the roller comes in contact with the groove when the bearing is under load. This gives nearly a line contact between the rollers and groove which permits them to be self-guiding and allows a larger load carrying capacity.

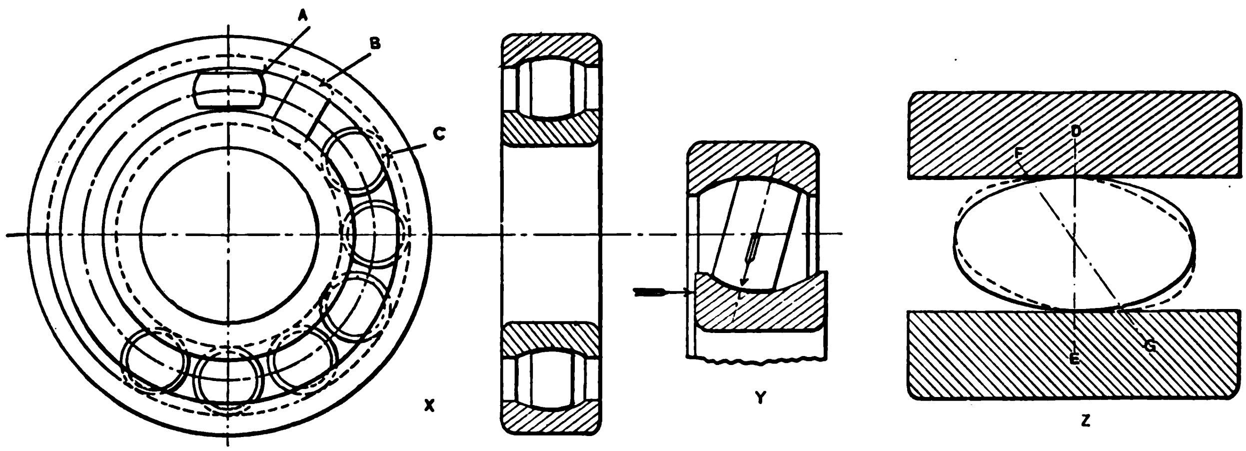


Fig. 1—Drawing showing the construction of the NKA disk bearing

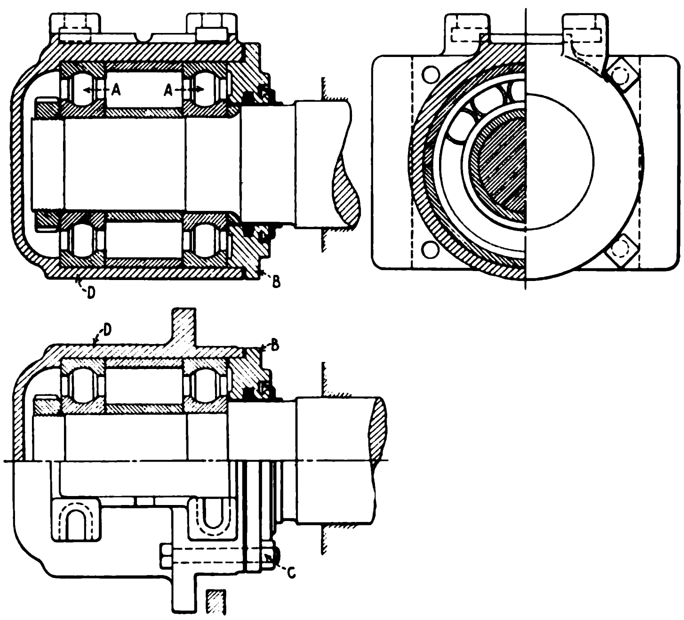

Fig. 2—Drawing showing the application of disk bearings to a railway car journal

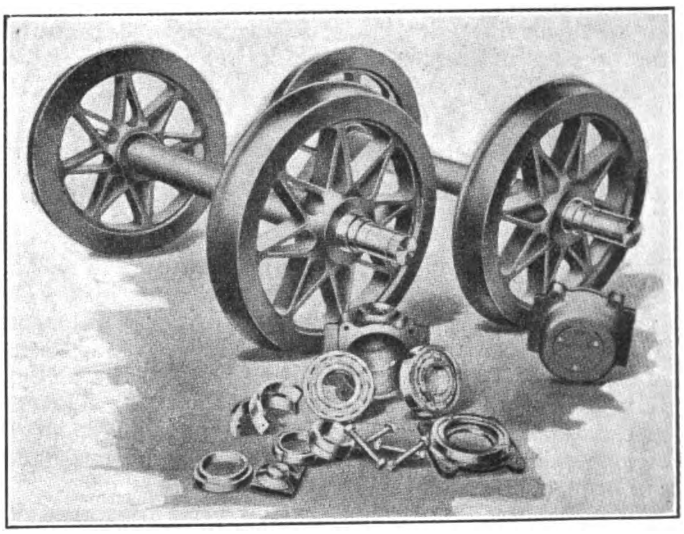
The self-guiding feature may be explained by referring to the drawing *Z* in Fig. 1. If we consider each disk to be cut from an ellipsoid of rotation and placed between two flat surfaces as shown at *Z*, the ellipsoid will roll on the smallest great circle and the contact surfaces will be symmetrical with the points *D* and *E*. If, for example, the disk should tend to turn to the right in the plane of the paper and the bearing continues to rotate, the ellipsoid will appear as shown on the dotted line with the points of contact moved to *F* and *G*. These points not being opposite to each other will produce a moment which will turn the disk to the left in the plane of the paper and back to its normal position. This action of the ellipsoid has been termed statical self-guiding. This statical self-guiding, however, is not sufficient to produce even running of the disks, because if the bearing is subject to radial pressure one-half of the disks will be without pressure and statical self-guiding cannot exist.

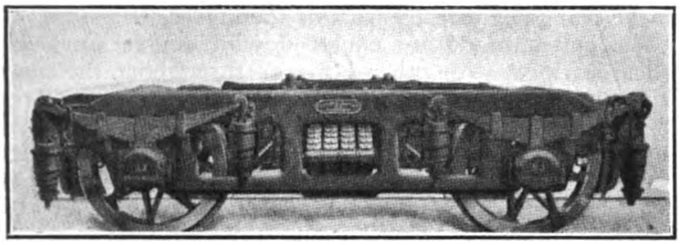
The moment of inertia about the normal axis of rotation is greater than the moment of inertia about any other axis due to the slight width. As a result, the disks are also termed to be dynamically self-guiding. It is well known that a free rotating body always tries to rotate about the axis which has the greatest moment of inertia.



Disk bearings disassembled from a European type railway car

If the disk bearing is subjected to an axial pressure only, the resultant force on each disk makes an angle with the axis of rotation of the bearing, and the disks take a

position as shown in drawing *Y* of Fig. 1 to react against the axial stresses. If a bearing is subjected to both axial and radial stresses, the various disks have different angles



European railway truck showing the application of disk bearings

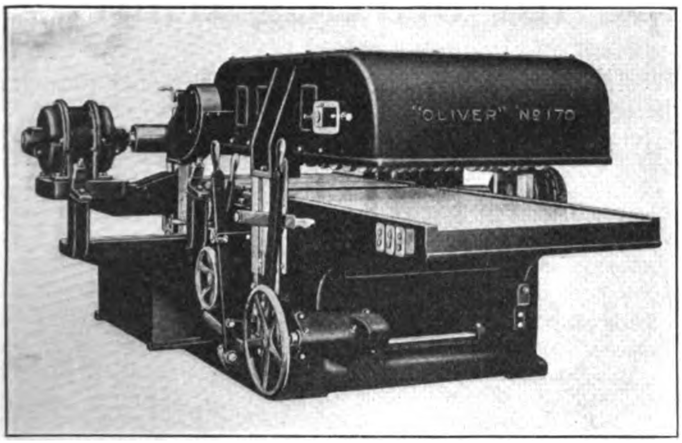
of reaction, the degree of which is decided by the resultant force which is exerted on them. The self-guiding properties of these disks have been verified by practical trials with bearings run without a cage. Their shape permits them to be inserted between the races shown at *A* in the drawing *X* of Fig. 1, twisted into position as shown at *B* and finally to the position *C*.

The NKA disk bearings have been used successfully on railway equipment of the Swedish State railways. The application of these disks to European railway equipment is shown in Fig. 2. Each journal has two bearings which are located at the ends of the journal. This design permits a distribution of the loading over a larger surface and it is also claimed that it can withstand shocks and temporary overloading to great advantage which is a much desired feature.

The work of development on European railway equipment was conducted by the manufacturers, Nordiska Kullager Aktiebolaget, Gothenburg, Sweden, from which the bearing derives its trade name.

Woodworking machines of unique design

The Oliver Machinery Company, Grand Rapids, Mich., has recently placed on the market under the trade name of "Straitoplane" a woodworking machine, the purpose of which is to do on one machine in one operation what heretofore has been done on two machines in two operations. The two machines referred



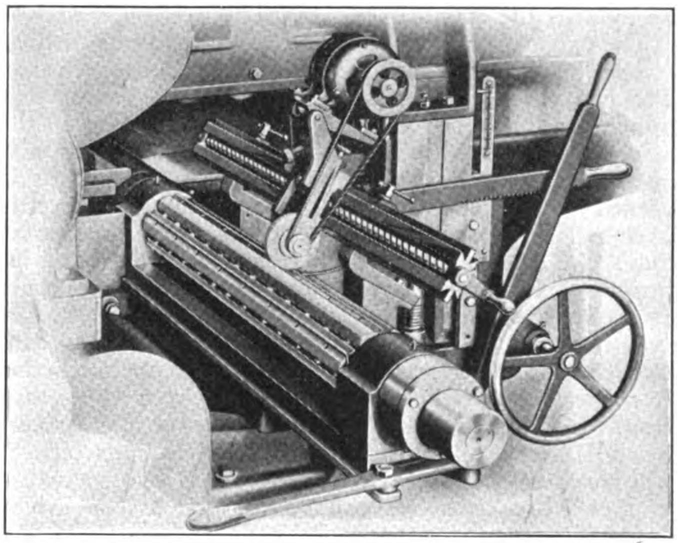
Front view of the Oliver "Straitoplane" showing the concentration of control levers

to are the hand planer and jointer, with some kind of a power feeding attachment and a surfacer. One of the outstanding features of the machine is its ability to take warped boards and finish them down to the desired dimensions, the finished product being smooth and straight.

The infeed table is a one-piece casting of arched ribbed construction. It has an actual feeding surface of 36¼ in. wide by 72 in. long. The end next to the bottom head is fitted with a steel plate. This table is supported by an inclined bed wedge which is a one-piece casting and rides on dovetailed gibbed ways for vertical adjustment by means of a ratchet lever on the left side of the machine, convenient to the operator. The frame of the outfeed table is a one-piece well ribbed casting with finished chilled plates bolted at the top to form an actual feeding surface of 36¼ in. wide by 41 in. long. In finished pockets at the sides of the outfeed table frame, bronze bearing boxes support the two lower feed rolls with adjustment for alinement. The outfeed table frame is supported by an inclined one-piece cast bed wedge in wide finished ways and is easily adjusted vertically to the cutting edge of the knives by means of a hand wheel conveniently located on the left, or operating side, of the machine.

The entire top section of the machine consists of two main castings securely bolted together. It is supported by four rectangular pillars fitted to the main frame in the slot gibbed ways and arranged to move vertically in unison by power, supplemented by a hand wheel micrometer set for the finished thickness desired. This top section carries the multiple contact conveyor, the top feed rolls, and the top cylinder unit with the chip breaker and pressure bar. The vertical movement is indicated by a scale and pointer within direct and convenient view of the operator.

The conveyor is of the wide chain mat type, having



View of the bottom head pulled out and resting on the self-contained bracket with the knife grinding attachment in use

cushion spring cam-dogs suspended from each link in such a manner as to assure a very sensitive, yet positive multiple contact feed. All essential parts of the conveyor are made of malleable steel. All parts are properly lubricated and positive take-up is provided to compensate for any possible elongation of the conveyor.

The main frame is a rigid casting with cored sides, girts, partitions and exhaust chute for the bottom head—

all cast in one piece. This frame supports, completely, all other parts of the machine on finished surfaces. The bottom is planed to give a solid continuous foundation support of 9½ in. wide by 72 in. long on both sides of the machine.

The top roll, ahead of the top cutter head, is sectional and is arranged with ample vertical movement for each section and also for the roll, as a whole, so that any desired top cut can be taken with ease. All other rolls are smooth, arranged for vertical adjustment to give proper alinement. The feed works are actuated through an initial belt, having a double idler take-up, controlled by a lever and ratchet stop, located at the left side of the operating end within easy reach of the operator, giving him easy control to throw the feed on or off, while the machine is running. Roller chains and sprockets are provided.

Both the top and bottom cutter heads are of 6-in. cutting diameter, fitted with six Tungsten thin knives. Provision is made for setting the knives easily and for joining and grinding the knives in the top cutter head when in place. The bottom cutter head is clamped in the frame with a tapered wedge going clear across the frame. This wedge is released by a convenient lever and the entire bottom head, with its bearings and housing yoke, are drawn out towards the left side of the machine, for setting and grinding the knives while resting on the sliding bracket which is fastened to the machine and always remains in place. The knives of the bottom head can be jointed in relation to the outfeed table, by raising the top section to the 6-in. limit and mounting the jointing head on the rear table directly back of the knives.

The cutter heads are equipped with double rows of roller bearings. All other bearings throughout the machine are of the bronze bushed type and all bearings are lubricated by the Alemite system. Complete control of the machine is located at the forward end of the left side so that the operator can, within easy reach of his natural position, stop and start the heads and feed and adjust vertically both tables as well as the entire top section.

Each machine, as regularly furnished, is so arranged as to be driven either by belted or by direct-coupled motors. The pulleys on the end of the heads also form the universal couplings so that by merely placing the motor brackets and motors each head can be direct driven. The power for the motor-driven machine is furnished by a 10-hp., 3,600 r.p.m. motor coupled to the bottom head; a 15-hp., 3,600 r.p.m. motor coupled to the top head, and a 7½-hp., two speed, 600 and 1,200 r.p.m. motor connected to the feed mechanism with a chain and sprockets. All three motors are provided with push-button automatic control, having the push buttons mounted on the front bed convenient to the operator. The two-speed motor has a high, low and stop push button.

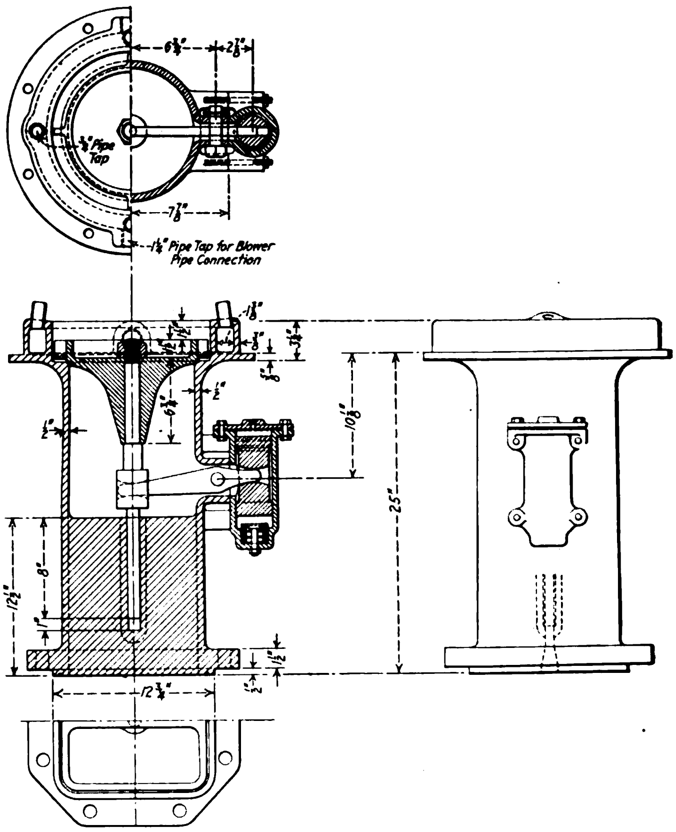
Locomotive exhaust pipe for braking trains

PATENTS have recently been granted to J. E. Osmer, Huron, S. D., on a locomotive exhaust pipe designed to operate in conjunction with a control valve, the function of which is to control a valve in the exhaust pipe which regulates the escape of exhaust steam from the cylinders and by means of the back pressure set up, retards the train.

The exhaust pipe tip, body and base are in one casting. A seat has been provided at the tip or nozzle for a valve. The body of the valve is designed with a contour that provides a variation of nozzle opening according to the height it is raised from the seat. The mechanism for raising the valve operates automatically when the throttle is opened and the valve reseats itself as soon as the throttle is closed. The closing of the exhaust nozzle as soon as the steam is shut off prevents cinders, and gases, injurious to lubrication, from being drawn into the steam chests and cylinders.

A feature of the device is that it can be used to control the speed of a train without the use of the air brake. A connection is made in the smokebox by a ½-in. pipe from the steam pipe to a steam cylinder on the exhaust pipe. Referring to the drawing of the exhaust pipe, it will be noted that the exhaust pipe valve is fitted with a stem which extends vertically down into a hole drilled in the dividing partition between the exhaust passages. A lever arm, operated by the piston in the small steam cylinder bolted to the exhaust pipe casting, engages the exhaust valve stem. A downward movement of the piston will raise the exhaust valve and vice versa. The piston is forced down by the steam which is carried to the top of the exhaust pipe cylinder by the ½-in. pipe. In order to raise the exhaust pipe valve the throttle must be opened.

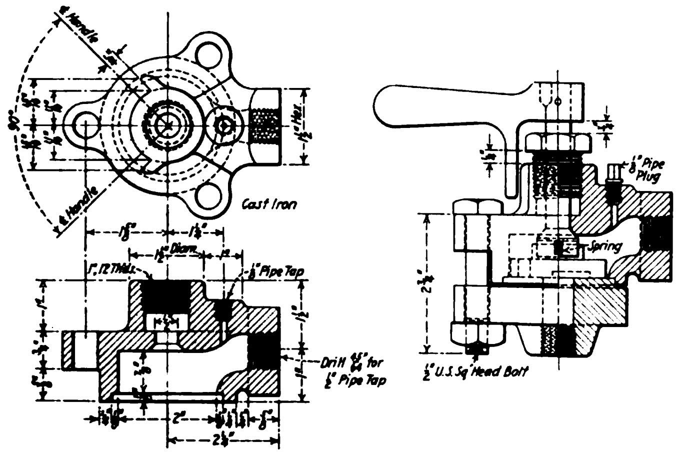
The exhaust pipe valve may be closed when the throttle is open by admitting steam at the bottom of the cylinder which forces the piston up and the valve down. Steam for this purpose is taken direct from the boiler through the control valve, a drawing of which is also shown. A ½-in. pipe is used to carry the steam from the control



An exhaust pipe which is closed by a valve when the locomotive is not working steam

valve, which is located in the cab near the air brake valve, to the exhaust pipe cylinder.

The closing of the exhaust pipe valve causes steam



The control valve

to be retained in the cylinders. This results in back pressure being built up, the amount of which may be controlled by the control valve and throttle. A gage is provided by which the engineman may know what pressure has been built up at the control valve and proper reduction may be made as deemed necessary. Braking is accomplished by means of the back pressure thus created. If it is desired to stop the locomotive, steam is admitted to the bottom of the exhaust pipe cylinder by means of the control valve, which holds the exhaust pipe valve in its seat. This confines the steam to the cylinders and builds up a high back pressure. In order to slacken speed, the throttle is opened wide which admits steam to the top of the exhaust cylinder and causes the exhaust pipe valve to rise, and the valve gear is placed in full travel position. The degree of the upward movement of the exhaust valve is regulated manually by the pressure on the bottom of the exhaust pipe cylinder piston. The engineman is thus able to control the amount of cylinder back pressure by adjustment of the throttle and control valve. The partial vacuum created within the cylinders when coasting with the throttle shut off tends slightly to bunch the train and at the same time to prevent pounding of the revolving and reciprocating parts.

Slipping while ascending a grade may be prevented by moving the handle of the control valve to "set" position, with the throttle left open.

Reversible placard holders for tank cars

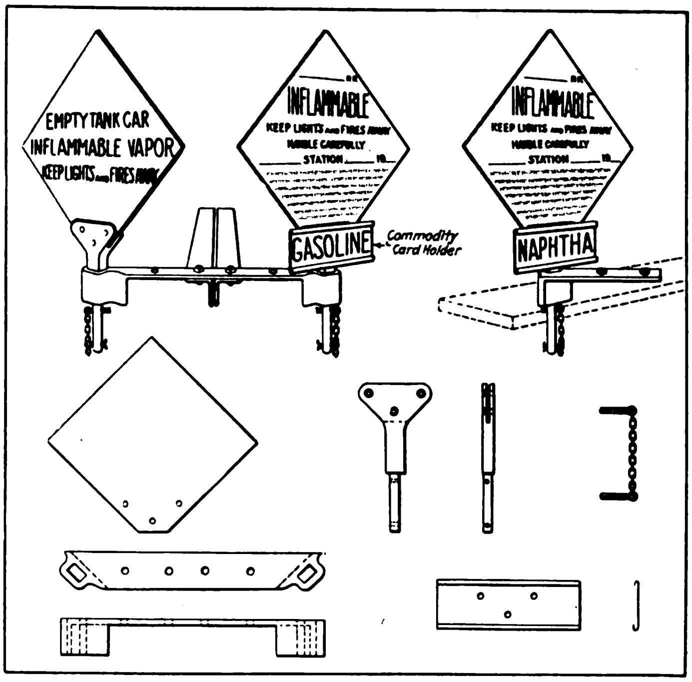
FOR the past several years the question of the application and removal of placards has been a live issue with the oil and other industries operating tank cars for transporting dangerous commodities. The device shown in the illustration, patented and marketed by E. A. Fall, 90 West St., New York, is designed to effect an improvement in existing conditions. The line drawing shows in detail the construction of the reversible placard holder and placard, assembled and knocked down. The general principles of the design have been approved by the Bureau of Explosives, and its application to tank cars is permissible under the rules and regulations set up and enforced by the Interstate Commerce Commission.

The base of the holder, shown in two forms, double and single, can be applied to the car in either form. Where the double base is used, it is applied diagonally across the steel sill brace at the corner of the car. This method immediately brings the two placards into proper location to serve the side and end running boards, insuring sufficient clearance of the placards from the running board to prevent the possible tripping and stumbling of trainmen. Where the single base is specified, the application of separate bases to the side and end running boards also insures sufficient clearance to avoid possible accident.

The upper part of the stem or shank has a rounded flare, which tends to strengthen the placard after the latter is placed in the slot in the head of the stem and securely riveted to prevent shifting. The center part of the shank is square in section and slightly tapered, while the bottom section is round, permitting free movement up and down. The lower section of the shank is provided with holes for the insertion of cotter pins whereby the placard is held in the desired position permanently or temporarily.

The base and shank of the holder are malleable iron, while the placard is 16 gage Armco iron, enamelled on both sides, which makes the holder and placard practical and durable for the class of service for which it is intended. The commodity car holder can, if desired, be quickly and easily applied at the time the placard is riveted to the shank.

The placard has printed on one side the information necessary when a tank car is loaded with an inflammable



Detail construction of reversible placard holder, assembled and knocked down

liquid and on the other the notice required when the car has been emptied of its contents. Thus, one placard serves the car when loaded or empty merely by reversing it in its holder to bring to the front whichever side is required.

Circular cross-cut and rip saw filer

WOOD-CUTTING saws of various types are used extensively by the railroads and in order to obtain maximum efficiency from them the saw blades must be frequently sharpened in the proper manner. The Wardwell Manufacturing Company, Cleveland, Ohio, has recently placed on the market a combination cross-cut and rip circular saw filing machine. It has a range of capacity for sharpening all cross-cut and rip circular saws up to 18 in. diameter, with teeth from the smallest up to ½ in. from point to point at a speed of 65 teeth per minute.

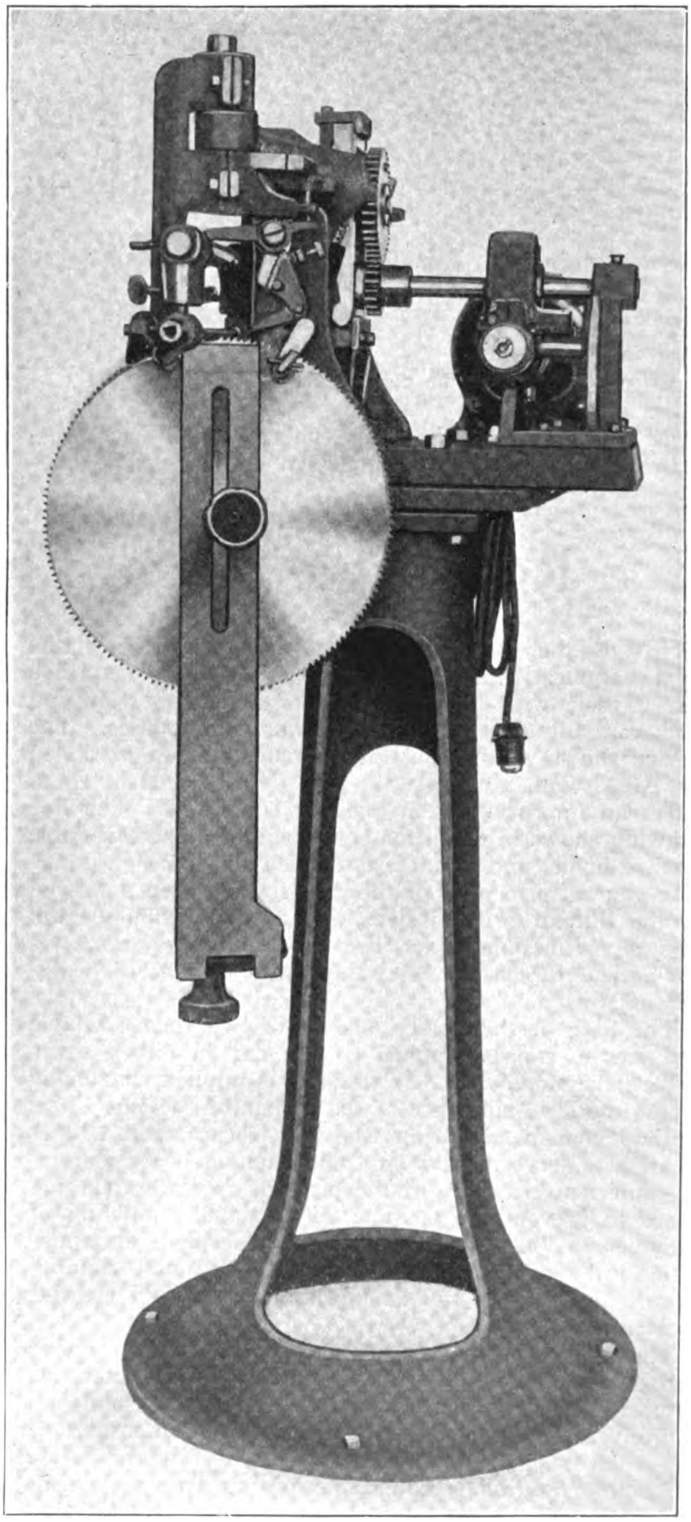
The frames, pulleys and the horizontal slide that carries the file are made of gray cast iron. The cam shaft bracket is babbitted and the swivel head bearings are fitted with radial adjustments. The vise contacts and all parts subjected to wear are made of steel. The filing arm works between heavy adjustable bronze gibs which insures accuracy.

The machine is automatic after starting. The bevelling of the cross-cut saw teeth is secured by the automatic swivelling of the vise frame holding the saw. The amount or degree of bevel can be regulated and adjustments can be made for saws of varying gages. The machine can handle three different degrees of bevels. Through the elliptical movement of the filing arm any hook of tooth can be filed and all teeth can be sharpened without a particle of a burr.

The operation of the machine is simple. To the main drive shaft is connected a cam which raises the slide frame at a slight angle out of the vertical, which gives an oblique movement to the file the same as in hand filing, and allows the file to enter and leave any hook of tooth. On the point of the cam is a hardened steel roller which operates the horizontal slide filing arm. Two adjustments cover the movement of the pawl lever attached to the swivelling head frame and rocked by a riding rod on the filing arm. One of these adjustments covers the length of stroke and the other the amount of cut removed from the face of the tooth. One elevating screw raises or lowers the saw at the point of filing. The saw is gripped rigid during the filing stroke, then is automatically released as the filing arm raises, thus paralleling the movement of hand filing.

The swivelling movement of the head and saw vise is secured through a two to one gear connection from the main drive shaft. The saw is turned alternately right and left to an amount depending on the number of degrees of bevel to be given the teeth. The teeth of crosscut saws are thus consecutively sharpened with alternate bevels through the swivelling of the saw between each stroke of the file. Rip saws, the teeth of which do not require bevelling, are filed straight across by slipping the gears out of mesh and tightening the vise head in position at right angles to the file. The saw vise is easily removed for cleaning when necessary. The saws are fed through a pawl movement. When this pawl or feed finger is allowed to feed one tooth behind the one that is being filed, the teeth are all jointed.

The machine shown in the illustration is mounted on a pedestal and is direct connected to a motor. The base is a casting, which supports both the motor and the machine. One cast iron bracket supports the end of the main drive shaft as well as the end of the shaft extending from the motor. A hardened cut worm and gear are used which run in an oil bath. A universal, flexible coupling permits of easily removing the motor as well as relieving the pressure on the armature. Each machine is furnished with a motor fully equipped with insulated wire and a plug for attaching to a lamp socket by a snap swivel. All the motors are self starting and driven from a lamp socket of light current.



Wardwell saw filer with direct connected motor, mounted on a pedestal

The speed of the motor is 70 r.p.m. If belt driven the pulley is 10 in. by 1¾ in. The machine requires a bench space of 12 in. by 10 in. The weight of the machine without the pedestal is 85 lb.

Universal cutter and tool grinder

A UNIVERSAL cutter and tool grinder suitable for the toolroom has recently been placed on the market by the Wilmarth & Morman Company, Grand Rapids, Mich. It can be furnished with either a belt or motor drive. The belt drive can be converted into a motor drive at any time by replacing the main head. In eliminating the belt drive the head or table can be swung 360 deg. Two motors are furnished, a ½-hp. motor on the main head and a ⅛-hp motor on the head stock.

Motor driven universal cutter and tool grinder

The machine contains several improved features. The longitudinal feed may be controlled from the front or rear of the machine. The micrometer adjustment of the table can be put in use at any angle of the table. The knee is supported by the full circumference of the column which is fully protected from dust and grit. The saddle is also constructed so as to protect all working parts underneath from dust and grit. All movements on the machine are provided with taper gibs or adjustable take-up nuts. All the attachments which go with the machine are interchangeable with the No. 1 universal grinder manufactured by this company.

The following are some of the specifications of the machine: The longitudinal, vertical and transverse movements of the table are 16 in., 8 in., and 8 in. respectively. The centers will swing work up to 10⅜ in. in diameter by 20 in. long. The internal grinder attachment has a speed from 9,000 to 18,000 r.p.m. and will grind from 9/16 in. diameter up, 3 in. deep and from 1¼ in. diameter up, 5 in. deep. The universal attachment will swing cutters 16 in. in diameter over the table and 24 in. in diameter over the sub-table. The gear cutter attachment will cut 120 pitch to one pitch in gear blanks ranging from 1¾ in. to 8½ in. in diameter. The steady rest and chuck have a capacity of 2½ in. and 4 in., respectively. The tilting and swivel vise base opens 2⅜ in. and the jaws may be temporarily removed, increasing the opening ¾ in. The table has a working surface of 5½ in. by 32 in. The spindle speeds are 3,000 and 6,000 r.p.m.

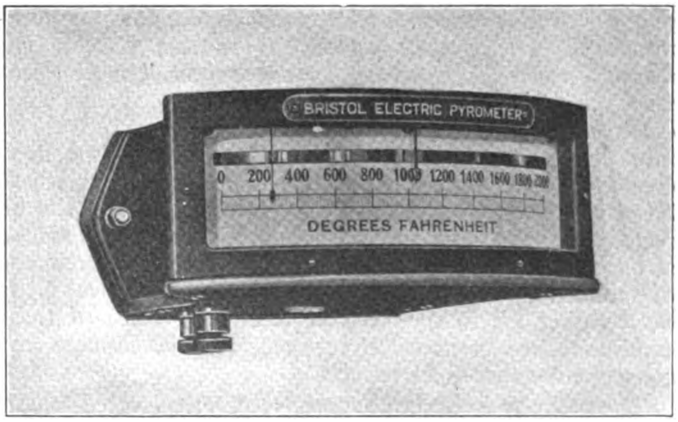
High resistance indicating pyrometer

THE Bristol Company, Waterbury, Conn., has recently placed on the market a new model high resistance indicating pyrometer. It has a scale seven inches wide which permits the pyrometer to be easily read at a considerable distance from it. As a further aid to easy visibility, a combination pointer is provided, having a broad section for distance reading and a knife blade section for accurate close-up work. In addition to these features, the scale is also provided with a mirror, which eliminates any possible errors in reading due to parallax.

A high resistance Weston millivoltmeter is used for the measuring element which is equipped with an accurately balanced moving coil and pointer. It has a resistance of 15 to 20 ohms per millivolt. An automatic cold-end compensator is provided to give an accurate scale reading without the necessity of making allowance for a correction.

There is an unavoidable variation of temperature in the pyrometer itself which influences the correctness of the reading. This factor has been taken into consideration when designing the instrument so that any effect of temperature changes on the accuracy of the pyrometer is minimized.

The case is made of cast aluminum and is of dust-proof construction. It is arranged for wall or switchboard mounting, having a demountable base for separately bolting to the wall and supporting the instrument. A small adjusting screw on the outside of the case provides an easy means of zero adjustment. A knob on the top of the case makes it possible to set the normal index spotter for the temperature desired for each individual piece of work.

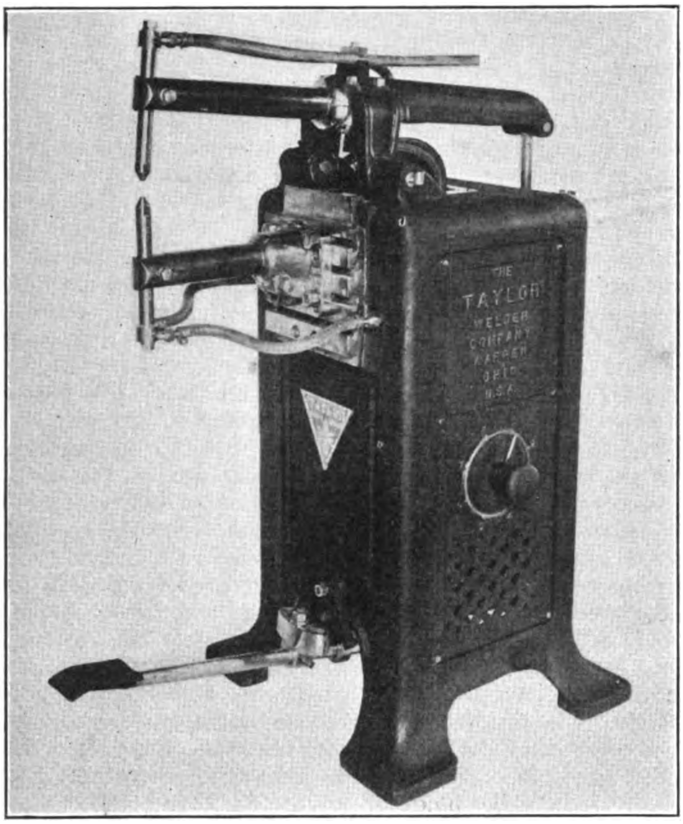


Bristol high resistance indicating pyrometer with an exceptional range of visibility

The pyrometer can be furnished for all ranges up to 5,000 deg. F.

Water cooled spot welding machine

ONE of the type N spot welding machines recently placed on the market by the Taylor Welder Company, Warren, Ohio, is shown in the illustration.



Taylor spot welder provided with adjustable horns

This machine is built in three sizes for welding work ranging from No. 30 gage material to two plates 3/16 in. thick. The overhang is from 6 in. to 30 in. The upper horn is adjustable in and out to permit the use of gooseneck welding points with one of the regular welding points, and both horns can be revolved in either direction to allow welding in corners and otherwise inaccessible places. The lower horn is adjustable up and down and sidewise in either direction.

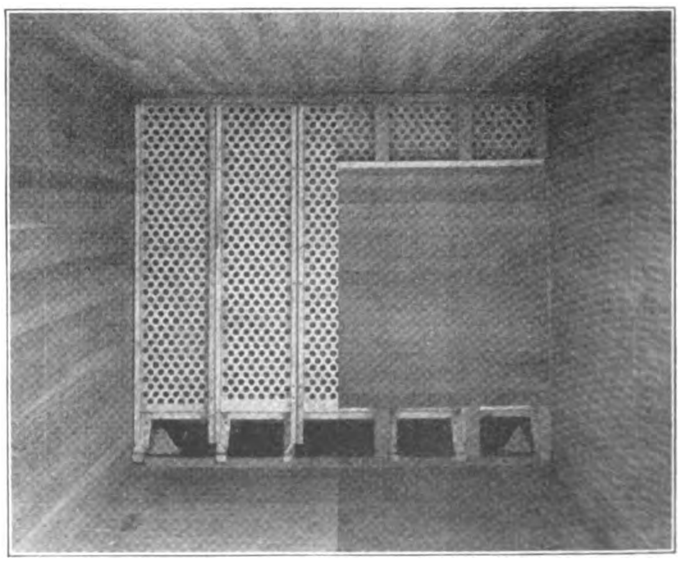
The smallest machine is equipped with a 10-kw. transformer, and the intermediate with a 15-kw. transformer. There is an eight-step self contained regulator for adjusting the current to take care of the lightest work up to the capacity of the machine. The switch is of an automatic and non-automatic type so designed that it cannot close until the electrodes have made proper contact with the work. No adjustments are required for different thicknesses of work or for wear of the electrodes. The switch is changed from an automatic to a non-automatic trip by operating a lever. The automatic trip is desirable for welding work that is buckled and does not fit together properly, as it permits a positive pressure to be applied to the weld after the current has been turned off, and thus prevents the weld from separating while in the molten state. It is desirable to set the switch in the non-trip position in welding wire and clean sheets, and also in operations where greater speed is wanted. The pressure on the electrodes is controlled by means of a handwheel.

In addition to the water circulation in the electrodes, the transformer is water cooled. The machine may be furnished with a quick change gear box and either a belt or motor drive. The foot-treadle is adjustable in or out and may also be swiveled to suit the convenience of the operator. The travel of the upper electrode and the foot-treadle can be varied for different thicknesses of work by means of a lever which is located on the front of the machine.

All-metal bulkhead and ice grate

THE Equipco all metal bulkhead and ice grate illustrated has been designed and constructed by the Equipment Specialties Company, Chicago, to give a strong, pilfer-proof ice compartment for refrigerator cars. The usual wooden ice grates are easily cut through with a saw or axe, or the bulkhead netting cut with clippers. Tools for this purpose are readily concealed about the person, and the thief merely drops down into the ice compartment and cuts through to the merchandise; no seals need be disturbed and he works where he cannot be seen. Besides preventing pilferage, the all metal bulkhead and ice grate is designed to provide a strong construction which will eliminate the breakage of bulkhead posts, due to shifting loads in the car body or wedging ice in the ice compartment. Both of these conditions are responsible for considerable damage and consequent expense in repairs.

The Equipco design consists of perforated metal sections which, when in place form a strong partition across the car. The posts are formed as integral parts of these sections. The tops of the sections are bolted directly to the ceiling and header, while the fastening at the floor is by means of post shoe castings secured to the floor rail. This gives the equivalent of an all steel end for refrigerator cars, located where it will afford the maximum protection, namely at the bulkhead and not at the car end as in the case of box cars. The actual trouble from shifting loads in refrigerator cars comes at the



Equipco all-metal bulkhead in refrigerator car—The left half of the wooden face of the bulkhead is cut away to show the perforated metal sections

bulkheads and not at the end walls of the refrigerator cars.

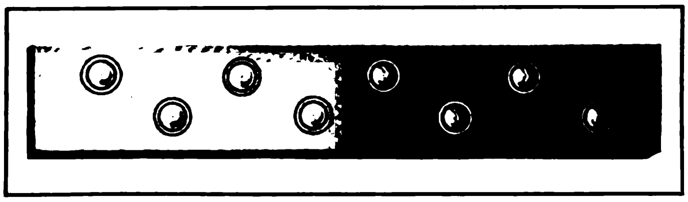
The so-called basket bunker generally used is maintained, but the piece of netting at the bulkhead is unnecessary as the perforated sections answer the same purpose. The sections are bolted to each other, and securely fastened to the side walls of the car.

The substantial pressed steel grates are individual bars, not made in sections as is the case with wooden grates. The grate bars are carried between the flanges of channel-shaped carriers, and they are locked in place by a key grate bar at the center. The fastening or lock for the key grate is accessible only from the inside of the car proper, and not from the ice compartment. Thus, unless this key grate is removed, none of the other bars can be disturbed. One of the illustrations shows a close-up view of the pressed steel grate bars and indicates how they are carried in the channels.

Further advantages claimed for the Equipco metal bulkhead and ice grate are minimum maintenance expense, easy application, and conformance to existing standards of ice capacity and distance between bulkhead faces. This equipment is already in service on three important refrigerator lines.

Ball parallels for use in drilling heavy work

BALL parallels for use in connection with the drilling or counterboring of heavy fixtures, jigs, dies and other heavy work are shown in the accompanying illustration. They are intended to permit the drill or counter bore to pull the work in line with the spindle.



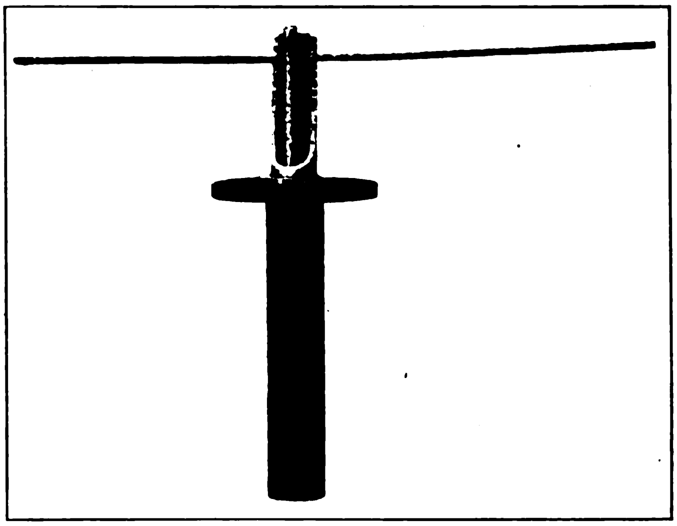
Ball parallels used in drilling heavy work

The manufacturer, the J. F. Smith Tool Company, Dayton, Ohio, is producing two sizes, one of which is 1 in. wide and 6 in. long and fitted with ¼-in. balls while the largest size is 1 in. by 7 in. and equipped with balls ⅜ in. in diameter.

Electrode holder for metallic arc welding

A NEW type of welding electrode holder, marketed by the General Electric Company, Schenectady, N. Y., allows welding operators to make a quick change from a burnt stub to a new electrode. The operator needs only to strike the stub end of the old electrode, causing it to drop out after which the new wire can be inserted without unnecessary effort.

The holder consists of a punched fibre tube with a tinned brass plug inserted in the end. A steel spring rod holds the electrode in place against one of a number of different sized notches provided for this purpose. The welding cable running to the source of power is soldered to the other end of the holder. The fibre tube and guard can be removed by loosening a single screw. The construction of this holder is such that the contact of



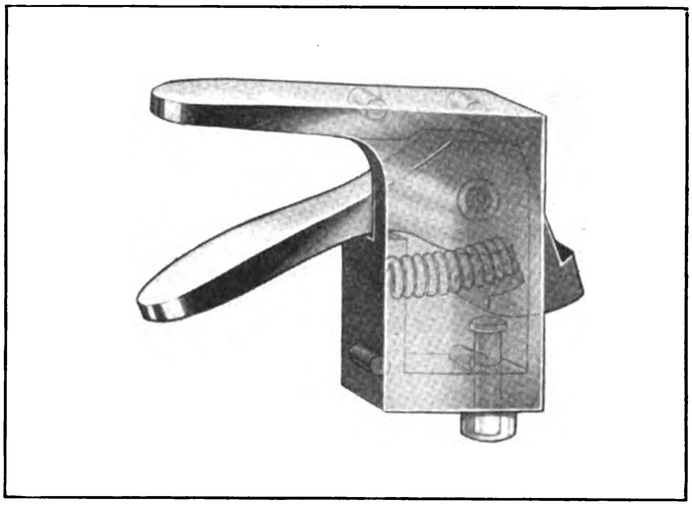
Electrode holder which permits a quick change of electrodes

the electrode is not weakened by heat, since it does not depend upon any heat-affected spring.

Combined sash lock and window opener

THE National Lock Washer Company, Newark, New Jersey, has placed on the market a unique device in the form of a combined sash lock and window opener.

From the illustration it will be noted that when the slightest pressure is imparted to the lower lever of the



Sash lock designed to open sticking car windows

sash lock, the lifting force is multiplied many times by a cam which pushes down a small plunger extending through the bottom of the sash lock case. This force is sufficient to start sticking or immovable windows. When the window has been so released it can be adjusted to any desired height in the normal way.

It is through the employment of a dowel and bolt construction that such a device is made possible. The phantom illustrations shown will give a clear idea of the construction of this device.

General News

Many aspects of the railroad problem were discussed briefly and pointedly in a bulletin distributed by the Atchison, Topeka and Santa Fe under the authority of W. B. Storey, president, as a New Year Greeting on January 1. The necessity for constant heavy expenditures for new equipment and facilities, the legislative situation in Congress, the employees and their wages, freight rates, increases in transportation costs, competition with motor trucks, and the necessity of efficiency in the use of equipment were discussed in the bulletin.

Soo line offers prizes for shop ideas

Six prizes totalling $100 have been offered by the Minneapolis, St. Paul & Sault Ste. Marie to its employees in the car and locomotive departments for the best ideas for improving and facilitating shop practice. First prizes of $25, second prizes of $15 and third prizes of $10 are offered to the employees of each department. The competition will close on April 1.

Southern Pacific lines offer safety prizes

Foreman of the maintenance of way, mechanical, stores and station service departments of the Southern Pacific, Texas and Louisiana lines, are eligible for prizes of $15 each, to be paid shortly after December 31, 1925, if they can complete the year without a single reportable accident in their gangs. The $15 prize is the minimum and applies to foremen in charge of gangs working 20,000 man-hours or less during the year. The prize is increased at the rate of $15 for each 40,000 additional man-hours worked without reportable accidents up to a maximum prize of $105, except that, regardless of the size of the gang, foremen having three or more reportable accidents are not eligible for any prize. This competition is open to all foremen of the maintenance, mechanical and stores departments whose gangs work more than 10,000 man-hours during the year, and foremen of warehouse and transfer gangs working 20,000 or more man-hours during the year.

Status of automatic train control orders

In addition to the railroads that have been allowed by the Interstate Commerce Commission an extension of time in which to complete their installation of automatic train control on a division as required by the commission's order of June 13, 1922, there are several roads that have not filed any petition for an extension of time, or whose petitions, if filed, have not yet been acted upon by the commission. Most of the roads have been granted extensions and four have been denied, but in addition the installations on the Atchison, Topeka & Santa Fe; Chesapeake & Ohio; Chicago & Eastern Illinois; Chicago, Rock Island & Pacific; Philadelphia & Reading, and Southern Pacific are regarded as completed, or practically so. The Atlantic Coast Line has filed a petition for an extension on which the commission has not yet announced its decision, and it is understood that the Chicago, Milwaukee & St. Paul; Long Island, Pennsylvania, and West Jersey & Seashore have not yet filed petitions for an extension.

The Chicago, Burlington & Quincy has petitioned the commission for an extension of time to June 30, 1925, to complete the automatic train control installation. The company has let a contract to the Sprague Safety Control & Signal Company which guarantees compliance with the commission's specifications.

The Richmond, Fredericksburg & Potomac, one of the four roads to which the Interstate Commerce Commission refused an extension of time beyond January 1 in which to complete the installation of automatic train control, has filed a petition with the commission for a rehearing. The petition says the road is a "bridge line" transferring the passenger and freight trains of six large roads and that therefore it is especially important that it have the best device obtainable. After the commission had authorized preliminary tests of 20-mile sections the company had contracted with the Union Switch & Signal Company on August 11 for an installation between Richmond and Doswell, Va., 20 miles, and expects to be in a position to request a preliminary inspection by the commission some time in March.

The Interstate Commerce Commission has granted the petition of the Richmond, Fredericksburg & Potomac for an extension of time in which to complete its automatic train control installation to July 1, although this was one of the four roads for which the commission had previously denied an extension. The commission has also granted an extension to July 1 on petitions filed since the first of the year by the Pennsylvania; the Pittsburgh, Cincinnati, Chicago & St. Louis; the West Jersey & Seashore and the Atlantic Coast Line.

The Central of New Jersey, which was also one of the four roads denied an extension of time, has filed a new petition asking for a reconsideration and for an extension to September 1.

New York Central to give lectures on railroading

Following a request from members of the New York Central Athletic Association at Rochester, N. Y., the New York Central has arranged for a course of lectures to be given on the science of railroading. The lectures will be in the nature of university extension courses and members will be invited to prepare papers on the subjects treated in each lecture for which prizes will be awarded. The lectures will be given on the last Thursday of each month.

On January 29 T. W. Evans, assistant vice-president of operation, lectured on the part played by the railroads in the economic life of the nation. On February 26 F. E. Williamson, general superintendent of the New York terminal district, will speak on transportation and supervision. On March 26 W. C. Wishart, controller, will speak on railroad financing and accounting. On April 30 G. W. Kittredge, chief engineer, will speak on the principles of railroad location and construction. The course will include lectures on locomotive and car design by F. H. Hardin, chief engineer of motive power and rolling stock; the maintenance of locomotives and cars by R. M. Brown, assistant superintendent of motive power; and on the maintenance of tracks, bridges and buildings, by J. V. Neubert, engineer maintenance of way. In addition, the faculty of Rochester University will participate.

Court news

FUSIBLE PLUGS NOT ESSENTIAL IN CROWN SHEETS UNDER BOILER INSPECTION ACT.—Action was brought in the federal district court for the northern district of Ohio, under the Federal Employers' Liability Act and the Boiler Inspection Act, against the Baltimore & Ohio for damages for the death of an engineman killed by an explosion of the boiler of his engine.

The trial court submitted for decision of the jury two issues: whether the explosion was caused in whole or in part by an unsafe and insufficient condition permitted by defendant in and about the crown sheet of the boiler; and, whether defendant's failure to have a fusible plug in the crown sheet violated Sec. 2 of the Boiler Inspection Act. Verdict and judgment were rendered for plaintiff. The Circuit Court of Appeals, Sixth Circuit, affirmed the judgment (288 Fed. 321), and the case was taken to the United States Supreme Court on certiorari.

1. The railroad asserted that Sec. 2 of the Boiler Inspection Act prescribes no definite or ascertainable standard of duty. The United States Supreme Court holds that the requirement of the statute "is as definite and certain as is the common law rule; and to hold that the duty imposed cannot be ascertained would be to declare that the common law rule which is ordinarily applied in personal injury actions brought by employees against employers is too indefinite to be enforced or complied with." This contention was therefore held to be without merit.

2. The railroad averred absence of evidence that the explosion

resulted from any defective or dangerous condition of the crown sheet.

There was no fusible plug in the crown sheet. The Supreme Court holds that Rule 25, approved by the Interstate Commerce Commission, does not purport to require fusible plugs to be used. It was shown that the boiler had seven broken staybolts, and that they had been broken some time before the day the explosion occurred; and it is held that use of the boiler in that condition violated Rule 25; but it was not shown what caused these to break. All persons on the engine—engineer, fireman and brakeman—were killed. The train had stopped for water at Foster's Tower, about three miles from the place of the explosion. A brakeman employed on another train, then at that station, testified that he went into the cab of this engine, and that, while there, he observed that water and steam were escaping from the boiler into the firebox; that he heard the sizzling of the water upon the fire; that, when he opened the firebox door, steam gushed out; that the fire was dead; that the steam gage showed 160 lb. pressure, and that water was being put into the boiler by the two injectors. The location of the broken staybolts in relation to the place of rupture was shown to be such that the explosion was not caused by them. But the court agreed with the Circuit Court of Appeals that, under Sec. 2 of the statute, there was sufficient evidence to sustain the verdict, wholly apart from the broken staybolts. The railroad was liable if its breach of duty contributed to cause the death. The credibility and weight of the brakeman's testimony as to the condition of the boiler at Foster were for the jury; and if the boiler was in the condition he described, it was held that it would not be unreasonable to conclude that a breach of duty of the railroad caused or contributed to cause the explosion. It did not conclusively appear that the failure of deceased properly to operate the engine was the sole cause of the explosion, so the evidence made a case for the jury.

3. The Supreme Court holds that the trial court erred in instructing the jury that the defendant was bound to avail itself of "the best mechanical contrivances and inventions in known practical use which are or would be effective in making safe a locomotive boiler as against explosions," and also erred in authorizing the jury to decide that "the standard of duty imposed by the law required a fusible safety plug to be installed." The carriers were left free to determine how their boilers should be kept in proper condition for safe use. The things required for that purpose were not prescribed or changed by the act. Defendant was not liable for failure to furnish the best mechanical contrivances or to discard appliances upon discovery of later improvements. * * * It is not for the courts to lay down rules which will operate to restrict the carriers in their choice of mechanical means by which their locomotives are to be kept in proper condition. The presence of absence of a fusible plug was a matter properly to be taken into consideration in connection with other facts bearing upon the kind and condition of the boiler in determining the essential and ultimate question, i. e., whether the boiler was in the condition required by the act."

Judgment for plaintiff was reversed.—Baltimore & Ohio v. Groeger. Decided January 5, 1925. Opinion by Mr. Justice Butler.

"B. & O. Plan" being put into operation in Moncton shops of C. N. R.

Steadier employment, better working conditions, greater output and improved service to the public are expected from the application of the "Baltimore & Ohio plan" which will be put into operation in the Canadian National shops throughout the Dominion. At the present time Captain O. S. Beyer, consulting engineer for the Railway Employees' Department of the A. F. of L. at Washington, is in Moncton, N. B., headquarters of the Atlantic Region of the Canadian National Railway, making the necessary arrangements. Surveys carried on for some months have been completed and at a recent meeting Captain Beyer addressed the men in Moncton and was given a cordial reception. When the plans are completed questions of interest to the management and the men will be dealt with through committees, which are already in existence, but which in the past have concerned themselves only with grievances.

Western roads settle with enginemen

Settlements on wage increases and changes in working rules for engine service employees have now been made by virtually all of the larger western railroads during the past week. The settlements in general follow the lines of the agreement of the Southern Pacific with its enginemen, which granted a wage increase of approximately 6 per cent, with minor changes in working rules.

The revisions of working rules made by the various roads are as follows. The Gulf, Colorado & Santa Fe adopted a 20 mile-an-hour speed basis for computing overtime in passenger service and adopted rules providing for no duplication in payment for arbitraries or special allowances with passenger road overtime; covering emergency side or lap back trips between terminals; and covering emergency short trips into and out of terminals in connection with their own trains. The wording in doubling hills and tonnage rules was also changed so that the management may avoid making ratings of engines over entire districts and giving the management an opportunity to change ratings at points where grades break in a district. The dead-head rule was also amended so as to provide that no compensation would be allowed for dead-heading resulting from the limitation of the Chicago joint working agreement. On the Chicago & North Western, a rule was adopted providing for emergency short runs in and out of terminals in connection with all trains to be paid continuous time or mileage when made under conditions such as engine failure, running for fuel or water, running for wreck car or carmen or on account of derailment. Rules were also adopted providing that in emergency combination hostler and road service or emergency com-

*Corrected figure.

Figures as to installations and retirements prepared by Car Service Division A. R. A. Figures cover only those roads reporting to the Car Service Division. They include equipment received from builders and railroad shops. Figures of installations and retirements alike include also equipment rebuilt to an extent sufficiently so that under the accounting rules it must be retired and entered in the equipment statement as new equipment.

bination hostler and yard service engineer or fireman will be paid for the entire service at the highest rate applicable to any class of service performed with a minimum of a day's pay for the combined service. On the Burlington, a rule was adopted providing that outside hostler's rate is not to apply on account of use of yard tracks supplying power with fuel, water and sand. Another rule was adopted that hostlers will be permitted to handle relief engines and be paid outside hostler's rates. The Los Angeles & Salt Lake revised several rules in accordance with the changes made by the Gulf, Colorado & Santa Fe.

Labor board decisions

The Railroad Labor Board has ordered the following wage increases in rates of pay of the clerical employees on the International-Great Northern represented by the Brotherhood of Railway and Steamship Clerks, Freight Handlers, Express and Station Employees: Storekeepers, assistant storekeepers, chief clerks, foremen and other clerical supervisory forces, two cents an hour; clerks with one or more years of experience, two cents an hour; clerks with less than one year's experience, one cent an hour; train and engine crew callers, assistant station masters, train announcers, gatemen and baggage room employees, two cents an hour; janitors, elevator operators and watchmen, one cent an hour; office boys and messengers, no increase; freight handlers and truckers, one cent an hour; sealers, scalers and inspectors, one cent an hour above truckers' rates; stowers, loaders and coopers, two cents an hour above truckers' rates; common laborers, an increase of two cents an hour; telephone switchboard operators, no increase.—*Decision No. 2784.*

The Railroad Labor Board has decided that an employee who is regularly assigned to positions with Sundays off shall be paid time and one-half for work performed on Sundays while working temporarily in place of another employee whose relief day is other than Sunday. The employee shall not be required to lay off on the relief day of the employee whose position he is filling temporarily if he desires to work.—*Decision No. 2892.*

New York Central employees buy twelve millions of stock

The New York Central announces that 41,570 employees have accepted the company's offer of stock in the corporation at 110, which is about $12 per share below the market price. Stock worth more that $12,000,000 was subscribed for. Approximately one employee out of every four on the system is on the list of subscribers and the number of common stockholders is more than doubled. Originally the offer was limited to 35,000 shares but 68,747 additional shares were later added.

All subscriptions for one or two shares will be filled under the allotment plan. Subscribers for three or four shares will receive two shares; subscribers for five to eight, three shares; nine to twelve, four shares; thirteen to sixteen, six shares. Payment is to be made in monthly installments. Before this offer was made the New York Central had 36,500 stockholders. There will now be about 78,000. Subscriptions from the various roads in the system were: New York Central, 23,689 individuals; Big Four, 8,821; Michigan Central, 3,624; Indiana Harbor Belt, 1,919; Chicago Junction Railway, 1,472; Pittsburgh & Lake Erie, 1,234; Boston & Albany, 811. Subscriptions for one share were received from 23,103 employees; for two to five shares from 15,963 employees; six to ten shares, 1,757 employees, and eleven to twenty shares, 747 employees.

Wage statistics for November

Class I railroads reported for the month of November, 1924, a total of 1,788,723 employees, a decrease of 33,893, or 1.9 per cent as compared with the returns for October, 1924, according to the Interstate Commerce Commission's monthly bulletin of wage statistics. This reduction in employment is largely attributable to seasonal reductions in the maintenance of way and structures forces. The total compensation decreased $19,421,725, or 7.6 per cent. The difference between the per cent of decrease in compensation and that in employment is explained by the fact that there were only 24 working days in November, while there were 27 in October. Compared with the returns for the corresponding month last year the employment shows a decrease of 5.8 per cent and the compensation a decrease of 5.5 per cent.

Meetings and Conventions

The following list gives names of secretaries, dates of next or regular meetings and places of meeting of mechanical associations and railroad clubs.

Air-Brake Association.—F. M. Nellis, Room 3014, 165 Broadway, New York City. Next meeting May 26-29, inclusive, Alexandria Hotel, Los Angeles, Cal.

American Railroad Master Tinners', Coppersmiths' and Pipefitters' Association.—C. Borcherdt, 202 North Hamlin ave., Chicago.

American Railway Association, Division V.—Mechanical.—V. R. Hawthorne, 431 South Dearborn St., Chicago. Business meeting to be held in Chicago June 16, 17 and 18. No exhibit of railway supplies and machinery will be held.
Division V.—Equipment Painting Section.—V. R. Hawthorne, Chicago. Next meeting September, 1925.
Division VI.—Purchases and Stores.—W. J. Farrell, 30 Vesey St., New York. Next meeting May 19, 20 and 21, at St. Louis, Mo.

American Railway Tool Foremen's Association.—G. G. Macina, 11402 Calumet Ave., Chicago. Annual convention August, 1925, Hotel Sherman, Chicago.

American Society of Mechanical Engineers.—Calvin W. Rice, 29 W. Thirty-ninth St., New York. Railroad Division. A. F. Steubing, Bradford Corp., 25 West Forty-third street, New York.

American Society for Steel Treating.—W. H. Eiseman, 4600 Prospect Ave., Cleveland, Ohio.

American Society for Testing Materials.—C. L. Warwick, 1315 Spruce St., Philadelphia, Pa. Annual meeting, June 22-26, Chalfonte-Haddon Hall, Atlantic City, N. J..

Association of Railway Electrical Engineers—Joseph A. Andreucetti, C. & N. W., Room 411, C. & N. W. Station, Chicago, Ill. Annual meeting October 20-24, Hotel Sherman, Chicago.

Canadian Railway Club.—C. R. Crook, 129 Charron St., Montreal, Que. Regular meetings second Tuesday in each month, except June, July and August, at Windsor Hotel, Montreal, Que.

Car Foremen's Association of Chicago.—Aaron Kline, 626 N. Pine Ave., Chicago, Ill. Meeting second Monday in month, except June, July and August, Great Northern Hotel, Chicago, Ill.

Car Foremen's Association of St. Louis.—R. E. Giger, 721 North 23rd street, E. St. Louis, Ill. Meetings, first Tuesday in month, except June, July and August, at the American Hotel Annex, St. Louis.

Central Railway Club.—H. D. Vought, 26 Cortlandt St., New York, N. Y. Regular meetings second Thursday each month, Hotel Statler, Buffalo, N. Y. Next meeting March 12. Paper on Uniform Interpretation of National Demurrage Rules and Charges will be read by J. F. Chalfaut, manager, department of demurrage supervision, A. R. A. Interim meeting April 9. Paper on Milling in Transit, Mixing in Transit and Reconsigning by W. B. Ewington, freight agent, Nickel Plate, Buffalo.

Chief Interchange Car Inspectors' and Car Foremen's Association.—A. S. Sternberg, Belt Railway, Clearing Station, Chicago.

Cincinnati Railway Club.—W. C. Cooder, Union Central Building, Cincinnati, Ohio. Meetings second Tuesday, February, May, September and November.

Cleveland Steam Railway Club.—F. L. Frericks, 14416 Adler Ave., Cleveland, Ohio. Meeting first Monday each month at Hotel Cleveland, Public Square, Cleveland. Next meeting March 20. Discussion A. R. A. rules.

International Railroad Master Blacksmiths' Association.—W. J. Mayer, Michigan Central, 2347 Clark Ave., Detroit, Mich. Next convention, Hotel Winton, Cleveland, Ohio, August 18, 19 and 20.

International Railway Fuel Association.—J. B. Hutchinson, 6000 Michigan Ave., Chicago, Ill. Next annual convention May 26-29, Hotel Sherman, Chicago.

International Railway General Foremen's Association.—William Hall, 1061 W. Wabasha Ave., Winona, Minn. Annual convention September 8-11, Hotel Sherman, Chicago.

Master Boiler Makers' Association.—Harry D. Vought, 26 Cortlandt St., New York, N. Y. Next convention May 19-25, Hotel Sherman, Chicago.

New England Railroad Club.—W. E. Cade, Jr., 683 Atlantic Ave., Boston, Mass. Regular meeting second Tuesday in month, except June, July, August and September. Copley-Plaza Hotel, Boston, Mass. Next meeting March 10. Forty-second annual meeting. Election of officers; reports. Address by Judge J. W. Redmond, general counsel, Central Vermont.

New York Railroad Club.—H. D. Vought, 26 Cortlandt St., New York. Meeting third Friday of each month except June, July and August at 29 West Thirty-ninth St., New York.

Niagara Frontier Car Men's Association.—George A. J. Hochgreb, 623 Brisbane Building, Buffalo, N. Y. Regular meetings, January, March, May, September and October.

Pacific Railway Club.—W. S. Wollner, 64 Pine St., San Francisco, Cal. Regular meetings second Thursday in month, alternately in San Francisco and Oakland, Cal. Next meeting March 12, Hotel Oakland, Oakland, Cal. Paper on Railroad Public Relations will be read by Ben S. Allen, director of public relations, Key System Transit Company. Railroad Advertising will be discussed by Charles W. Duncan, advertising counsellor, Foster & Keliser. Election of officers.

Railway Club of Greenville.—F. D. Castor, clerk, maintenance of way department, Bessemer & Lake Erie, Greenville, Pa. Meeting last Friday of each month, except June, July and August.

Railway Club of Pittsburgh.—J. D. Conway, 515 Grandview Ave., Pittsburgh, Pa. Regular meeting fourth Thursday in month, except June, July and August. Fort Pitt Hotel, Pittsburgh, Pa.

St. Louis Railway Club.—B. W. Frauenthal, Union Station, St. Louis, Mo. Regular meetings second Friday in each month, except June, July and August.

Southeastern Carmen's Interchange Association.—J. E. Rubley, Southern railway shops, Atlanta, Ga.

Traveling Engineer's Association.—W. O. Thompson, 1177 East Ninety-eighth St., Cleveland, Ohio. Annual meeting September 15-18, 1925, Chicago.

Western Railway Club.—Bruce V. Crandall, 189 West Madison St., Chicago. Next meeting March 16. Paper on Training of Apprentices will be read by C. G. Juneau, master car builder, C. M. & St. P.

Supply Trade Notes

The Chicago Metal Packing Company, Chicago, has changed its name to the Chicago Rhopac Products Company.

The Pantasote Company has removed its New York office from 11 Broadway to 250 Park avenue, New York City.

The Moline Foundry Company, Moline, Ill., has changed its name to the Moline Foundry & Machine Company.

The Weston Electrical Instrument Company, Newark, N. J., has changed its name to the Weston Electrical Instrument Corporation.

Harry S. Smith has been appointed railroad sales representative for the McMaster-Carr Supply Company, with headquarters in Chicago.

C. F. McCuen, formerly general sales agent of the Camel Company, Chicago, has been placed in charge of sales of W. H. Miner, Inc., Chicago.

W. R. Danley is now president of the Roto Company, Hartford, Conn., makers of boiler tube cleaners. Mr. Danley succeeds J. D. Cherry, who died on January 3.

James F. Twohy, secretary of Twohy Bros., railroad contractors, Seattle, Wash., has been elected vice-president of the Pacific Car & Foundry Company, Seattle, Wash.

W. R. Danley is now president of The Roto Company, Hartford, Conn., makers of boiler tube cleaners. He succeeded as president J. D. Cherry, who died on January 3.

A. S. Taylor, formerly sales engineer of the United Alloy Steel Corporation, Canton, Ohio, is now sales engineer of the Central Steel Company, Massillon, Ohio.

The Orton & Steinbrenner Company, Chicago, has appointed the William M. Bailey Company, Pittsburgh, Pa., representative for Pittsburgh and surrounding territory.

Lawrence Wilcox has been appointed representative in charge of the Columbus, Ohio, district of the Westinghouse Air Brake Company, to succeed S. D. Hutchins, deceased.

Glenn Grenville Howe, for many years senior vice-president of the Link-Belt Company, Chicago, died on December 25, at his home, in Muskegon, Mich., after a long illness.

John Y. Sloan, sales agent of the Pullman Car & Manufacturing Corporation, with headquarters at Chicago, has been promoted to manager of sales, with the same headquarters.

A. C. Cook, general sales manager of the Warner & Swasey Company, Cleveland, Ohio, has been promoted to vice-president and has been elected a member of the board of directors.

Norman J. Keyser, traffic manager for the Buffalo Forge Company, Buffalo, N. Y., has resigned to become head of the traffic division of the Kardex Company, at Tonawanda, N. Y.

James F. Hamilton, engineering and sales representative of the Worthington Pump & Machinery Corporation, has been promoted to manager of the newly opened sales office in Milwaukee, Wis.

E. R. Kenner, assistant sales manager of the Wellman-Seaver-Morgan Company, Cleveland, Ohio, has been appointed special representative of the H. K. Ferguson Company, Cleveland, Ohio.

The Joseph Dixon Crucible Company, Jersey City, N. J., has removed its Boston, Mass., office from 49 Federal street to 80 Federal street, which is the new Chamber of Commerce building.

The Ralston Steel Car Company, East Columbus, Ohio, is planning the construction of a one-story addition to its main plant, a new axle and wheel building and a paint and waste storage building.

The Premier Equipment Corporation, Houston, Tex., has been organized to take over the Houston Railway Car Company and will repair, buy and sell locomotives, cars, and other railway equipment.

Carl A. Pinyerd, representative of the Safety Car Heating & Lighting Co., at Chicago, has been appointed district engineer in charge of engineering and service matters, with headquarters at Chicago.

Walter S. Austin, mill representative of A. M. Castle & Co., with headquarters at Chicago, has been appointed general manager of sales for the Los Angeles Iron & Steel Company, Los Angeles, Cal.

The Landis Machine Company of Waynesboro, Pa., manufacturers of thread cutting die heads and threading machinery, has opened an office in Detroit at 5928 Second boulevard, in charge of J. W. Frey.

C. L. Wilkins, representative of the Walworth Manufacturing Company, with headquarters in Chicago, has been promoted to manager of the railroad and industrial department, to succeed J. E. Walsh, resigned.

John Heller, whose appointment as sales manager of the International Oxygen Company, Newark, N. J., was reported in the February issue of the *Railway Mechanical Engineer*, has been elected secretary of the company.

Lynn W. Nones has been appointed eastern sales manager of the Diamond Power Special Corporation, in charge of the Atlantic Coast offices from Boston, Mass., to Charlotte, N. C., inclusive. His office is at 90 West street, New York.

The American Car & Foundry Company will remove its operating and auditing departments about May 1, from 165 Broadway to the sixth floor of 30 Church street, New York City. The executive and other departments will follow about May, 1926.

W. H. Wiewel, assistant general sales manager of the United Alloy Steel Corporation, Canton, Ohio, has been appointed district sales manager of the Standard Seamless Tube Company, with headquarters at New York, to succeed B. F. Bart, resigned.

Carter P. Whitcomb, assistant sales agent of the Griffin Wheel Company, Chicago, in the New England territory, with headquarters at Boston, Mass., has been transferred as sales agent to the Pacific Coast territory, with headquarters at San Francisco, Cal.

Herbert H. Moffitt has been appointed southeastern representative of the Union Railway Equipment Company, with headquarters at Washington, D. C.; S. Clyde Kyle and N. Elliott have been appointed Pacific coast representatives, with headquarters at San Francisco, Cal.

H. Barney Gegenbach has been appointed western sales manager of the Hale-Kilburn Company, Philadelphia, Pa., in charge of its western sales office in Chicago. Mr. Gegenbach has been serving as acting western sales manager for over a year, since the death of Harry R. Rochester.

At a special meeting of the board of directors of the American Car & Foundry Export Company, New York, Oscar B. Cintas was elected a vice-president and director succeeding Charles S. Gawthrop, deceased. Mr. Cintas until his recent election was representative for the company in Cuba.

William R. Van Nortwick, who for the past seven years has been district sales manager at New York for the Roto Company, Hartford, Conn., has severed his connections with that company. Mr. Van Nortwick has opened offices at 50 Church street, New York, for the sale of material to buyers in the combustion field.

The Electric Arc Cutting & Welding Company, Newark, N. J., has opened a branch office at Syracuse, N. Y., in charge of William P. McCarthy. This office is completely equipped to handle all sales and distribution of welding machines and supplies for the entire state, exclusive of the Metropolitan district.

N. A. Campbell, field representative of the New York Air Brake Company, New York, died suddenly in Boston, Mass., on February 4, at the age of 60. He had been connected with the New York Air Brake Company for 25 years as field representative, originally in the western territory, but in recent years he covered the New England territory.

The Harnischfeger Corporation, Milwaukee, Wis., has moved its Atlanta, Ga., office to 303 Peninsular Casualty building, Jacksonville, Fla. W. J. Dugan, southern sales manager, will be in charge of the office and F. W. Truex, sales engineer at Atlanta, has been transferred to Jacksonville. G. H. Lillard and H. A. Wolcott have been appointed sales engineers, with headquarters at Jacksonville.

Willard D. Smith has been appointed manager of railroad sales of the Davis Boring Tool Company, St. Louis, Mo. C. C. Koeln, formerly in charge of production, has been transferred to the New York territory to take charge of eastern sales. Mr. Koeln should be addressed at the home office in St. Louis until his headquarters have been definitely located in the east.

Lewis O. Cameron, Munsey building, Washington, D. C., has been appointed district representative of the General American Car Company, Chicago. Mr. Cameron will handle sales on the southeastern railroads. He was formerly with the Pressed Steel Car Company, and for the last few years has been representing railway equipment companies in Washington.

Lynn B. Easton, manager of the Laidlaw works of the Worthington Pump & Machinery Corporation, New York, died at Cincinnati, Ohio, on January 24 at the age of 40. Mr. Easton had served for over 20 years at Laidlaw, in the sales department of the corporation, having started as time clerk, and then held many positions until he became manager of the works.

J. E. Walsh, manager of the railroad and industrial department of the Walworth Manufacturing Company, with headquarters in Chicago, has been appointed vice-president of Warren Corning & Co., to succeed T. R. Riley, resigned. H. F. Freyberg, office manager of the Vacuum Oil Company, with headquarters in Chicago, has been appointed secretary-treasurer to succeed H. G. Cook, resigned.

The sales department of the Baltimore office of the Symington Company has been removed to New York and continues under the jurisdiction of R. H. Gwaltney, vice-president in charge of eastern and southern sales, with headquarters in the Woolworth building, New York. I. O. Wright, sales engineer, with office in the Maryland Trust building, will continue to represent the Symington Company on the railroads having their principal offices in Baltimore. C. R. Naylor, sales agent at 2108 Straus building, Chicago, has been appointed manager western sales.

Charles J. Graham, vice-president of the Graham Bolt & Nut Company, Pittsburgh, Pa., who in December bought the Gould Coupler Company and the Gould Storage Battery Company from Commodore Charles A. Gould, has disposed of his holdings to a group of New York bankers who are acting for the Symington interests. The new company will be the Gould Coupler Company of Maryland, and William S. Gould, vice-president of the old company, will be president of the new company. The policies of the old company will be continued under Mr. Gould's direction, and there will be no material change in the management. This statement is authorized by Charles J. Symington, president of the Symington Company.

Frederick C. Riddile, general manager of the Edgewater Steel Company, Pittsburgh, Pa., died on December 21 at the Columbia Hospital, Pittsburgh, after a short illness, at the age of 59 years. Mr. Riddile was born in Burgettstown, Pa. His early life was spent in Pittsburgh, and as a young man he entered the employ of the Oliver Iron & Steel Company, later becoming associated with the Latrobe plant of the Railway Steel Spring Company. He then went to Chicago Heights, Ill., as general superintendent of the Inter Ocean Steel Company, and since the organization of the Edgewater Steel Company in 1916 he has been its general manager.

E. I. Cornbrooks has been appointed sales manager of the Newport News Shipbuilding & Dry Dock Company, Newport News, Va., succeeding Benjamin G. Fernald, who has resigned on account of ill health. Mr. Cornbrooks has been connected with the company for nearly twenty years, serving first as chief draftsman in the hull department and later as superintendent of hull construction and superintendent of construction. He has had an important part in the development of the company's new products, including railroad equipment and large hydraulic turbines and accessories such as regulating gates, valves, penstocks and surge tanks.

L. D. Whitaker, who recently severed his connection with the United States Steel Corporation, has become associated with Ralph W. Payne in the railway supply business at Washington, D. C. He was born at Salisbury, N. C., on May 25, 1898. He was educated in the North Carolina public schools and is a graduate of Emerson Institute, Washington, D. C., and the Law School of George Washington University, also spending three years in the arts and sciences department of that institution. He was connected with the American Surety Company of New York, from 1914 to 1917, and then entered the Washington sales office of the United States Steel Corporation, where he has since been located with the exception of one year in the marine corps during the war.

Albert Waycott, founder and former president of the Damascus Brake Beam Company, Cleveland, Ohio, died on January 15 in a hospital in San Francisco, Cal., following an attack of heart disease, which occurred while he was returning from a trip to Panama. He was born in St. Andrews, New Brunswick, and came to St. Louis, where he organized the firm of Albert Waycott & Co., in 1897, and engaged in the sale of brake beams. In 1903 he organized the Damascus Brake Beam Company in St. Louis, Mo., and was president of this company until 1917, when he became chairman of the board. In 1918 he moved to New York and became an inactive member of the board, remaining so until the sale of the Damascus Brake Beam Company to the American Steel Foundries Company, which occurred in 1924.

The Youngstown Steel Door Company has been incorporated in Chicago to engage in the manufacture and sale of steel doors for railway freight cars and has acquired all of the assets and patent rights of the Steel Door, Inc., and the American Steel Door Company. James A. Campbell, president of the Youngstown Sheet & Tube Co., is president of the new company. Charles B. Moore, vice-president of the Oxweld Railroad Service Company, Chicago, is vice-president. John P. McWilliams, general manager of the Oxweld Railroad Service Company, with headquarters at Chicago, has been appointed vice-president and general manager, with headquarters in Cleveland, Ohio. Directors of the new company are J. A. Campbell, Youngstown, Ohio, H. S. Coulby, Cleveland, H. D. Dalton, Cleveland, J. T. McWilliams, Cleveland, C. B. Moore, Chicago, F. F. Prentiss, Cleveland, and J. L. Severance, Cleveland. John P. McWilliams was born on January 8, 1891, in Chillicothe, Ohio, and graduated as a civil engineer from Princeton University in 1913. He entered railway service in 1913 as a timekeeper on the Grand Trunk Pacific, which position he held until October, 1914, when he entered the employ of the Oxweld Acetylene Company. He was promoted to sales manager in 1916. In 1917 he entered the employ of the Oxweld Railroad Service Company as assistant to the vice-president. He was commissioned a captain in the Motor Transport Corps of the United States Army in 1918 and later served as an executive officer of the Welding School at Camp Holabird, Md. He re-entered the employ of the Oxweld Railroad Service Company in 1919 as assistant to the president, with headquarters at New York, which position he held until 1921, when he was promoted to general manager, with headquarters at Chicago. He held the latter position until December 31, 1924, when he resigned to become vice-president and general manager of the Youngstown Steel Door Company.

J. P. McWilliams

David B. Rushmore, one of the consulting engineers of the General Electric Company, Schenectady, N. Y., has resigned and is now located in New York City, with headquarters at the University Club. He graduated from Swarthmore College in 1894 with the degree of bachelor of science and engineering and from Cornell University the following year in the electrical engineering course. In 1897 he received the degree of civil enginer from Swarthmore College and in 1923 the honorary degree of doctor of science from the same college. Mr. Rushmore was with the Westinghouse Electric & Manufacturing Company, and later with the Royal Electric Company of Montreal previous to his service of 25 years with the General Electric Company and the Stanley Electric Company, Pittsfield, which was absorbed by the General Electric Company. In 1905 he went to Schenectady, and for 17 years was engineer of the power and mining department.

The firm of Cook & Riley has been incorporated in Chicago to deal in railway and industrial supplies. It will represent the J. Milton Hagy Waste Works, the E. Arnstein Paint Company, and the Universal Coupling Company. The organizers are T. R. Riley, vice-president, and H. G. Cook, secretary and treasurer of Warren Corning & Co., Chicago.

Laughlin & Cheney, Inc., has been organized, with headquarters at 310 South Michigan avenue, Chicago, by P. L. Laughlin, district sales manager of the Verona Tool Works, with headquarters at Chicago, and B. M. Cheney, general inspector of permanent way and structures, Chicago, Burlington & Quincy, with headquarters at Chicago. The new firm will deal in railway supplies, specializing in the products of the Verona Tool Works.

Le Roy Kramer, vice-president in charge of western sales of the Symington Company, with headquarters at Chicago, has been appointed vice-president in charge of manufacturing and sales of the General American Tank Car Corporation, with headquarters in Chicago. He spent several years in the operating department of the St. Louis-San Francisco and the Chicago, Rock Island & Pacific and from 1912 to 1918 was vice-president of the Pullman Company in charge of the manufacturing and repair shops. During 1918 and 1919 he was federal manager of the St. Louis-San Francisco and the Missouri-Kansas-Texas. In 1919 he was appointed vice-president of the Willys-Overland Company and in 1921 he was appointed vice-president in charge of western sales of the Symington Company, with headquarters at Chicago.

Le Roy Kramer

American Car & Foundry Company

At a special meeting of the board of directors of the American Car & Foundry Company, New York, on February 15, Herbert W. Wolff, vice-president of the company and G. R. Scanland were elected directors. Mr. Scanland, who has for years been auditor of the company, was elected also vice-president in charge of finances and accounts; S. A. Mallette, assistant treasurer, was elected treasurer to succeed S. S. DeLano, deceased; E. S. Block, assistant auditor was made auditor and Miss Alma E. Jackson was appointed assistant treasurer. Mr. Wolff will retain his office in Chicago and continue in charge of sales in that territory. The other officers will be located in New York. G. R. Scanland, the new vice-president and director, was born at Pittsfield, Ill., on May 8, 1877. He entered the employ of the American Car & Foundry Company as a clerk in the auditing department in 1899 and five years later was appointed local auditor of the Memphis district. In 1905 he was appointed traveling auditor and in December of the following year was elected assistant auditor. In November, 1917, Mr. Scanland was elected auditor and now becomes vice-president in charge of finances and accounts and a director. S. A. Mallette, the new treasurer, was born at Union City, Conn., in 1870. He served in the automatic block signal field after leaving school and joined the American Car & Foundry Company when it was organized in 1899. In 1905 he was elected assistant treasurer. E. S. Block, who has been appointed auditor, was born at St. Louis, Mo., on Aug. 31, 1879. He began work as a clerk in the general auditing department of the American Car & Foundry Company in 1900 and was appointed general bookkeeper in 1906. He was appointed traveling auditor in 1911 and in November, 1917, was elected assistant auditor. Miss Alma E. Jackson, who has been appointed assistant treasurer, was born in Callaway county, Mo., and was educated in the public schools, graduating from the St. Louis high school in 1899. She began work with the American Car & Foundry Company in 1900 as a stenographer and now becomes assistant treasurer.

Trade Publications

RIVETERS.—Bulletin R-201, illustrating and describing Hanna pinch bug riveters, has just been issued by the Hanna Engineering Works, Chicago, Ill.

CRANES.—A new general catalogue and a new locomotive crane catalogue have been prepared by the American Hoist & Derrick Company, St. Paul, Minn.

CENTRIFUGAL PUMPS.—"Worthington Centrifugal Pumps Serving Every Industry," is the title of Bulletin No. W-607 which has recently been issued by the Worthington Pump & Machinery Corporation, New York.

ELECTRIC TRAMRAIL.—An eight-page circular illustrating a few of the various plants served by Cleveland hand or electric tramrails, has been issued by the Cleveland Crane & Engineering Company, Wickliffe, Ohio.

CO_2 EQUIPMENT.—Bulletins No. 118 and 118A descriptive of the Apex CO_2 recorder and the principle of operation of the Apex pneumatic CO_2 meter and indicator, have been issued by the Uehling Instrument Company, Paterson, N. J.

LOCOMOTIVE HOISTS.—A circular briefly outlining the savings which may be effected through the use of a locomotive hoist and showing various applications of the Whiting hoist, has been issued by the Whiting Corporation, Harvey, Ill.

COMBINATION GRINDING AND BUFFING MACHINES.—Bulletin No. 1582, descriptive of four new types of motor driven combination grinding and buffing machines, built in ½ and 1 hp. sizes with open and encased spindle extensions, has been issued by the Hisey-Wolf Machine Company, Cincinnati, Ohio.

OIL-ELECTRIC LOCOMOTIVE.—Bulletin No. 44103.1, descriptive of the 60-ton oil-electric locomotive developed by the General Electric, the American Locomotive and the Ingersoll-Rand Companies, is being issued by the General Electric Company, Schenectady, N. Y. Photographs of the locomotive in service, views of the interior, and tables of operating data and specifications, as well as a general description, are included in the booklet.

BORING TOOLS AND REAMERS.—Railroad catalogue No. 25, giving a complete description of Davis expansion boring tools as standard equipment for railroad shops, has been issued by the Davis Boring Tool Company, St. Louis, Mo. The catalogue contains a complete treatise on Davis expansion car wheel boring tools for the car department, and a completely new line of boring tools and reamers recently developed for the locomotive departments of the railroads.

STOKERS.—A bulletin descriptive of the self-contained traveling grate stoker, which has been installed throughout the British Isles and Continental Europe, has been issued by the Combustion Engineering Corporation, New York. The stoker is adaptable to a wide range of fuels, including non-coking bituminous coals, anthracite coals, coke breeze and lignites, and may be applied to boilers of all sizes and types, it being particularly suited to boilers ranging up to 600 hp.

BALANCING GRINDING WHEELS.—The Norton Company, Worcester, Mass., has issued a 24-page brochure entitled, "The balancing of grinding wheels," in which the advantages and economy of balancing the grinding wheel are briefly outlined. Balancing for precision grinding and the balancing of flanges for off-hand grinding are then discussed and directions for balancing off-hand wheels given. The principle of adjusting the balancing weights to obtain a range from the maximum to the minimum counter-balance is also shown.

CAR SILL SECTIONS.—Sectional drawings of center sill section B 112 and side sill channel C 211 are shown in an eight-page brochure issued by the Carnegie Steel Company, Pittsburgh, Pa. The center sill section is the A. R. A. design incorporated in 1923 in the proposed designs for four standard box cars, a relatively large number of which have since been built. The side sill channel, while not an A. R. A. design, has been accepted for use on cars already built, considerable lateral stiffness being afforded by the wide flanges with which it is rolled and to which side framing and floor system can be readily attached.

Personal Mention

General

T. M. KIRKBY, mechanical assistant to the general superintendent of motive power of the Chicago, Milwaukee & St. Paul, with headquarters at Chicago, has been promoted to special representative, with the same headquarters.

J. S. NETHERWOOD, whose promotion to assistant superintendent of motive power and equipment of the Southern Pacific, Louisiana lines, with headquarters at Algiers, La., was reported in the January issue of the *Railway Mechanical Engineer,* was born on November 18, 1889, at Lohn, Tex. He graduated from the Agricultural and Mechanical College of Texas in June, 1911, and entered railway service immediately thereafter as a draftsman in the office of the mechanical engineer of the Southern Pacific at Houston, Tex. He was promoted to chief draftsman in February, 1913, and held that position until September, 1918, when he was promoted to mechanical engineer of the Texas lines, with headquarters at Houston, Tex. Mr. Netherwood remained in that position until his recent promotion to assistant superintendent of motive power and equipment.

P. W. KIEFER, whose promotion to engineer of rolling stock of the New York Central, with headquarters at New York, was announced in the February issue of the *Railway Mechanical Engineer,* entered railway service as an apprentice in the mechanical department of the Lake Shore & Michigan Southern (now a part of the New York Central) and in 1916 he entered the equipment engineering department. He later served as locomotive designer, leading draftsman and on dynamometer car tests and in July, 1920, he was promoted from the position of chief draftsman in the locomotive department of the equipment engineering department to the position of assistant engineer in the office of the engineer of rolling stock. In March, 1923, Mr. Kiefer was promoted to assistant engineer of rolling stock and in May, 1924, he was promoted to engineer of motive power of the Lines East and West of Buffalo, N. Y.

H. W. WILLIAMS, special representative to the general superintendent of motive power of the Chicago, Milwaukee & St. Paul, with headquarters at Chicago, has been promoted to superintendent of motive power of the Western Lines, with headquarters at Tacoma, Wash., succeeding Frank Rusch, deceased. Mr. Williams graduated from Purdue University in June, 1910, and after one year as an instrument man on the Chicago Junction, entered the service of the Chicago, Milwaukee & St. Paul as a draftsman in the office of the engineer of design. He was transferred to the construction forces at Lewistown, Mont., in December, 1913, and in March, 1914, was promoted to structural draftsman in the electrification department. Mr. Williams was promoted to chief draftsman in January, 1915, and to assistant engineer in 1917. He was appointed special representative to the general superintendent of motive power in November, 1920.

Master Mechanics and Road Foremen

GEORGE HIGGS has been appointed road foreman of engines of the Central of New Jersey, succeeding A. Kirkendall, deceased.

F. T. MCCLURE has been appointed road foreman of engines of the Eastern division of the Atchison, Topeka & Santa Fe, with headquarters at Ottawa, Kan.

E. C. CAREY has been appointed assistant road foreman of engines of the Norfolk & Western, with headquarters at Bluefield, W. Va., succeeding W. F. Perkins, promoted.

G. F. BURKE, general foreman of the Southern Pacific, with headquarters at Roseville, Cal., has been promoted to master mechanic, with headquarters at Tucson, succeeding O. B. Schoenky.

O. B. SCHOENKY, master mechanic of the Southern Pacific, with headquarters at Tucson, Ariz., has been promoted to superintendent of motive power, with headquarters at Los Angeles, Cal., succeeding Patrick Sheedy, who has retired.

JOHN P. MORRIS, whose appointment as master mechanic of the Atchison, Topeka & Santa Fe, with headquarters at Chicago, was announced in the January issue of the *Railway Mechanical Engineer,* was born in 1889 at Fort Madison, Iowa. He attended the Fort Madison public schools, entering the employ of the A. T. & S. F. as a machinist helper on September 27, 1904. He became a machinist apprentice in June, 1906, and from February, 1911, to January, 1916, he was a machinist on the Missouri division. In January, 1916, he was promoted to assistant roundhouse foreman, with headquarters at Shopton, Iowa; in July, 1917, promoted to roundhouse foreman at Fort Madison; and in April, 1923, to general shop foreman, locomotive department, in which capacity he remained until his appointment as master mechanic at Chicago.

J. E. STONE, whose appointment as master mechanic of the Salt Lake division of the Southern Pacific was announced in the February issue of the *Railway Mechanical Engineer,* was born on July 19, 1885, at Shoshone, Idaho. He entered railroad service in 1902 as a machinist apprentice on the Oregon Short Line. From August, 1906, until December, 1908, he was machinist and shop draftsman at Pocatello, Idaho; from January, 1909, until May, 1911, draftsman in the office of the superintendent of motive power at Salt Lake City, Utah; from May, 1911, until April, 1912, draftsman of the Ray Consolidated Copper Company, Ray, Ariz., and from April, 1912, until March, 1913, assistant machine shop foreman of the Oregon Short Line at Ogden, Utah. He was then appointed general foreman. On July 1, 1914, the Southern Pacific took charge of the Ogden shops and Mr. Stone was retained as general foreman until August, 1920, when he was transferred to Sparks, Nev., as assistant master mechanic of the Salt Lake division.

Car Department

W. G. BROWN has been appointed division car foreman of the W. N. & P. division of the Boston & Maine, with headquarters at Worcester, Mass.

ANDREW CRAIG has been appointed division car foreman of the Terminal division-freight, of the Boston & Maine, with headquarters at Charlestown, Mass.

Shop and Enginehouse

FRANK FOUSE has been appointed shop superintendent of the Lehigh Valley, with headquarters at Packerton, Pa.

A. J. DIETRICH, roundhouse foreman of the Atchison, Topeka & Santa Fe at Barstow, Cal., has been transferred to Bakersfield, Cal., succeeding R. T. Gorman.

C. H. WALL, division foreman of the Atchison, Topeka & Santa Fe at Barstow, Cal., has been appointed roundhouse foreman, with headquarters at Richmond, Cal.

R. T. GORMAN, roundhouse foreman of the Atchison, Topeka & Santa Fe at Bakersfield, Cal., has been appointed division foreman, with headquarters at Barstow, Cal.

Purchasing and Stores

D. W. CORCORAN, traveling storekeeper of the Chicago & North Western at Chicago, has been promoted to assistant general storekeeper, with the same headquarters.

F. B. TAYLOR has been appointed division storekeeper of the Iowa division of the Chicago & North Western, with headquarters at Clinton, Iowa, succeeding E. J. Leonard.

W. H. FITZPATRICK, traveling storekeeper of the Chicago & North Western, at Chicago, has been promoted general storekeeper, with the same headquarters, succeeding A. L. Tucker, who has retired.

Obituary

C. F. LAPE, for nine years master mechanic of the Atchison, Topeka & Santa Fe, with headquarters at San Bernardino, Cal., died on January 6, at the age of 81.

ARTHUR KIRKENDALL, road foreman of engines of the Central of New Jersey, with headquarters at Jersey City, N. J., died at his home in Westfield, N. J., on February 4, at the age of 63. He had been in the service of the Central of New Jersey for 42 years.

M. B. RICHARDSON, *Associate Editor* H. C. WILCOX, *Associate Editor*

Entered at the Post Office at New York, N. Y., as mail matter of the second class.

Request for change of address should reach the New York office two weeks before the date of the issue with which it is to go into effect. It is difficult and often impossible to supply back numbers to replace those undelivered through failure to send advance notice. In sending us change of address, be sure to send us your old address as well as the new one.

Subscriptions, including the eight daily editions of the Railway Age published in June, in connection with the annual convention of the American Railway Association, Mechanical Division, payable in advance and postage free: United States, Canada and Mexico, $3.00 a year; foreign countries, not including daily editions of the Railway Age, $4.00. Foreign subscription may be paid through our London office, 34 Victoria Street, S. W. 1, in £ s. d. Single copy 35 cents.

The *Railway Mechanical Engineer* is a member of the Associated Business Papers (A. B. P.) and the Audit Bureau of Circulation (A. B. C.).

Railway Mechanical Engineer

Vol. 99 April, 1925 No. 4

Casehardening valve motion parts

The even distribution of steam in the cylinders of a locomotive depends on the proper functioning of the valve motion which, in turn, depends largely on the amount of wear in the pins, bushings, etc., of the gear. The wear of these parts varies, other conditions being equal, to the degree of their surface hardness. The carburization and casehardening of valve motion parts is the key to the situation which is clearly set forth in an article on this subject that appears elsewhere in this issue. There are still many shops and enginehouses that use the old fashion method of casehardening with potash, which hardens only the skin of the parts and does not penetrate into the metal. As a result, regardless of lubrication, the parts wear quickly which soon leads to the improper functioning of the motion.

The installation of a highly developed system for casehardening valve motion parts would eliminate this trouble. First, there should be installed at the larger shops of the railroads a modern, electrically controlled furnace for casehardening. Those who operate the furnace and are in charge of the work should have complete information pertaining to the subject. With the right equipment and properly trained men in charge a system of production can be worked whereby every locomotive repair point on the road may carry in stock valve motion parts properly hardened ready to be touched up on a grinder and applied to the locomotive. Hit and miss methods of heat treatment in railroad shops have passed by and are being rapidly superseded by equipment and practices which produce accurate results.

High purity oxygen economical

The railway industry is a large consumer of oxygen but is it adequately informed of the fact that the higher the purity of the gas, the more economical is its consumption? This fact, along with many other interesting characteristics of oxygen are clearly set forth in an article on the economies effected by the use of high purity oxygen which appears on another page of this issue. It is pointed out that as the purity of the oxygen increases, the consumption and cutting time decreases. Take for example, the cutting of 3/8 in. steel, using 100 cu. ft. of 99.5 per cent oxygen as a basis of comparison. By reducing the purity to 99.0 per cent the consumption is increased to 114.1 cu. ft. Thus, a cylinder containing 200 cu. ft. of 99.0 per cent oxygen would yield, in reality, only 171.8 cu. ft. A car shop using 50 cylinders of 99.0 per cent oxygen a day would lose a potential consumption of 1,410 cu. ft. which would otherwise be available by using 99.5 per cent oxygen. Figuring on a basis of 26 working days a month, a total of 36,660 cu. ft. of the gas, or 183 more cylinders are consumed than would have been necessary by using 99.5 per cent oxygen. This means that 183 more cylinders of oxygen would have to be purchased or, figured on the basis of $1.50 per cylinder, a loss of $274.50.

Now let us turn to the savings effected in the cutting time by using higher purity oxygen. The time required to cut a given length of 3/8 in. steel using 99.5 per cent oxygen is 74 min. and 18 sec. To cut the same steel using 99.0 per cent oxygen requires 84 min., 45 sec., or a difference in time of 10 min., 27 sec. By using 98.5 per cent oxygen, the cutting time is increased 19 min., 6 sec. above the time required for the 99.5 per cent gas. Thus it can be readily seen that a large amount of time would also be lost daily by using oxygen that was not up to a high standard of purity. Since small increments of change in the purity of oxygen have a marked effect on operating costs, the railroads should establish a standard of purity and religiously adhere to it when purchasing oxygen.

Anti-friction bearings for railroad equipment

The demands on a railway car journal are of an exacting nature and they will become more so as cars of greater capacity are built. The problem of increased train tonnage is gradually reaching the stage which will eventually demand a reduction in journal friction. Experience in other industries has indicated that ball bearings can carry comparatively heavy loads at reasonably high speeds, but in order to be successfully applied to railway rolling equipment, ball bearings will have to be of dimensions which are quite impracticable. The roller bearing was developed in the search for an anti-friction bearing that would carry heavier loads. In recent years, we have seen various modifications of both the ball and roller bearings as well as designs involving combinations of the two.

The conditions under which railroad equipment will be operated in the future will demand a journal bearing having a minimum of friction, capable of handling both radial and thrust loads, and easy to maintain; that is, have no loose parts and be capable of quick inspection.

A number of attempts have been made to apply both ball and roller bearings to car journals. However, the capacity of these bearings over the static load was not sufficient to give the long life necessary to economical car maintenance. The greater number of tests of anti-friction journal bearings have been performed on European railway equipment, which is considerably lighter than that used in this country. However, considerable data of value have been obtained as a result of these experiments. The Swedish State railways have conducted a number of experiments with an especially designed shock absorber and data have been collected as to the radial and lateral shocks incurred by a car journal box in actual service. Undoubt-

edly this progress in anti-friction journal bearing design will become as important to the car designer as the three-cylinder or steam turbine developments have been to the locomotive designer. The mechanical engineer employed in the design and maintenance of railway rolling equipment should watch closely the further development of anti-friction journal bearings.

Are brains an asset?

Word was recently passed along the line on a certain railroad that one of its shop superintendents was slipping. An extensive area of the top of his desk had recently begun to show through the piles of correspondence with which it had once been covered. Furthermore, on several occasions he had been found in his office doing nothing, apparently thinking intently. The fears for this officer's future which have begun to find lodgment in the minds of other officers and men up and down the line, and the facts on which they are based are significant. It may be inferred, first, that unless the desk of a minor managing officer is not buried in correspondence, he is not as busy as he should be; and, second, that with no evidence of industry before him, he should never be found sitting at his desk. Apparently he should be seen hurrying from place to place in the shop demonstrating his superior ability by "bawling out" his foremen for their shortcomings. Undoubtedly there should be a place in every superintendent's daily schedule for a personal inspection of the operations over which he has general supervision. With a good organization and competent foremen, however, this need not occupy all or even a major part of his time. Time spent in quiet reflection on the problems of more and cheaper output need by no means be considered as wasted. Men must have four personal instruments with which to make themselves useful; their hands, their feet, their mouths and their brains. The mechanic's usefulness lies largely in the skill with which he can use his hands. It is being recognized more and more, however, that his brains are an asset which also ought to be utilized. The foreman is expected to use his feet and his mouth, the skill and tact with which he uses the latter instrument largely determining the quality of his personality. Here, again, the value of brains in directing the feet and the mouth is constantly receiving more recognition in the attention which is being given to the better selection and training of these direct supervisors. But in the case of an officer who may be responsible for the results of the labor of several hundred men, using several million dollars' worth of facilities, the attempt to make a little more intensive use of his brains in constructive planning than is expected of the mechanic or the foreman should not excite unfavorable comment. If brains are valuable, why not give a little more scope to their activity where it will accomplish the biggest results?

Foreman training

The *Railway Mechanical Engineer* has had much to say in recent years about the necessity of special coaching and training of foremen and supervisors in the art of leadership. It is essential, if the railroads are to be operated economically and efficiently, that there be intelligent and enthusiastic co-operation on the part of all the workers—supervisory and in the ranks. This objective, however, cannot be attained if the foremen and supervisors are indifferent or if they do not have a keen appreciation of the importance of the human element in the organization.

The truth of this has been steadily growing in the consciousness of railway managements in recent years and is indicated in many ways. A notable illustration of this interest is contained in the annual report of the Boston & Maine for the year 1924. This report contains several paragraphs relating to relations between the employees and the management and includes this significant statement: "Educational work of a practical nature has been extended during the year, as opportunity would permit. The foremen's clubs in the mechanical department, organized last year at several points, have been extended over the system and are discussing problems of proper supervision as well as of shop practices, with increased attendance and interest."

Clubs of this sort naturally function best during the winter months, although much can be done among the foremen along educational lines during the entire year. Foremen's clubs of various sorts have functioned to advantage on several railroads during the past year. Attempts to develop such clubs, on the other hand, have failed or have had little results in other places. The importance of the question has been entirely overlooked on not a few railroads. Now is the time to take stock and to consider what steps should be taken to promote this constructive development next year. Why has the movement failed on some roads and been a notable success on others? The foremen are the liaison officers between the management and the men and they can immensely improve an organization or greatly weaken it, depending on whether or not they have a large appreciation of their responsibilities and utilize every advantage to inform themselves as to the best ways of successfully discharging their difficult responsibilities.

Here is another significant quotation from the Boston & Maine report: "It (the management) would fail in its duty alike to the property, to the public and to its own organization if it were to regard the building up of an effective co-operation as of less consequence than the technical problems of operation, maintenance and finance. Urgent as these problems are, under all circumstances, it remains permanently true that the labor and supervision cost is the largest item in the budget, and justifies, for this reason alone if on no broader grounds, special attention to the proper basis for a service distinguished by voluntary interest and good will rather than a mere perfunctory discharge of assigned duties."

Apprentice conferences

Readers of the *Railway Mechanical Engineer,* and its predecessors, have noted not a few times during the past 15 years, reports of system conferences of apprentice instructors. A rather unusual development which has taken place within the past year has been system gatherings of apprentices or younger railroad employees. The Santa Fe had a system apprentice conference at Albuquerque, N. Mex., in March, 1924; it was promoted by some of the boys who attended the first Railroad Younger Men's Conference of the Y. M. C. A., held in St. Louis near the end of 1923. The second apprentice conference on the Santa Fe was held at San Bernardino, Cal., February 19-21 of this year and was attended by 150 picked young men who were sent as delegates from the apprentice clubs on the system. These clubs are maintained by the boys themselves, for their physical, mental and moral development and improvement. The three-day program included reports and discussions on the activities of the various clubs and as to how to make them more effective. The delegates, upon their return home, reported orally to their local clubs and presented written reports of their observations to the local master mechanic or superintendent of

shops. The general results were summed up as follows in an article in a recent issue of the Railway Age: "It is difficult to estimate the good derived from a meeting of this kind. Certainly leadership was developed. Each delegate returned to his home station with a greater love for the work of his trade, a greater appreciation of the plans and purposes of the railway management, and a greater conception of the nobler things of life, a greater degree of co-operation with officials and fellow employees, and a greater determination to make the best of every opportunity offered."

The Chesapeake & Ohio has just held a similar system conference at Huntington, W. Va., but including representation from all of the classes of boys and young men on the railroad, although the larger proportion of the delegates came from the mechanical department apprentices.

The Younger Railroad Men's Conference of the Y. M. C. A. held a second meeting at Detroit last November, at which 279 young men were present, representing 48 railway systems, from 33 states and provinces, and 58 different classifications of occupations.

It will be interesting to watch the development of this new movement and try to trace the beneficial results which will come from it. It would seem that the young men would gain a far greater appreciation of the importance of the railroads from an economic point of view and that they would be inspired to take a larger and more intelligent interest in their work. Instances are already on record where young men going home from these conferences have had a strong and beneficial influence upon their comrades who were not so fortunate as to attend the conference. In applying scientific methods to improve the morale in the army in recent years, a new slogan has been adopted—"The Army Builds Men." The objective is to develop each man in the organization to the fullest extent of his ability. This new movement among the younger men on the railroads would seem to tend in the same direction and should result in getting the young men into that particular class of work for which they are best suited, in making them more happy and contented in their work, and in fitting them to carry larger responsibilities in the future.

Air compressor misalinement

The standards of air compressor maintenance should be kept as high as possible. One of the details which probably gives more trouble than any other single item is inaccurate alinement of the cylinders which may be due to any one of a number of conditions. Whatever the reason, the result is the same—decreased air compressor efficiency, shorter compressor life, increased failures and generally increased operating costs. The following are some of the observed results: Misalinement sometimes causes reversing valve rod chatter, resulting in failure due to a crystallized and broken valve rod. Misalinement causes the pistons to bind and wear on one side at the bottom of the stroke and on the opposite side at the top of the stroke. This binding will continue until the cylinder walls and pistons are worn enough to give free travel; the result is out-of-round cylinders and pistons with excessive clearance and ring gap. Continual binding may also result in the pistons becoming loose on the piston rods and the nuts coming off.

There are cases where the piston has stayed tight on the rod but the continual binding action has crystallized the rod with the result that it snapped off close to the piston. Misalinement causes the piston rings to shift continually in the piston, resulting in undue wear of the rings and grooves and permitting the air to blow by, thus shortening the life of these parts as well as contributing to compressor inefficiency.

One of the greatest difficulties resulting from cylinder misalinement is packing trouble, caused by the side motion of piston rods. Stuffing box nuts must of necessity be drawn exceedingly tight to prevent leaks under this condition and the life of the packing is correspondingly shortened. The air compressor is subjected to continual laboring on account of the tight packing and naturally more steam is consumed in operating pistons that are so hard to move. This excess packing pressure greatly increases wear on the piston rods which is also undesirable.

Fortunately these difficulties can be entirely overcome. Several machines, both grinders and boring machines, are fitted with revolving indexing tables and there is no reason why the same principle may not be adapted to others. With the pump mounted on the indexing table the cylinders may be bored without breaking the joints between the cylinders and the center castings. After boring one end the table may be revolved and accurately set at 180 deg. from its original position, which removes all guess work as to the accuracy of alinement of the cylinders.

Since the misalinement of air compressor cylinders is responsible for so many evils as outlined, it behooves shop superintendents, air room foremen and others responsible for the work of repairing air compressors to check their practice in this respect. If they are having difficulties, probably the method mentioned may solve the trouble.

New Books

Master Blacksmith's Proceedings. *Edited by William J. Mayer, Secretary, 2347 Clark Avenue, Detroit, Mich.* 133 *pages* 5½ *in. by* 8 *in. Bound in Cloth.*

Those interested in the methods employed in the manufacture and repair of car and locomotive parts in the blacksmith shop should obtain many helpful suggestions from the papers contained in this report of the proceedings of the twenty-eighth annual convention of the International Railroad Master Blacksmiths' Association, held at the Hotel Sherman, Chicago, August 19, 20 and 21, 1924. Considerable attention is given to the manufacture and repair of frames, springs, draw bars and pins. The book is well illustrated.

Traveling Engineers' Association. *Edited by W. O. Thompson, Secretary, Cleveland, Ohio.* 386 *pages,* 5½ *in. by* 8½ *in. Bound in Cloth.*

A wealth of material of interest to traveling engineers, road foremen of engines and others, is contained in this report of the proceedings of the thirty-second annual convention of the Traveling Engineers' Association, held at Chicago, September 16, 17, 18 and 19, 1924. Following a list of the 1924-1925 officers in the front of the book is the constitution of the Traveling Engineers' Association and a brief report of the subjects considered at each convention since the first held at Chicago in 1893. The report of the convention is divided into seven parts, one for each session. Among the nine papers read during the convention were those dealing with the following subjects: Conservation of locomotive fuel; Lubrication and its effect on locomotive service; Locomotive boosters and their effect on locomotive design and train operation; Relation between terminal facilities and locomotive service; Automatic train control devices. These papers have been for the most part, printed in abstract in the

Railway Mechanical Engineer. A comprehensive index in the back of the book enables any of the papers as well as the discussions by the various members, to be located readily.

What Our Readers Think

What advantages have floating bushings?

San Antonio, Tex.

To the editor:

Will you please advise what advantage floating bushings on back end main rods and middle connections have over the solid stationary middle connection bushing and the old style two-piece back-end brass? I have in mind heavy power, with 25 in. by 30 in. cylinders. These rods develop a pound in five to ten thousand miles and run very hot even after 90 days' wear.

The information desired is, what are the advantages of floating bushings for heavy power and are they more economical than the old style referred to? S. J. Stark,
General roundhouse foreman, International-Great Northern.

Question pertaining to the wear of locomotive air compressor cylinders

Lincoln, Neb.

To the editor:

It has come to my attention recently that the air cylinders of 9½-in. and 11-in. air pumps wear most at the end while the air cylinders of 8½-in. compound pumps wear most near the middle. The first case is not uncommon, but the latter appears to me as a rather unusual place for the cylinder walls of compound pumps to wear as they are more evenly balanced in their action than the single acting pumps.

I would like to see published in the columns of your magazine an explanation as to why air pump cylinders wear in this manner, and also if there are any possible means of overcoming this trouble. R. J. K.

Derailments of locomotives—a criticism

Philadelphia, Pa.

To the editor:

I think you have met the needs of many master mechanics and motive power men in the article on the derailments of locomotives on curves, published in the December, 1924, and January, 1925, issues of the *Railway Mechanical Engineer,* quite creditably. The authors have given an interesting picture of the tracking of a locomotive around a curve.

In the tracking of a locomotive around a curve, knowing the extent of both the flange and hub plays, the elevation of the outer rail, the speed and center of gravity of the locomotive and the drawbar pull, assuming that the locomotive is equipped with flat tires, and accurate data is available relative to the truck hangers and back lash of the truck, only one assumption is needed for the determination of all the forces, and that is the co-efficient of friction at the various wheel contacts with the rail. Several trial assumptions of the center of rotation or friction center will facilitate a solution of the general equations, but there is only one center of rotation which will satisfy the center of rotation of the wheel base. It is interesting to know that the center of rotation can be determined experimentally. This was actually done on the Chicago, Milwaukee & St. Paul's electric locomotives and with all the above data available, the computations checked fairly accurately with the actual test loads, etc.

A moment's inspection of Fig. 5, which is shown on page 17 of the January, 1925, *Railway Mechanical Engineer,* will show that the forces considered are inconsistent with the condition of kinetic equilibrium and that a very important reaction has been omitted in the analysis; that is, the reaction of the inner rail on the fourth driver outwards. No assumption is needed for the friction center, though trial values would facilitate the solution of the equations. Moreover, if traction is assumed, the friction center would probably lie beyond the outer rail, while without traction on the curve, the center of rotation must lie along the center line of the locomotive. The assumption of the main driving axle for the position of the friction center is possible, though my trial value would be at first, at the fourth driver.

In the configuration diagrams of the wheel base on a curve, the diagrams indicate a swing of the trailing truck comparable to the swing of the engine truck. This is, of course, due in greater part to the assumed forward position of the center of rotation. It is interesting to note, however, that the swing of the trailing truck is but from one-third to one-half of that of the engine truck.

One serious objection to this article is the lack of the use of some exaggerated graphical method for giving the configuration on the track as is given by the Roy diagram. Then too, no consideration is given to flange and hub plays which have an erroneous bearing on the configuration of the wheel base, especially in such types as the Santa Fe locomotives.

The analysis of the reactions of the truck are in error, due to failure in considering the lateral thrust at the center pin bearing U. Thus the vertical forces should be

$$Z_1 = \frac{Z\,s}{r+s} + \frac{U\,h}{r+s}\,;\; Z_2 = \frac{Z\,r}{r+s} - \frac{U\,h}{r+s},$$

where h is the height of the horizontal component at the pin above the point of contact of the rockers on the inclined planes. The co-ordinates r and s are poorly chosen. They should be at some fixed point such as the bottom bearings or at the center between the bearings of the rockers.

The resolution of the forces for the wheel contact with the rail is incorrect. It should be remembered that the friction component has its horizontal component as well.

I think the article meets its purpose very well indeed and should give the majority of your readers an interesting insight as to the nature of the tracking of a locomotive around a curve. The analysis of the factor of wheel bearing has not been sufficiently extended for me to give any further comment on this particular phase.

The Roy diagram offers such a satisfactory method for the real understanding of the tracking of a locomotive, even from a practical point of view, that it is suggested that this method be given consideration.

R. Eksergian,
Baldwin Locomotive Works, Philadelphia, Pa.

The answer

Greenville, Pa.

To the editor:

Relative to the outward reaction of the inner rail on the fourth driver, I formerly held the same opinions as Mr. Eksergian. This reaction was taken into account at the

time of the original investigation in 1919. From the configuration diagrams which we made at that time, and from our analysis of the problem, we were led to believe that such a reaction existed. Since that time, I have frequently noticed that the driving wheels, both in cases of derailment and otherwise, did not line up on the track the way our configuration diagrams showed that they should. I have never seen the flange of the fourth driver in contact with the inner rail although particular pains were taken in various investigations to discover such a contact if there were any. That the inner flanges do not bear against the inner rail is further shown by the fact that on a wye which is used exclusively for turning Santa Fe locomotives, there is not the slightest sign of wear on the inner rail. These observations led to the conclusion that there is no outer reaction of the inner rail on the flange of the fourth driver of a Santa Fe type locomotive. It also shows as a corollary, that the center of rotation is at or ahead of the main driver, for otherwise, the clearance between the fourth inside driver flange would be taken up, which is contrary to fact. The resolution of the forces and the determination of the center of rotation, in our article have been made to agree with our observations of tracking conditions as they actually existed on a certain road.

In regard to the configuration diagrams showing the swing of the engine and trailing trucks to be about equal, I am inclined to think that this is about right. If the swing of the trucks is about equal, the center of rotation must be approximately at the center of the locomotive, that is, if the radius bars are about the same length. Conversely, if the center of rotation is at the center of the locomotive, we would expect the swing of the trucks to be about equal. In the case of the Santa Fe type locomotive, used as an example in the article, the permissible swing of the leading truck is 4½ in. each side of the center, and the permissible swing of the trailing truck is also approximately 4½ in. each side of the center of the truck.

An examination of a number of locomotives of this type revealed that the frames had been severely punished by the trailing truck wheels. They frequently came in from their runs with the frames worn bright. There is nothing to show that the 4½-in. permissible movement of the engine truck is not sufficient. I take these facts to indicate that the swing of the trailing truck is as great as that of the engine truck which simply confirms in another way the conclusion that the center of rotation is at or ahead of the main driver. It is interesting to know that U. S. R. A. 2-10-2B type locomotives do not give any trouble in this respect as they have approximately 8-in. permissible movement of the trailing truck on each side of the center.

Relative to the omission of a consideration of the lateral thrust of the center pin bearing, it is agreed that such a force exists and the omission is acknowledged. This force has been analyzed and used in a number of investigations, but we neglected to take it into account in this instance. This is the force which causes the couple shown in the sketch published in the answer to a question on this subject on page 138 of the March, 1925, *Railway Mechanical Engineer*. However, in reference to the quantities r and s, these are not co-ordinates, but simply moment arms of the vertical force Z which shows that the proportions of Z are resisted by the reactions at different ends of the bolster.

The friction component normal to the side of the rail head was taken into account as well as its vertical component in the resolution of forces for the wheel contact with the rail.

The Roy diagram will give the configuration on the track from the geometrical standpoint from which the flange and hub plays and other characteristics may be easily worked out. But in this case, we have assumed that the tracking is all right and are solving for the nature and intensities of the forces necessary to turn the locomotive against friction. Of course, if a locomotive will not traverse a curve without binding, these forces will be altered in nature and increased in intensity. This, however, is outside of our problem. Flange and hub plays, aside from the fact that they must exist in sufficient degree to prevent binding, do not enter into the case. We are dealing with forces and reactions and the balancing of their moments. The fault that I have to find with the Roy method is that it assumes that the rear axle is radial to the curve, which I believe is erroneous, both from an analysis of the configuration and from actual observation of locomotives on curves. In the case of the Santa Fe type locomotive used as an example, proper tracking by the Roy method would doubtless be shown, but if it had more freedom of trailing truck movement it would be a better curving locomotive.

A proper solution of this problem should be of interest to many railroad men and the criticisms you have made are constructive and should be considered in future investigations.

Roy C. Beaver,
Assistant mechanical engineer, Bessemer & Lake Erie.

Old style hand brake wheels vs. new designs

Mobile, Ala.

To the editor:

It seems that there is an opinion abroad that the time has arrived when the hand brake wheel should be discarded and something new designed to take its place. There are a large number of innovations being put forward and the final outcome will probably be something with decided advantages over the hand wheel now generally used by the railroads.

In the meantime, there are several important points that should be borne in mind. When a hand brake is needed, it is very often more or less a case of emergency, as preventing a car rolling out of the clear, stopping it on an incline, letting it down an incline or for setting a certain percentage of brakes on a heavy train.

Many switchmen and trainmen do not take readily to new mechanical contrivances, and when it is necessary to stop a car quickly, the urgent need is for a brake with which no mistake can be made and which requires no fumbling and fooling in order to understand how to operate it. The old brake wheel certainly meets these requirements. I have asked many trainmen which of the new style brakes they like best. They usually don't know them apart, but often the answer is that some of them are good brakes if you know how to work them. Many trainmen heartily condemn all new styles. One serious objection to most of the new style brakes is that when the end of the car becomes bulged to any extent, the brake shaft supports are thrown out of alinement and it is impossible to entirely release the brake without the use of a wrench or some other similar tool.

The hand brake is too vital a thing to be experimented with extensively. If there is to be a new one it should be adopted and made standard so that all concerned could familiarize themselves with it so that parts could be kept in stock for making repairs, as a defective hand brake puts a car completely out of commission under the Safety Appliance law.

T. J. Lewis,
Car inspector, Southern Railway.

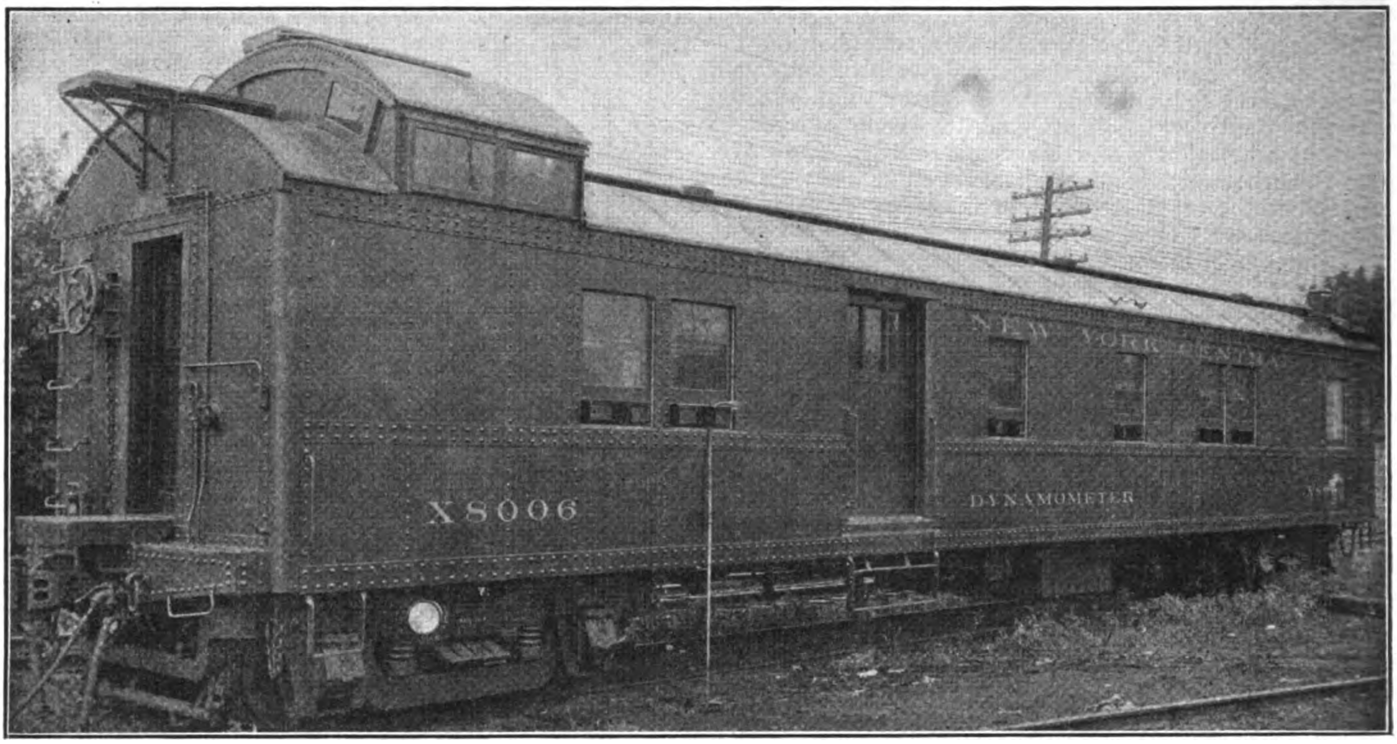
N. Y. C. all-steel dynamometer car

Complete facilities for obtaining a wide range of operating data are provided and conveniently arranged

THE New York Central has had a dynamometer car of all-steel construction in service for something more than a year. The car is unusually well equipped, and its accommodations are well arranged. It was designed under the direction of F. H. Hardin, chief engineer of motive power, New York Central, and the late F. S. Gallagher, engineer of rolling stock, and built at the West Albany shops of the railroad. The dynamometer apparatus was designed, built and installed by the Burr Company, Champaign, Ill.

The car has an inside length of 52 ft. 2-7/16 in. and an inside width of 8 ft. 8⅜ in. The dynamometer or office compartment occupies 21 ft. 6¾ in. of the length of the car, while the remainder is devoted to sleeping and dining accommodations for the crew. As shown in the drawing of the floor plan of the car, accommodations are provided for a crew of seven men and additional accommodations can be provided for two more if necessary. The berth and dining compartment is accessible from both the kitchen quarters and dynamometer compartments. When desired it can be isolated from either end by closing the doors between the sections. Ample toilet, lockers and wardrobe facilities make the car convenient and practical for carrying on the work for which it was designed.

One of the features incorporated into the design of the car is the ⅝-in. steel floor plate which extends over the entire dynamometer end of the car. This plate gives added strength to the frame and assists in taking the high stresses incidental to the measuring of the draw bar pull and buff. Another feature designed for facilitating the work of the crew is the work table which is supplied with reels, interchangeable with those on the chronograph table. It has an approximately length of 12 ft. which permits the operating crew to analyze at one time the record covering a considerable extent of track. Connections to the train air line and brake cylinders are located in close proximity to the chronograph table so that the gages can be easily read. Locomotive steam pressure is carried back to a gage which is also located over the chronograph table.



Dynamometer car built by the New York Central and the Burr Company, Champaign, Ill.

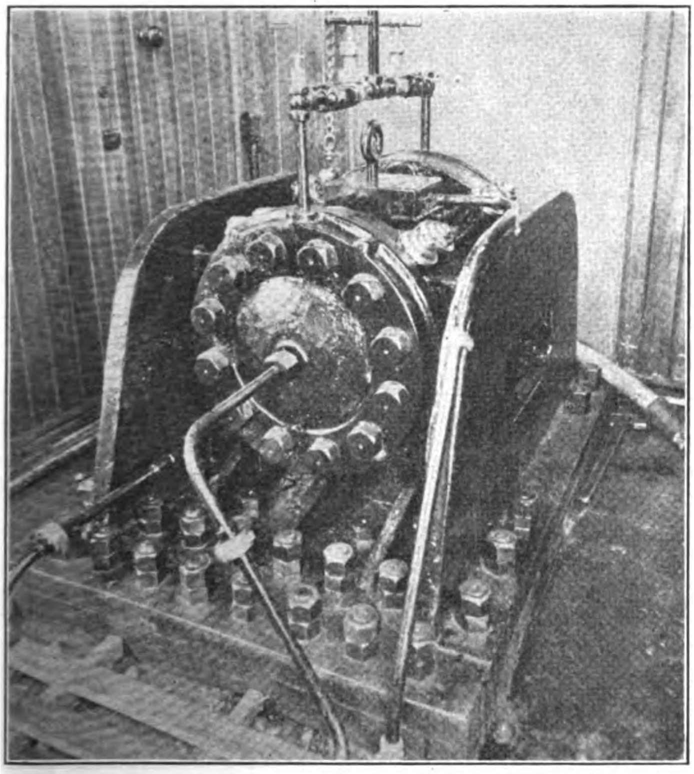
The dynamometer apparatus

The dynamometer has a capacity of 500,000 lb. maximum draw bar pull and a maximum buff of 1,000,000 lb. The apparatus provides facilities for taking 17 graphic records, two of which are for time intervals, which are recorded automatically and simultaneously on the traveling paper ribbon. There are also extra electric recording circuits which may be used for special records when desired. The traveling paper is sufficiently wide so that memoranda may be entered thereon in proper relation to the various graphic records, which are as follows: draw bar pull, draw bar buff train speed, train line air pressure, locomotive steam pressure, brake cylinder air pressure, time intervals, position of the locomotive throttle, locomotive reverse lever position, location of track curves, grades, power delivered through the drawbar to the train, train location, distance traveled, time indicator cards were taken, time and amount of firing the locomotive, and provisions for three unassigned records.

The dynamometer car recording equipment consists of a diaphragm dynamometer, a recording machine, an electric

system which includes only that used in connection with the recording apparatus and an axle drive transmission unit. The electrical equipment does not include that which is used in connection with the car proper.

The draw bar dynamometer consists of a standard draw bar fitted with a special yoke connected to the dynamometer weighing head. The weighing head is designed to receive the full pull or buff from the draw bar and



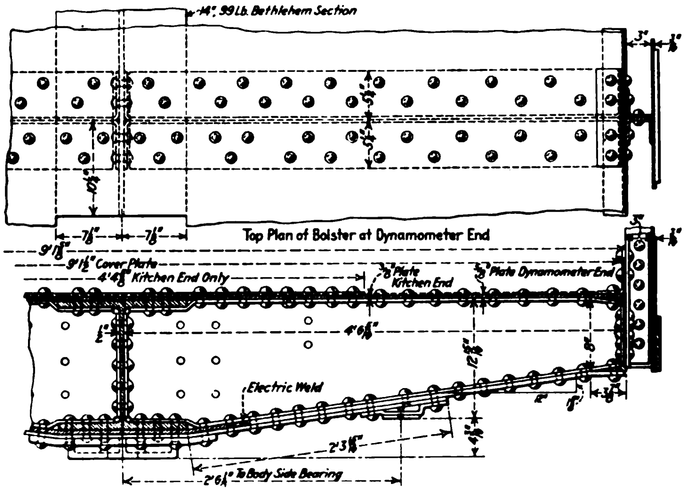
The dynamometer weighing head is designed for a drawbar pull of 500,000 lb. and 1,250,000 lb. buff

transmit the force by means of pistons to pressure cylinders. The forces are here converted into liquid pressure which is transmitted to the chronograph and automatically recorded in proper relation to the time and other records.

The dynamometer weighing head is equipped with locking devices for holding the piston inactive so that the car may be moved in an inoperative condition. It is mounted on the ⅝-in. steel floor plate in a rigid position so that it can take and record the maximum pull and buff without vibration or damage from sudden shock. The weighing head is also equipped with limit alarms to insure the floating action of the pistons. Special indicators are used for recording the draw bar pull and buff records. These are provided with a full set of reaction springs which cover the entire range of operations for which the car is designed.

The chronograph makes all of the records simultaneously on the traveling paper ribbon without interference or space corrections, with the exception of the five magnet records, which are placed back of the straight line chronograph record. The movement of the paper ribbon can be proportioned to the distance traveled or it can be run at a constant speed as desired.

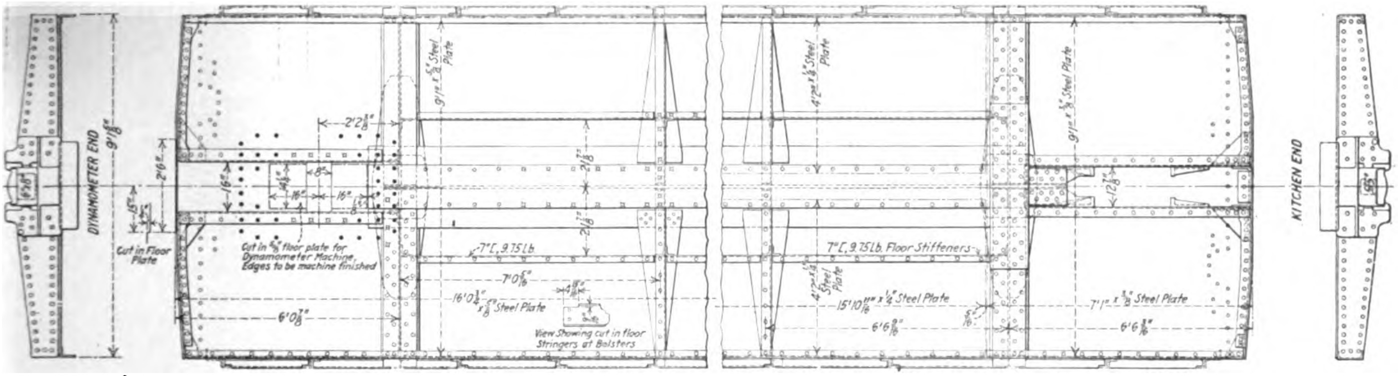
Special pens are used for each chronograph recording instrument mounted on a rigid supporting arm which is controlled by the testing instruments. All the instruments, together with the indicating gages and magnet control circuits, are placed in such a manner as to be readily accessible to the operator, so that he may readily observe and control the chronograph record and make necessary memoranda on it.



Drawing of the body bolster at the dynamometer end

The driving transmission

The driving transmission includes a clutch control equipment for shifting the driving mechanism from the car trucks to an electric motor operated from the train line battery. It also includes the shift gears for changing the travel ratio of the paper ribbon and provides an automatic reverse drive clutch so that the paper will always travel forward regardless of which direction the car travels. The transmission gears are enclosed in a dust proof oil case of rigid construction. Bevel gears are used for connecting the drive to a telescopic torque shaft con-

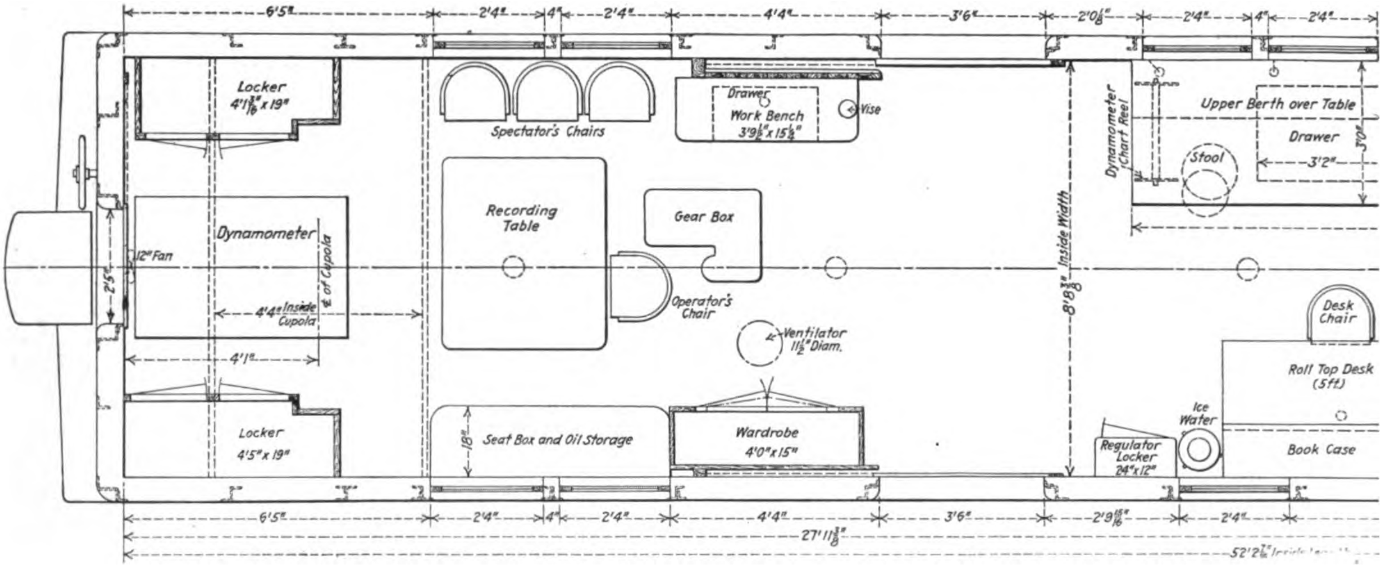


Underframe of the New York Central dynamometer car

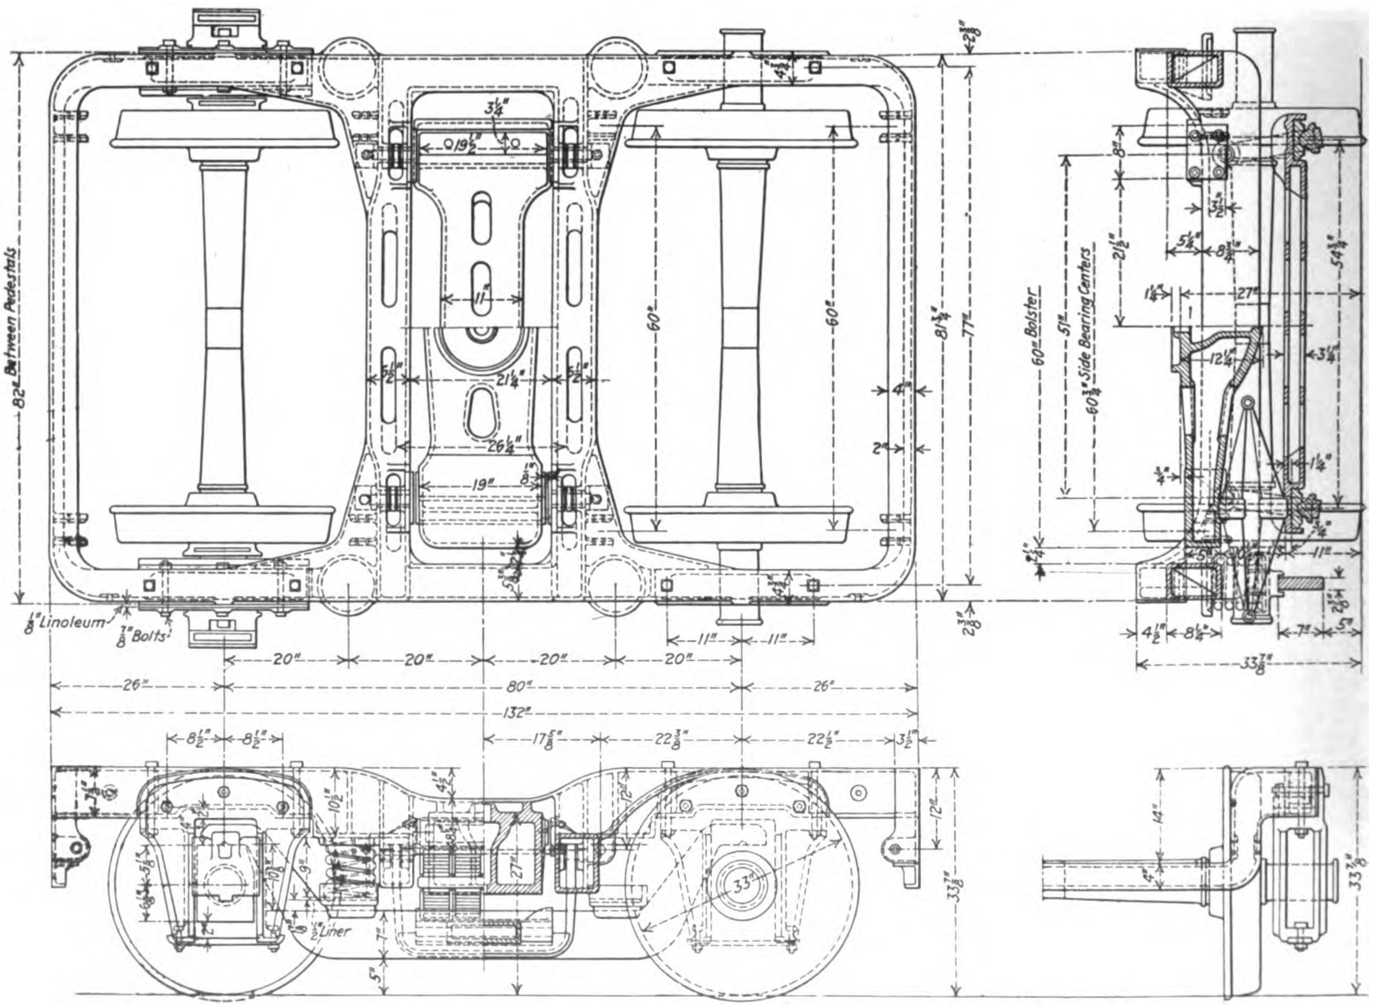
nected to the rear axle of the forward truck under the dynamometer end. This drive on the forward truck is also mounted in a dust proof gear case and is provided with a disengaging clutch for disconnecting the entire gearing system when the car is being moved in an inoperative condition.

The distance timer, which is on the transmission unit, makes automatic electric contact for every 100 ft. of train travel. A constant speed motor is used for the speedometer as well as for the purpose of keeping the paper in motion when the car is at rest. All the transmission levers, the motor rheostat and switches for the entire apparatus are located within easy reach of the operator.

The kitchen is located at the opposite end of the car from the dynamometer compartment, as shown in the floor plan. It is equipped with a range, refrigerator,

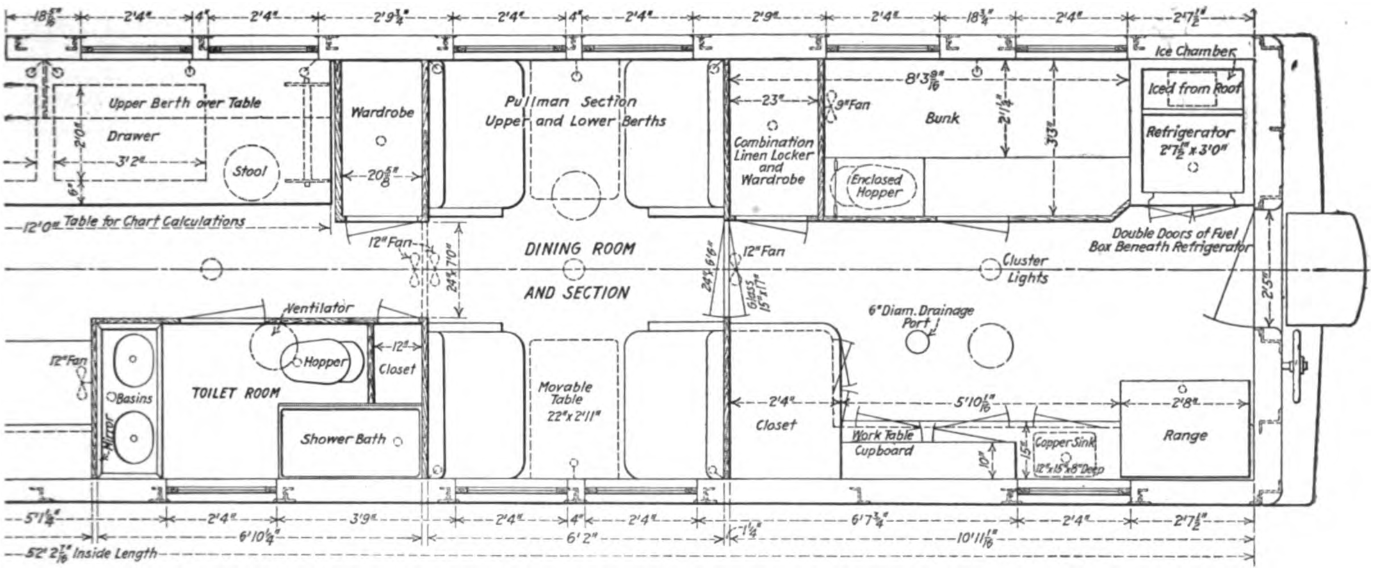


Floor plan of the dynamometer



The trucks are of the equalized type, with cast steel frames and bolsters

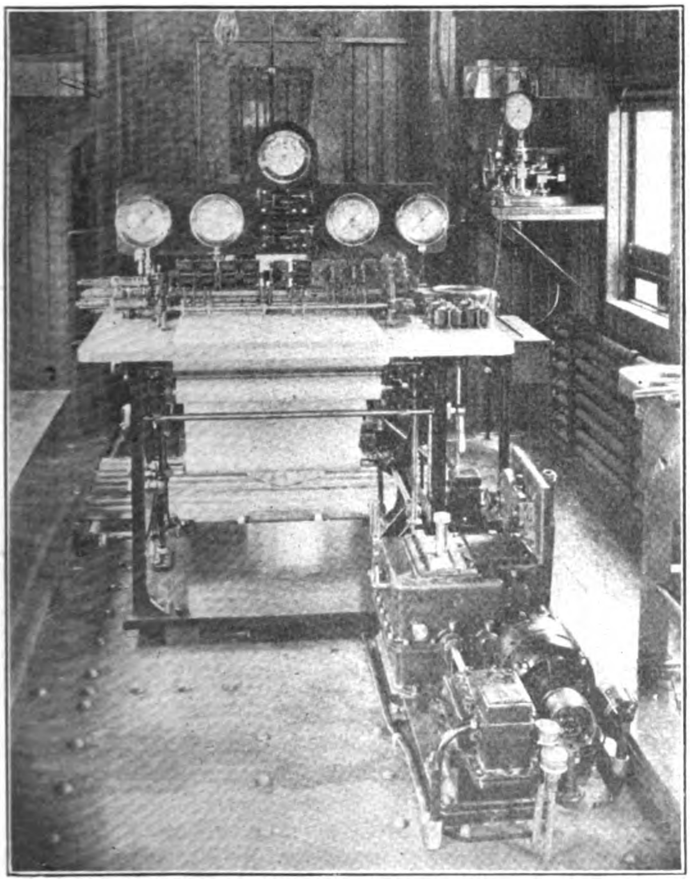
copper sink, work table with cupboards above and below, china closet, a fuel box which is located beneath the refrigerator, combination linen locker and a wardrobe compartment equipped with a bunk and enclosed hopper for calculations. The equipment in this section also includes file cases, stools, dynamometer chart reels, two upper berths, a roll top desk and chair, a bookcase and water cooler stand, drinking cup container and a wardrobe and



car built by the New York Central

the use of the porter who takes care of the car service.

The dining room section is provided with two Pullman sections of upper and lower berths and two removable tables. The section between the dining room and side doors, which is shown in one of the illustrations, is provided with a table, equipped with two drawers, for chart



The dynamometer recording apparatus with the traveling paper in position ready for operation

closet. The section between the side doors and the dynamometer end of the car is provided with a work bench, gage tester, gage board, vise, instrument board, chairs for spectators, lockers, recording table, dynamometer, and a chair for the operator.

Special features

The car is heated with the vapor system and is ventilated by means of five 6-in. Globe ventilators. The sides, end walls, cupola and roof sheets are insulated with a ½-in. thickness of special hair felt, applied next to the outside sheathing. Three ply hair and asbestos insulation is applied over the entire surface of the steel floor plates and to the inside surface of the outside sheathing and the under side of the bottom course of the flooring.

General data and dimensions

Maximum draw bar pull	500,000 lb.
Maximum buff	1,000,000 lb.
Length, inside	52 ft. 2 1/16 in.
Length over platform end sills	55 ft. 0 1/16 in.
Length, center to center of trucks	42 ft. 5 in.
Truck wheel base	6 ft. 0 in.
Width over side sills	9 ft. 1⅝ in.
Width over all at eaves	10 ft. 0⅞ in.
Height, top of rail to the top of roof carlines	12 ft. 6 3/16 in.
Height, top of rail to the top of running board over cupola	14 ft. 8 in.
Height, top of rail to the top of floor	3 ft. 11⅝ in.
Height, maximum, top of rail to center of coupler	2 ft. 10½ in.
Height from underside of the side sill to the top of side plate	7 ft. 6¼ in.
Width, inside of car	8 ft. 8⅜ in.
Height, inside of car (at center)	8 ft. 3⅝ in.
Width of door opening, one each side	3 ft. 6 in.
Width of end door opening	2 ft. 5 in.
Length of center sill	44 ft. 9¾ in.
Thickness of bottom cover plate	0 ft. ½ in.
Size of belt rail	5 ft. by ¼ in.
Size of side plate angle	5 in. by 3 in. by 5/16 in.
Thickness of sheathing above the belt rail......Angle	0 ft. 3/16 in.
Thickness of sheathing plate below the belt rail..Angle	0 ft. 3/16 in.

Current for the lighting equipment is supplied from a three-kilowatt low speed generator operated from the car axle. The lighting equipment can also be operated on battery discharge on layovers up to eight hours.

The water supply is contained in two overhead water tanks, located in the kitchen, one on each side of the car and formed to the contour of the roof. Each tank has a capacity of 100 gallons. These tanks can be filled simul-

taneously from the ground on either side of the car or from a filling opening in the roof. The tank on the range side of the car is used for hot water which is heated in pipes passed through the range. Additional heating facilities are also provided by the use of a steam jacket which surrounds two of the radiator pipes on the range side of the car. The sink basins and shower are provided with supply pipes for hot and cold water.

Every possible short cut for saving time and labor in the final computations has been incorporated in the design and operation of the car. A special method has been provided for integrating the area under the draw bar pull curve. Special devices designed to protect the delicate instruments from unnecessary vibration and shock have been provided. When the liquid in the dynamometer cylinder becomes dangerously low, an electric contact is made automatically, which rings a warning bell. The entire design of the machine is dependent throughout on line contact and is, therefore, quite free from friction. The piston movement for the maximum draw bar pull is .006 inch. Every provision possible has been made to eliminate the effect of friction and the weights of the various parts have been reduced as much as possible in order to decrease the effect of inertia. In order to facilitate the work of compiling data the speedometer is geared so that the height of the speed curve taken in passenger traffic is double for that taken in low speed freight traffic.

The principal feature of the car is the large number of records and miscellaneous information which can be taken, relating to successful train operation. This information can be so arranged that it will not only be of value to the Motive Power Department, but to the various other departments as well.

Locomotive feedwater heating*

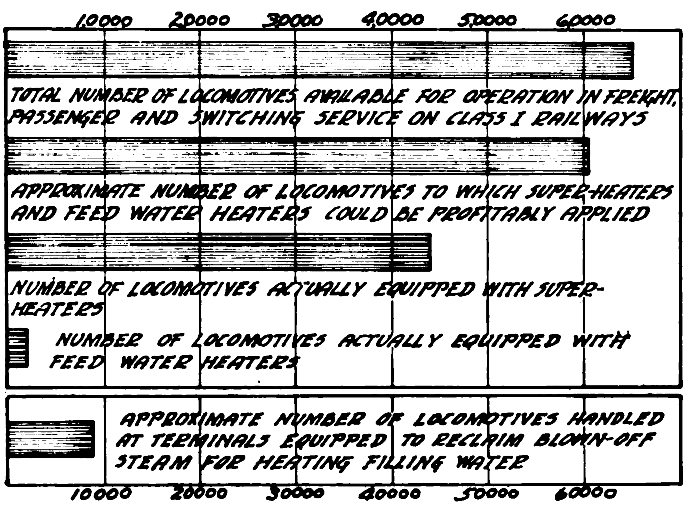
Proper methods of testing important—Building up feedwater temperature and boiler pressure by direct steaming at terminals

By L. G. Plant

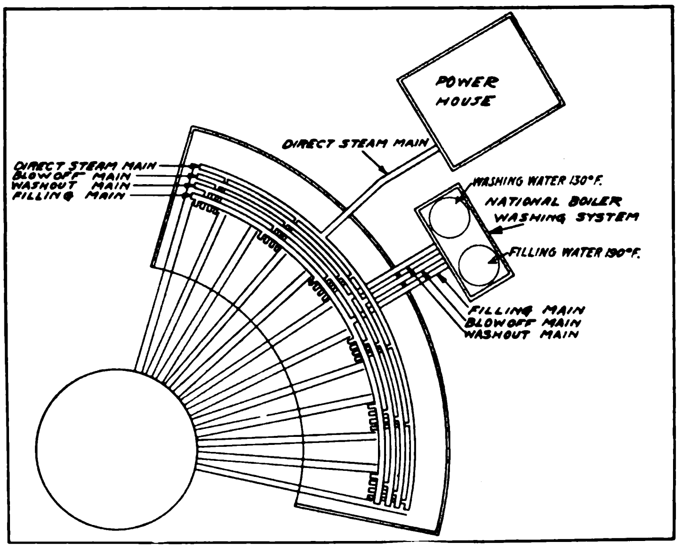
Assistant to president, National Boiler Washing Company, Chicago

RECENT developments in feedwater heating represent the most fundamental improvement to locomotive economy since the advent of superheating. The application to railway motive power of a long established practice for feedwater heating in stationary power plants is only another belated response to the same economic cause that led to the introduction of superheated steam and other revolutionary changes in locomotive practice.

Each of the several types of feedwater heaters afford so practical a means for applying to locomotive operation a practice that has long been regarded essential in every efficient stationary power plant that it is difficult to understand why the application of this equipment has been so retarded. Aside from the inertia that accompanies every departure from accustomed practice, there are certain features in the application, operation and maintenance of live steam injectors that exert a strong hold on locomotive practice, so admirable is this device adapted to its requirements. From the standpoint of reliability in service, simplicity in operation and ease of maintenance, there is no locomotive water feeding device comparable with the live steam injector.



Proportion of locomotives equipped with superheaters and feedwater heaters



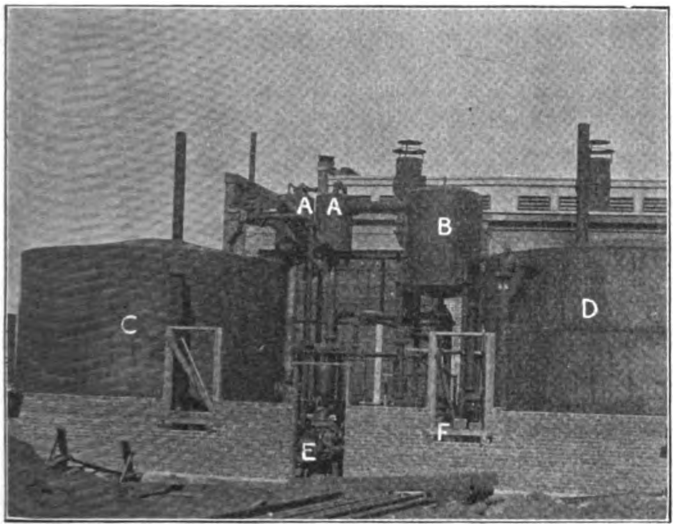
Plan of enginehouse designed to provide direct injection of live steam and hot filling water into the locomotive boilers

Testing methods can be improved

Another factor that has retarded the development of locomotive feedwater heating is the lax and indecisive testing methods to which the application of this equip-

*Abstract of an address at the February meeting of the Central Railway Club, Buffalo, N. Y.

ment is frequently subject. The speaker recalls that about ten years ago he had occasion to investigate the performance of a Caille-Potonie feedwater heater that had been tested on a southeastern railroad some years prior. This is a closed type of heater which was developed in France many years ago and is now extensively used in that country. One of the directors of the American railroad had become interested in the possibilities of such equipment and a heater of this type together with the pump and accessory apparatus had been imported for test on the railroads in this country. The only record of this test disclosed in the files was a report to the superintendent of motive power to the effect that the



A-A—Twin condensers; B—Separator; C—Washout tank; D—Filling tank; E—Washout pump; F—Filling pump.

Boiler washing and filling system in the process of erection

road foreman had made two round trips on the locomotive and had not noticed any improvement in performance due to the application of the feedwater heater. As a result of this exhaustive test the apparatus was dismounted from the locomotive without further investigation and shipped back to France. "Tests" of this general character have cost American railroads a good many millions of dollars.

It is significant that railroads on which the most exhaustive tests of locomotive feedwater heaters have been made are now becoming the most extensive and consistent users of this equipment. There is no lack of authentic data on the performance of locomotive feedwater heaters available to any railroad that is not in a position to make exhaustive tests of this device. In fact, the technical aspects of locomotive feedwater heating are no longer problematical. Tests to determine the practicability and value of this practice are as out of date as similar tests of the superheater. On matters other than maintenance, the relative efficiency of types and improvements to existing equipment, etc., sufficient data is already available and the question of applying feedwater heaters is entirely an economic problem.

Where tests are made, it is particularly important in the case of the locomotive feedwater heater to concentrate attention upon those factors that are strictly relative to the actual value or relative merits of this equipment. Otherwise, the real issues involved may be obscured by a mass of irrelevant data and over-all generalities. The first consideration is that of temperatures attained by water in relation to the temperature of exhaust steam available for heating. Next comes the cost of maintaining this equipment with particular reference to the facilities available for this purpose.

The most important operating characteristic of a locomotive feedwater heater is the temperature at which it can deliver feedwater to the boiler. The economy from feedwater heating increases with each degree rise in temperature of the water delivered to the boiler. Under the conditions usually assumed for locomotive operation, every 12½-degree increase in feedwater temperature accomplished by waste heat represents an increase of one per cent in the steaming capacity of the locomotive. [Mr. Plant here showed curves representing a record of both the feedwater and exhaust steam temperatures observed at different rates of evaporation in the Pennsylvania tests of a decapod type locomotive equipped with an open-type feedwater heater.—Editor.]

The gain in locomotive efficiency by feedwater heating can be determined from these temperatures after the heat content in steam used by the pump has been deducted and the effect of any reduction in back pressure on account of exhaust steam diverted to the feedwater heater has been credited to its performance. No tests of this equipment are complete without a complete record of exhaust steam and feedwater temperatures, a measure of the steam used by the pump and a determination of the back pressure at given cut-offs with and without the feedwater heater in operation.

A partial record of the feedwater and exhaust steam temperatures in the test of a Canadian National Mikado

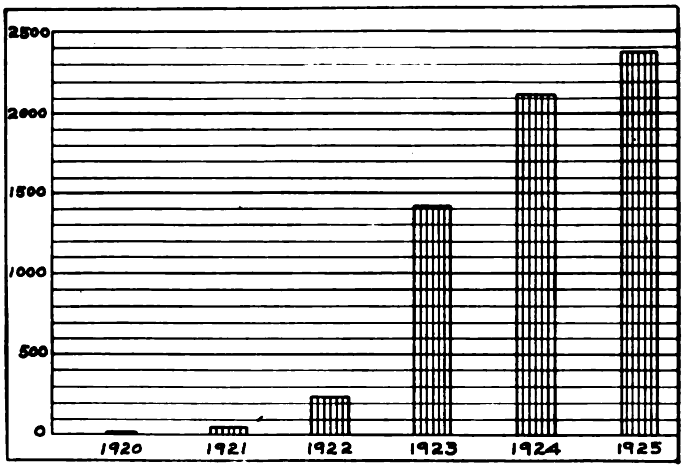


Chart showing yearly growth in the number of heaters in service

type freight locomotive equipped with a closed-type feedwater heater is illustrated.

Feedwater heating at terminals

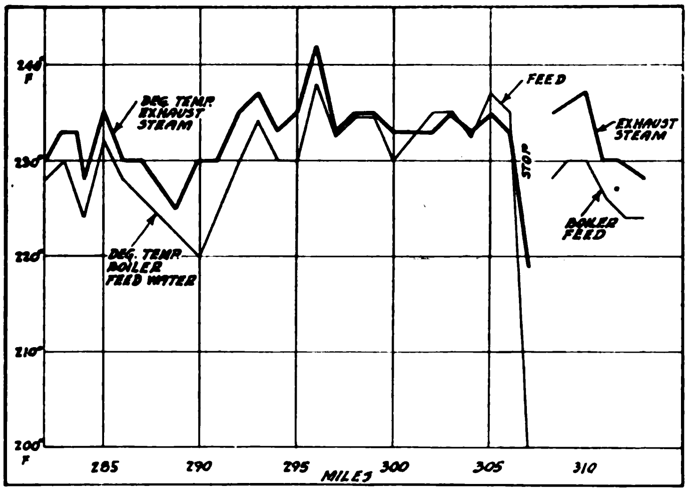
A consideration of the situation at all important locomotive terminals will further enlarge our conception of the realities and possibilities of locomotive feedwater heating. It is estimated that approximately 20 per cent of all locomotive fuel is consumed at terminals. A considerable part of this fuel is consumed in firing up locomotives and the amount required for this purpose depends upon the temperature of the water with which the locomotive boiler is filled. The law requires all boilers to be emptied and washed at least once each month and on many railroads operating conditions necessitate refilling boilers much more frequently. Equipment for washing and filling locomotive boilers with hot water has been generally regarded as merely a convenient maintenance facility.

With the emphasis that is being placed on the economy of feedwater heating on the road, it is only appropriate to direct attention to the fact that it requires about 1,200 lb. less coal to fire up a modern locomotive filled with water

at a temperature of 180 deg. than when the locomotive boiler has been filled with cold water. If the heat required to elevate the filling water to this temperature is reclaimed from the heat content of steam blown off from incoming locomotives, this reduction of 1,200 lb. coal in the quantity of fuel required to fire up the locomotive represents a true saving. One of the illustrations shows the equipment required to obtain this economy, indicating the separator into which the blown-off water and steam from incoming locomotives is first discharged. The water gravitates to the washout tank from which it is drawn for boiler washing purposes. The exhaust steam flows to twin condensers of the jet type, and here again we have an application of the principle involved in the operation of the open-type feedwater heater. Fresh, cold filling water flows to the reservoir from which it is drawn for filling locomotive boilers at temperatures ranging from 180 to 210 deg. Higher delivery temperatures are not practical since the system is operated at atmospheric pressure.

Building up boiler pressure by direct steaming

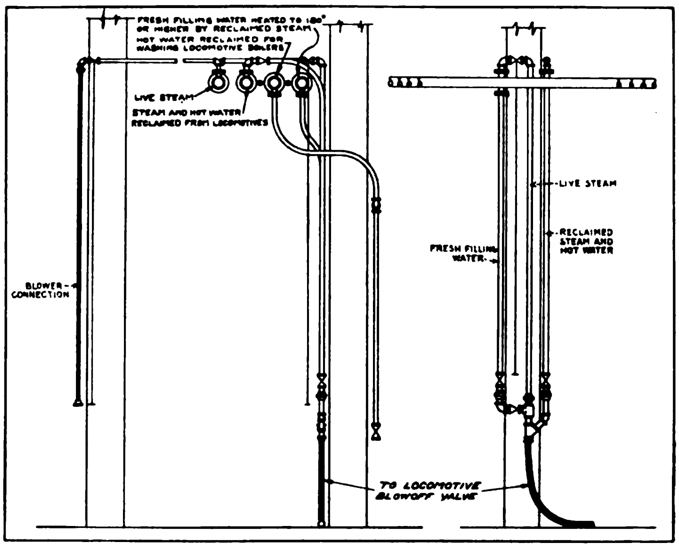
Tests recently conducted on a western railroad develop the fact that for each 20-deg. increase in the temperature at which the locomotive boiler is filled there is a saving of about 8 gal. of oil or its coal equivalent in the quantity of fuel and approximately 10 min. in the time required to fire up a large Mikado type locomotive. These tests, however, are related to a new and even more significant aspect of locomotive feed water heating at terminals. This is the direct injection of live steam and hot filling water by means of the system of mains shown in one of the drawings. The use of live steam drawn direct from a stationary power plant as indicated together with hot filling water, enables a locomotive to be filled and steamed



Temperature record with Elesco feedwater heater on Canadian National 2-8-2 type locomotive

up to a pressure approximating the stationary boiler pressure without lighting the fire in the locomotive firebox. The time required for this operation is about the same as in the usual procedure, but there is a gain in efficiency due to the elimination of the houseblower which ordinarily consumes steam at the rate of 40 boiler hp. per hour or higher. Furthermore, steam supplied from modern stationary boilers can be more efficiently generated than in a locomotive boiler during the firing up stage so that there is a further gain in efficiency on this account. The elimination of smoke and of blower steam within the enginehouse are factors of no little importance. The operation of smokeless enginehouses in which all locomotives are steamed up by this method can be anticipated. In this case all fires would be dumped before locomotives are placed in the house and the fires are not lighted until the locomotive is placed in a firing-up shed adjacent to the enginehouse.

The enginehouse pipe connections required for this method are illustrated. These provide a live steam drop in connection with the hot filling water main and a blow-off connection. In filling a locomotive both the live steam and filling water valves are opened and the boiler filled through the blow-off valve with this mixture of steam and water. As soon as the water shows in the glass it is shut off and the steam allowed to flow into the boiler until the desired pressure is built up. With this arrangement, it is possible to hold locomotives under a working steam pressure. If the fire is lighted as soon as the water shows in the gage glass, the time required to fill and steam up



System of drops for direct steaming of locomotives without fire on the grates

modern locomotives to a working steam pressure can be reduced to approximately half an hour.

The largest factor for increasing locomotive output may be anticipated in the form of facilities for increasing the percentage of time that locomotives are available for active service. This will come in the form of better equipment for maintaining motive power and turning it rapidly at terminals. Not to exceed 9,000 locomotives are now being operated through terminals having modern equipment for filling boilers with hot feed water heated by blown-off steam. The installation of this type of feedwater heating equipment at all large locomotive terminals would add the equivalent of approximately 1,700 locomotives to the power available for service.

This enlargement in motive power capacity will be accompanied by a reduction in fuel consumption of corresponding proportions so that the outlook for locomotive feed water heating is truly a great prospect.

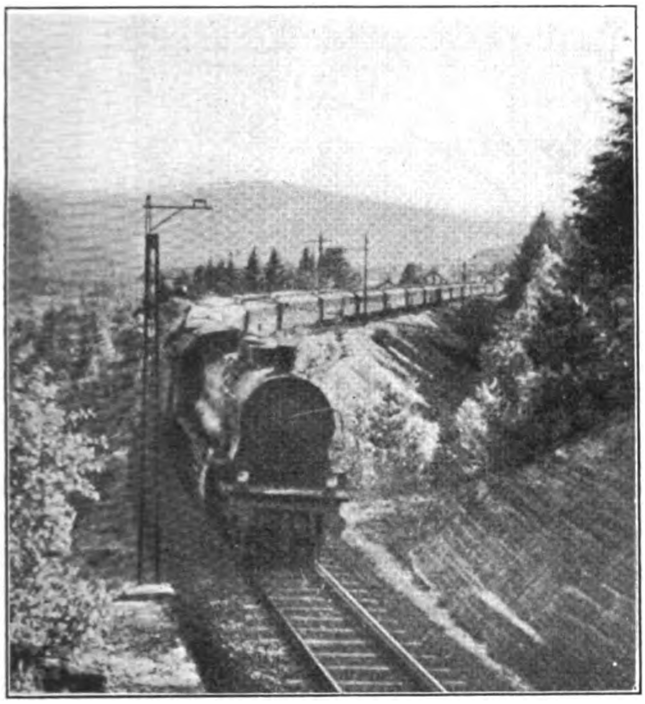
A NEW MOTOR CAR and trailer, built by the Sykes Company, St. Louis, and the St. Louis Car Company, St. Louis, Mo., has recently been delivered to the Boston & Maine. It is planned to place this train in operation between North Adams, Mass., and Troy, N. Y., about March 15. The motor car is 51 ft. over all, comprising a 16-ft. baggage compartment and accommodations for 30 passengers. It is equipped with a Sterling, six-cylinder heavy duty gasoline engine developing 225 hp. The trailer is of the vestibule type and is 45 ft. 6 in. over all and has a seating capacity of 52 persons, making a total of 82 passengers for the train. This is the third motor car unit to be placed in operation on the Boston & Maine.

German State Railway's brake tests

Comparative tests are made with the Westinghouse and Kunze-Knorr types in order to obtain shorter braking distances

London. Eng.

THE first of a series of train brake tests conducted by the German State Railways were inaugurated in March, 1924, and were carried through the year until the latter part of September, when a test train of 23 vestibule coaches was made up and run on September 27, 1924, in connection with the Engineers' Meeting at the Berlin Railway Exposition. The object of the experiments was to determine the efficiency of the Kunze-Knorr brake on express, passenger, freight and mixed trains. It was at first desired only to determine as to what extent the weight and speed of express trains could be so that increased speeds would be possible. The distance between the warning signal and home signal on the main line averages about 2,297 ft. The speed, therefore, depends to a large extent on the ability of the engineman to bring the train to a stop within that distance. The engineers who conducted the tests reported that it was possible to bring the average express train to a stop within this distance with the Kunze-Knorr apparatus from an initial speed of 74.5 miles an hour, as compared with an initial speed of 65.25 miles per hour with the type of Westinghouse quick-action brake used in Germany.



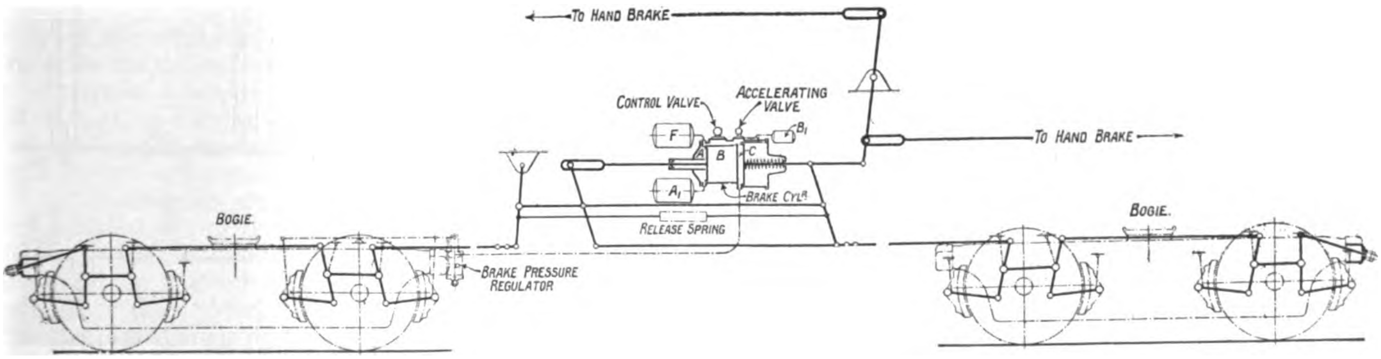
Test train used for the trial runs made during the Berlin Railway Exhibition

A profile of the section over which the trials were made is shown in one of the drawings. The dimensions shown are in the metric system. As will be noted, a number of sharp grades are encountered between Wannsee, a station near Berlin, and Belzig which made this section of track ideal for conducting brake tests. All of the grades, however, were negotiated with the original power until the trains reached Baitz. Pusher service was furnished at this point to take the train up a 2.03 per cent grade to Belzig, which is the ruling grade for the section over which the tests were run.

Results of the second test in which Westinghouse brakes were used

Out of the total of seven trial runs reported, the second run was the only one in which the Westinghouse brakes were used, and even in that test, they were not used exclusively but were in a train which also contained Kunze-Knorr express, passenger and freight type brakes.

The train used in the second run consisted of a ten-wheel type locomotive and 17 cars, which had a total of 52 axles. Of this number 47 axles, or 90 per cent of the total, were braked. Of the 17 cars composing the train, three passenger cars, having two four-wheel trucks, were equipped with the Kunze-Knorr express brake; three four-wheel passenger cars had the Kunze-Knorr passenger brake; four six-wheel passenger cars and three passenger cars having two four-wheel trucks, were equipped with the Westinghouse quick-acting brake; and three four-wheel box cars were equipped with the Kunze-Knorr freight



Layout of the foundation rigging of the Kunze-Knorr air brake as applied to a passenger car on the German State Railways

safely increased, but while these trials were still in progress, the increase in freight traffic created a demand for an air brake suitable for freight service.

Operating conditions also called for a brake that could stop trains in shorter distances than previously required brake. A dynamometer car, an interior view of which is shown in one of the illustrations, was attached to the rear end of the train. This location was chosen for all seven trials on account of the fact that shocks due to braking are more severe at the rear end of the train than

at the front. The dynamometer car was equipped with two four-wheel trucks.

The maximum braking power on the three passenger cars equipped with the Kunze-Knorr express brake was 127 per cent of the total car weight at the beginning and 85 per cent at the end of the stop. In the case of the

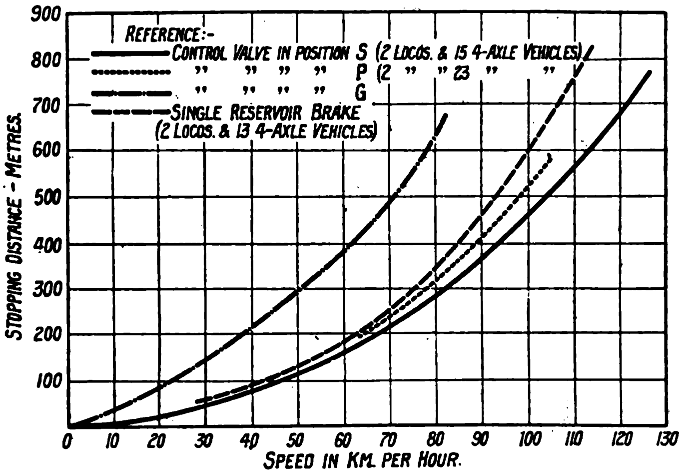


Chart showing the stopping distances for emergency applications made while running on level track

four-wheel passenger cars equipped with the Kunze-Knorr passenger brake, a maximum braking power of 80 per cent of the total car weight was obtained. The Westinghouse quick-acting brake on the six-wheeled passenger cars recorded a maximum braking power of from 55 per cent to 60 per cent of the total weight of the car. This equipment also recorded a maximum braking power of from 77 per cent to 84 per cent of the total weight on the braked wheels of the three passenger cars, while 75 per cent was the average obtained on the three four-wheel box cars equipped with the Kunze-Knorr freight brake, or 56 per cent of the total weight.

The total weight of the cars in this train amounted to 435 tons. The total weight, including the locomotive, was 536 tons. The maximum brake shoe pressure exerted on the wheels of the train was 442 tons, giving a percentage of brake shoe pressure to the total weight of the train of 83 per cent.

The sixth trial run was the only other test made with mixed equipment. This train, however, had a total of 54 cars with 120 axles hauled by two ten-wheeled type locomotives. Of this number only 75 axles or 62.5 per cent were braked, which does not give sufficient data to make a comparison between the second and sixth tests to ascertain the relative merits of the two brake systems. All of the cars used in the sixth test had Kunze-Knorr brakes. The fifth and seventh test trains were composed entirely of passenger equipment, while the third and fourth test trains were composed of express, and passenger and express equipment, respectively. The first test train,

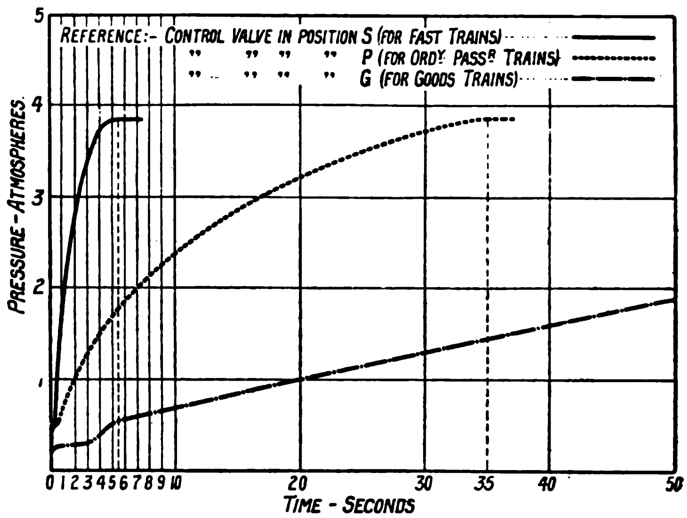

Chart showing the increase in pressure (in atmospheres) for different positions of the Kunze-Knorr control valve

which was run March 11, 1924, consisted of freight equipment.

Referring to the statement made in a preceding paragraph, in which is given the initial speeds from which a train can be stopped in 2,297 ft., the average braking power required for the Kunze-Knorr brake between the wheel and the rail must, therefore, be approximately

$$\frac{65.25^2}{74.5^2} = 1.3 \text{ times as great as that of the Westinghouse}$$

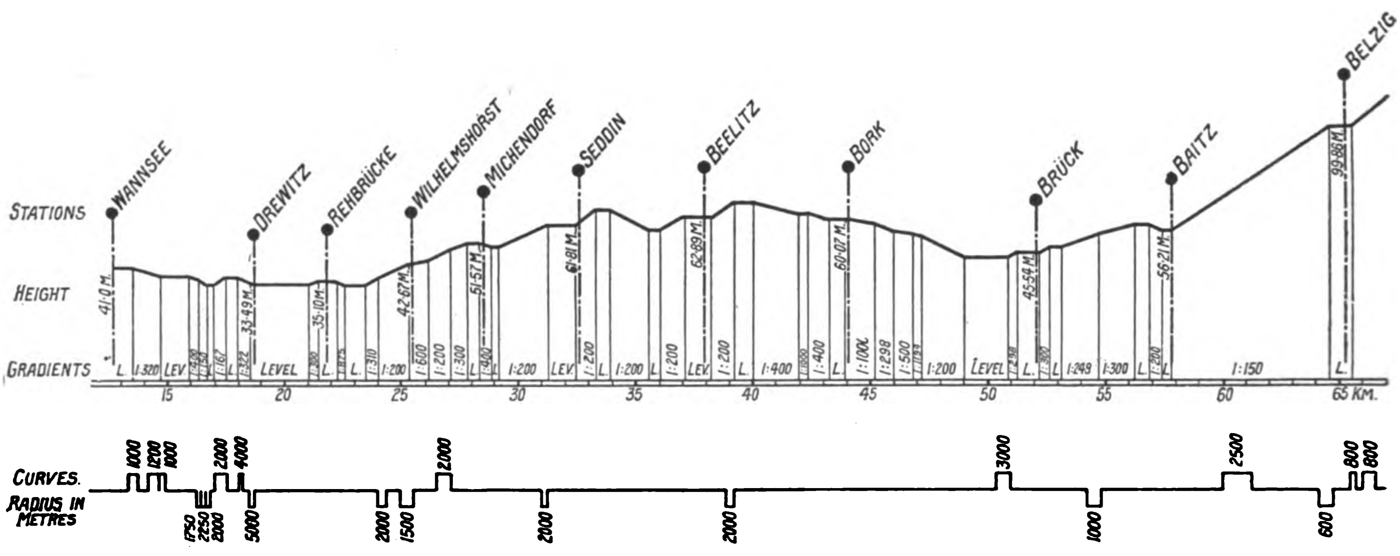

Diagram showing the profile of the track over which the tests were run (distances are shown in kilometers, grade ratios in meters)

brakes, which are at present used on the German State Railways. During the seventh test, a description of which was published in the October 24, 1924, issue of *The Railway Gazette*, London, Eng., the brake shoes of one of the cars, which weighed about 41 tons, were pressed against the wheels with an approximate pressure of 1.3 times the weight of the car, making a total pressure of about 54 tons. While the speed decreases, the coefficient between the brake shoes and the wheels increases and this pressure must be reduced towards the end of the braking distance or the wheels will skid. This factor has been taken into consideration in the design of the Kunze-Knorr brakes, skidding being prevented by

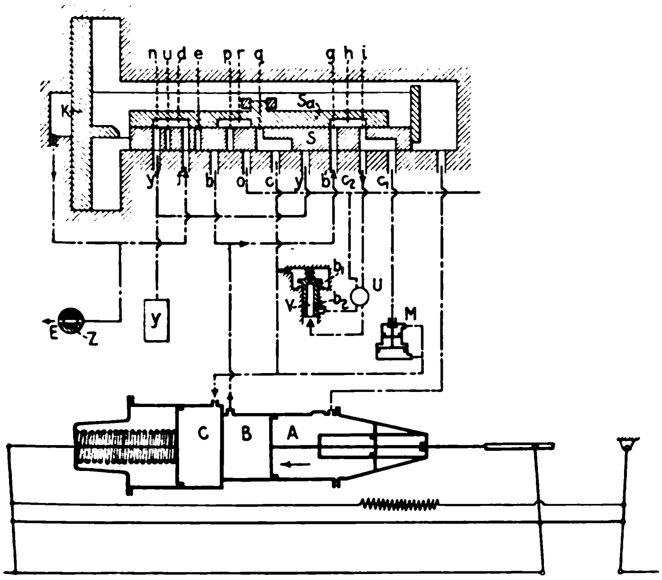

Fig. 1—Diagram showing the arrangement of the Kunze-Knorr brake for freight trains—Triple valve in service position

a pressure regulator *M*, referring to Fig. 1, which is a part of the equipment on each car. This regulator, as soon as the braking power exceeds the given maximum, allows the air to escape from a single-chamber brake cylinder.

The Kunze-Knorr brake

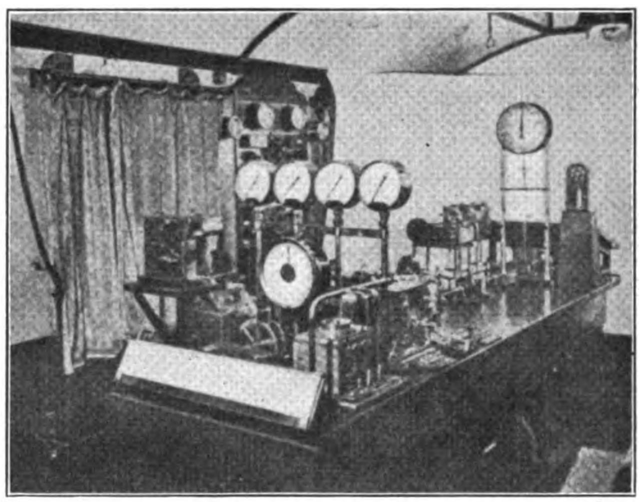
As described by the manufacturers, the Kunze-Knorr brake is an automatic air brake which embodies all the features of the Westinghouse brake in use in Germany combined with a differential brake cylinder which, it is claimed, affords flexibility in braking and a high degree of safety. The designers of the Kunze-Knorr brake have combined the semi-automatic brake, or one-chamber system, with the differential brake, or two-chamber system, which permits graduating the release of the brake.

Referring to Fig. 1, quick propagation of the braking effect throughout the length of a freight train in order to obtain smooth stops is obtained by the propagation pocket *Y*, which is made an integral part of the triple valve body. The restricted size of this pocket limits the brake-cylinder pressure at the first service application by taking up the amount of air pushed forward into the brake valve *K* by the triple valve piston. The direction of air travel from *K* to the propagation pocket *Y* is shown by the arrows. As the triple valve piston moves forward, the ports *y* and *f* are uncovered by the ports *n* and *d*, which permits a direct passage from *K* to *Y*. As the triple valve piston moves forward, it accelerates the action of the compressed air in the brake pipe *E*, which induces increasing pressure and the train comes to a stop. *Z*, which is shown located in the brake pipe, is the isolating cock.

In order to eliminate the shock and dangerous stresses occurring in the handling of long freight trains, the pressure control valve *M* has been inserted in one of the two air passages between the triple valve and the brake cylinder *C*. When the brake is being applied at first, compressed air from the chamber *B* is passing into the brake cylinder *C* through the throttled port $c2$ and the larger port $c1$, which leads through the pressure control valve *M*. But as soon as a pressure of about 10 lb. has been reached, the double piston in the pressure control valve *M* closes so that any further rise of brake cylinder pressure is comparatively slow, depending on the amount that the port $c2$ is throttled.

The double or differential piston cannot exert any braking effect as long as the same air pressure is acting upon either side of the piston. The control valve *V* being located in the passage between the triple valve slide valve *S* and the brake cylinder the connection between the two chambers *B* and *C* is intercepted as soon as the pressures have equalized so that the spring on top of the valve *V* forces the valve down on its seat. Any further reduction in brake pipe pressure connects the chamber *B* with the atmosphere by the uncovering of the ports *b* and *o* by *p* and *q*, so that this chamber is vented and the full pressure in chamber *A* is acting upon the differential cylinder which increases the braking power accordingly. This additional braking force is used in the Kunze-Knorr system to provide the necessary braking power for loaded cars. Thus, the same approximate braking ratio is available for empty and loaded cars.

The passenger and express equipments are each



Interior view of the dynomometer car, showing the recording apparatus

provided with an accelerating valve designed to increase the speed of the propagation in order to obtain a smooth stop in a short distance from relatively high speeds. The three designs of the Kunze-Knorr brake apparatus are essentially the same. The apparatus may be made applicable to the three different types of service by moving the handle of the change-over cock *V* to one of three positions.

It may be of interest to call attention to the type of draft gear with which the coaches used in the trial runs were equipped. The friction buffers, similar in general appearance to the European style of equipment, applied to these cars were what is known as the "Uerdingen" type which is designed primarily to absorb heavy shocks. It is of the friction type which releases slowly after being compressed.

A dynamometer car was used in all of the trial runs,

the tests comprised emergency and ordinary service stops from both high and low speeds. Records of the speed in kilometers per hour were taken at different points where the train made a test stop, or reduced speed. A profile map of the section over which the trial runs were made, was mounted in the dynamometer car below the speedometers in such a position, as to make it comparatively easy to verify the speeds at a glance on up and down grades and on the level. Both telephone and electrical communication were established between the locomotive and dynamometer car. In order to determine the figures of retardation, a meter of new design was used which directly recorded the retardation figures during braking in meters per sec^2. The speedometers were also driven from the same measuring axle as that of the brake distance meter. The temperature of the brake shoes was measured by a pyrometer connected to thermo-elements screwed into the brake shoes.

Various service applications were made during the tests with the idea of duplicating as closely as possible the ordinary conditions of passenger train operation over the same section of track. A number of emergency applications were made from the dynamometer car. The engineman being entirely unaware of the moment at which the emergency application was to be made. A number of service applications were also made from various speeds.

Eight-wheel switchers for the D. T. & I.

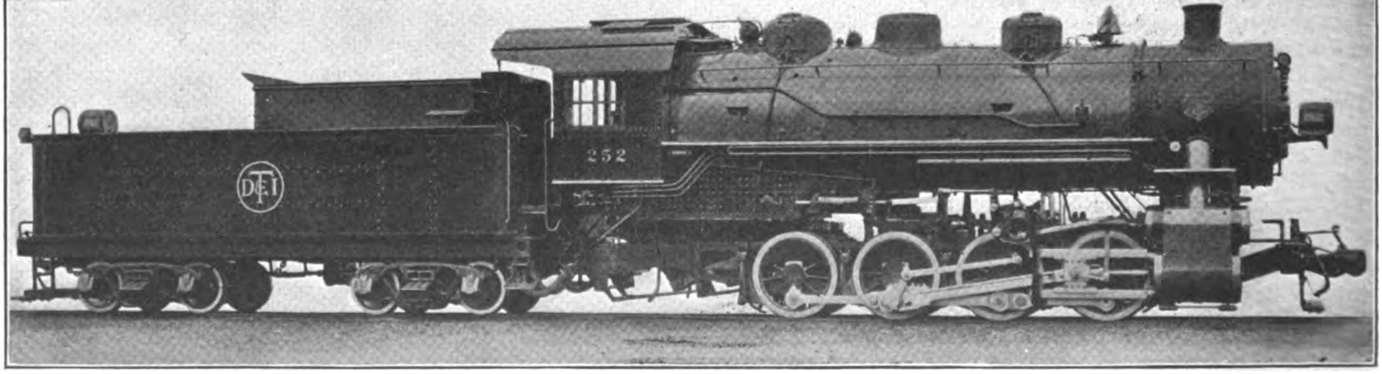
Six of this type recently delivered to Ford's railroad by the Lima Locomotive Works

The Detroit, Toledo & Ironton has recently received six 0-8-0 switching locomotives which were built by the Lima Locomotive Works. They have a total weight, in working order, of 219,000 lb. for the engine and 155,000 lb. for the tender. The tractive force is 51,200 lb.; factor of adhesion, 4.28; cylinders, 25 in. bore by 28 in. stroke, and the driving wheels are 51 in. in diameter. The height to the top of the stack is 15 ft. and the width over cab footboards, 10 ft. 2 in. The locomotives are designed for maximum grades of 2 per cent and for a maximum curvature of 19 deg.

The boiler is of the straight-top type, radially stayed,

Table of dimensions, weights and proportions

Builder	Lima Locomotive Works
Railroad	Detroit, Toledo & Ironton
Type of locomotive	0-8-0
Service	Switching
Track gage	4 ft. 8½ in.
Cylinders, diameter and stroke	25 in. by 28 in.
Valve gear, type	Baker-Pilliod
Valves	Piston type, size 14 in.
Maximum travel	6¾ in.
Outside lap	1 in.
Exhaust clearance	line and line
Lead in full gear	⅛ in.
Weights in working order:	
On drivers	219,000 lb.
Total engine	219,000 lb.
Tender	155,000 lb.
Wheel bases:	
Driving	15 ft. 0 in.
Total engine and tender	53 ft. ½ in.
Wheels, diameter outside tires:	
Driving	51 in.
Journals, diameter and length:	
Driving, main	10 in. by 12 in.
Driving, others	9 in. by 12 in.
Boiler:	
Type	Straight top
Steam pressure	175 lb.
Fuel, kind	Bituminous
Firebox, length and width	102⅛ in. by 66¼ in.
Tubes, number and diameter	230—2 in.
Flues, number and diameter	36—5½ in.
Length over tube sheets	15 ft.
Grate area	47 sq. ft.
Heating surfaces:	
Firebox and arch tubes	208 sq. ft.
Tubes and flues	2,569 sq. ft.
Total evaporative	2,777 sq. ft.
Superheating	610 sq. ft.
Comb. evaporative and superheating	3,387 sq. ft.
Tender:	
Style	U-shaped
Water capacity	8,200 gal.
Fuel capacity	11 tons
General data estimated:	
Rated tractive force, 85 per cent	51,200 lb.
Weight proportions:	
Weight on drivers ÷ tractive force	4.28
Total weight engine ÷ comb. heat. surface	64.6
Boiler proportions:	
Tractive force ÷ comb. heat. surface	15.1
Tractive force x dia. drivers ÷ comb. heat. surface	77.1
Firebox heat. surface ÷ grate area	4.4
Firebox heat. surface, per cent of evap. heat. surface	7.5
Superheat. surface, per cent of evap. heat. surface	22.0



Eight-wheel switcher built by the Lima Locomotive Works for the D. T. & I.

without combustion chamber, and with two circular courses 80 in. and 81-7/16 in. outside diameter. The working pressure is 175 lb. per sq. in. The boilers are equipped with Type A double loop, 36-element superheaters. There are 230 tubes, 2 in. in diameter and 36 superheater flues 5½ in. in diameter; the length over the tube sheets is 15 ft. The firebox is 66¼ in. wide and 102⅛ in. long with grates of the rocking bar type and a grate area of 47 sq. ft. The ash pans are of the center-hopper type. Hancock No. 11 Type A lifting injectors supply the feedwater. The total evaporative heating surface is 2,777 sq. ft. and the superheating surface, 610 sq. ft. Consolidated safety valves are used.

Steam distribution is effected by means of Baker-Pilliod valve gear, the diameter of the piston valves being 14 in. The valves are set with a travel of 6¾ in., 1-in. lap, ⅛-in. lead and line and line for the exhaust. A Lewis power reverse gear is applied. The air brake equipment was furnished by the New York Air Brake Company, and includes one 8½-in. cross-compound pump and two 18½-in. by 120-in. air reservoirs. The headlight equipment is Sunbeam with lights on both the front of the engine and the rear of the tender. The piston and valve rod packing is U. S. King type metallic. The Franklin unit drawbar and radial buffer are used between engine and tender. The material for axles and piston rods is alloy steel after Lima specifications, while that used for the side and main rods and crank pins is after specifications furnished by the Ford Motor Company. Brass shoes and mild steel wedges are used in connection with the usual type of cast steel driving boxes.

The tender is of the U-shaped level top tank type with a water capacity of 8,200 gal. and coal space for 11 tons. Bituminous coal is used. The tender tank is supported on a Comsco cast steel tender frame and four-wheel tender trucks which have cast steel truck side frames, elliptic springs and steel wheels. The important dimensions and proportions are given in the table.

Increasing income by reducing repair costs

By H. Y. Carpenter

Mechanical engineer, Davenport Locomotive Works, Davenport, Iowa.

A NUMBER of articles have appeared in recent issues of the *Railway Mechanical Engineer* in which comments have been made relative to the difficulties encountered in the making of certain locomotive repairs, due to faulty design. Many specific items were brought out, which, if corrected in the design of locomotives to be ordered in the future, would facilitate the work of maintenance and shorten the amount of time and labor required to do the work.

The biggest problem of the mechanical department is to keep its locomotives and cars on the road and to minimize the time they are held out of service for repairs. Men engaged in locomotive repair work can see practically every day many changes which could be made that would reduce the work of making certain repairs in both the back shop and enginehouse, and in some instances the repairs could undoubtedly be avoided altogether. The attention of the proper officers is often directed to certain difficulties encountered in the repair of a certain class of power, yet new locomotives are ordered having the same faults as those against which complaints have been made. Locomotives held out of service for any reason are actually draining the profits of those that are on the road and everything possible should be done to keep the equipment in service and out of the shop.

All too frequently such conditions are due to the manner in which the road purchases its locomotives. It reflects no discredit on the builders. Take, for example, a road that has never had any Mikado type locomotives and decides to place an order for a number of this type. Specifications are generally started about the time the operating department has begun to feel the pinch for additional power, and it is a matter of great importance that the earliest possible delivery be obtained. Specifications stating the size and type of engine, wheel loads, and various dimensions that appear to be about right for the conditions to be met, are sent to the builders together with a number of prints of a few parts which are fairly standard on the road. From this data, the builder must design and construct a locomotive and deliver the same in the shortest possible time. He adheres to the information given him and delivers a locomotive that is economical and satisfactory from an operating point of view, but when these engines begin to require extensive repairs, it is found that they do not fit in with the other power on the road, resulting in an increased stock for the stores department to carry. An increase in stock at one point is bad enough, but usually the locomotives are distributed over the system which makes it necessary for the stores department to carry increased stocks at many points to avoid delays by having to wait for deliveries from the general stores.

Co-operation with the builders is essential to standardization

In a case like this the builder's main concern is to build a locomotive to meet the specifications and blue prints furnished him and to meet the delivery date. With that he has his hands full. He has no time to investigate local conditions to see whether or not he can use rod brasses which would be common to some other type on the road and thereby keep down the number to be carried in stock. If he can use parts that are duplicates of what he has already made for some other road, it is to his advantage to do so, and so long as such a procedure does not conflict with the specifications and information furnished him, it is entirely legitimate to do so. But the point is that new parts are brought into existence which are not quite similar in design to others used on that road. The builder could have perhaps just as easily furnished parts that would have been common to one or more existing classes had he known what these were, but in cases of rush orders, he does not know nor does he have time to investigate. If only one part on a locomotive order for a single type was involved, the result would be negligible, but the chances are that it is many parts.

Take for example, a road that already has had one order of Mikado type locomotives and orders more from the same builder. Unless there is a great difference in the size of the locomotives on the two orders, a large number of the parts will be interchangeable. If a set of drawings accompanies the second order, the chances are that these drawings will be exact duplicates of those which the builder furnished with the first order. Unless these drawings have been revised to remove the objectionable features the second lot of locomotives will have as many objectionable features from the shop point of view as its predecessors.

Here is where closer co-operation between the shop and the office becomes noticeably desirable. If every man who had encountered any difficulty in the repair or operation of these locomotives submitted an account of his difficulties together with a proposed remedy, the mechanical engineering department could immediately incorporate

such suggestions into the design of the locomotives on the second order, if possible, and a decidedly better locomotive than those on the first order would result. To be sure, some criticisms do come in, but not all that should do so. A shop superintendent or a master mechanic may report some objection he has noticed, but the erecting gang foreman and the enginehouse foreman are seldom heard from. These men are the ones who find the small things, such as the side from which a pin should be put in, the application of which has required a disproportionate amount of time for repair.

The importance of following standard practice

There are unquestionably many parts that could be reduced from nearly as many varieties as there have been orders for locomotives to a few parts that would be standard to practically all classes. Among these are rod brasses, crank pins, driving and truck boxes, valve motion pins and bushings, crosshead pins, etc. For example, in the case of rod brasses, when a locomotive came into the shop which required new ones and those it had were not of standard design, more time than is usual would be required in applying it. But the next and each succeeding time the locomotive came in for repairs the time required to renew the brasses would be reduced to a minimum and there would be more of a possibility of the brass being in stock. It was found by one railroad that by redesigning its car trucks to be equipped with cast steel side frames, it could use one entirely new bolster and one new side frame on five different classes of 50-ton cars which had previously required as many different styles of side frames and bolsters.

Another fault to be found with many railroads has been the policy of purchasing a new type of locomotive before its adaptability to the operating conditions on the road has been fully determined. A case is known of one road which once purchased a number of Mallets only to find them unsuited to its operating conditions. The locomotives were sold to another road a few years later. The policy of the Pennsylvania of getting only one locomotive of a new type which is thoroughly tried out in service before an order for any quantity is placed, certainly has much to commend it. "It is better to have only one lemon than a bagful."

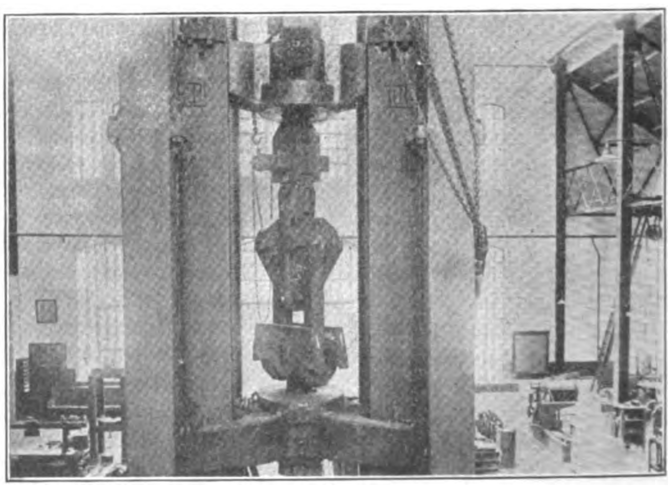
Locomotives should be designed by the mechanical engineering department

In the October number of Baldwin Locomotives, published by the Baldwin Locomotive Works, Philadelphia, Pa., is the third of a series of articles on the "Motive Power Development on the Pennsylvania System." The need of standardization was realized early in the history of the Pennsylvania and its locomotives have been developed one from another in a most logical and creditable manner. While the Pennsylvania has perhaps more locomotives of a single class than many roads possess altogether, what it has done can also be done to good advantage on many of the larger roads, even though they do not attempt to build any locomotives in their own shops.

The most feasible method of accomplishing the best results is for the mechanical engineering department of the railroad to design its own equipment, to fit the local conditions, which no builder can be expected to know sufficiently well to serve to the best advantage. By that, general design is not implied, but detail design; design that covers every part, so that when an order is placed a complete set of drawings accompany the specifications. The builder can then construct a locomotive which will fit in with the other equipment on the road. Sufficient inspectors should be provided to see that there is no deviation from the specifications, for even as small a matter as threads may cause considerable aggravation and delay in repairs. If such a course were adopted it should certainly lead to a considerable saving in maintenance. It would insure interchangeability of parts and would also result in getting locomotives which would come nearer to suiting local operating conditions.

This, however, cannot be done with the force usually allowed the mechanical engineer on many roads. As a rule, his department is only sufficient to handle the usual routine work. It should be large enough, however, to anticipate the needs of the future by preparing designs in advance. His office should receive reports of all engine failures, and be a clearing house for criticisms and suggestions relative to the road's equipment from the lowest man in the organization to the president. With a large amount of such data on file, with more arriving every day, each new design should be a distinct improvement over its predecessors. It is evident that the staff of the mechanical engineer should be adequate both in numbers and ability to carry the load that is thus imposed. While this department should be in close touch with the shop, it should not be relegated to unsuitable quarters, as the case on one large road, the mechanical engineering department of which is located just across the turntable pit from the enginehouse.

Many light repairs can be made without bringing locomotives into the enginehouse. This not only eliminates the delay incident to the two movements in and out of the house, but keeps it out of the way of other locomotives at busy times. It is such repairs as these that often necessitate putting a locomotive inside and making a short job a long one, on account of the parts being inaccessible or because the part furnished by the builders was not identical with that which the road carried in stock. Such cases can be cured by closer co-operation between the shop and the office, and by providing the mechanical engineer with complete failure reports together with unrestricted and uncensored criticisms, and by performing the complete detail design of future power in the road's own mechanical engineering department. This requires a broad minded policy on the part of the management as well as a sufficient and competent force under a mechanical engineer who is alive to the responsibilities imposed upon him. It will reduce the time required to make repairs, the amount of materials carried in stock and equipment will be in service more of the time.



Coupler yoke being tested for tensile strength at Lehigh University

Precipitation of water in compressed air systems*

By D. W. Lloyd

Assistant to general manager, Westinghouse Air Brake Company, New York

MANY technical articles have been prepared and are available for study, fully covering the laws governing the absorption and precipitation of moisture by air under pressure and temperature changes. Early investigators and scientists determined these laws many years ago. It is not the purpose, however, of this discussion to encroach at all upon this field of technical data but it is hoped that a strictly non-technical explanation concerning the working of these established laws may be of some assistance in obtaining a general understanding concerning them.

Atmospheric air always contains more or less moisture. Probably the most important function of the atmosphere is to convey and distribute moisture over the earth. Below the "dewpoint" or 100 per cent humidity mark, this moisture is in gaseous form, entirely invisible and as "dry" in the ordinarily accepted sense of the word as the air itself. When the saturation point or 100 per cent humidity mark is exceeded the excess water vapor condenses and becomes visible in the form of fog, which is made up of drops of water floating in the air. The atmospheric humidity varies continuously with changes in conditions, and the average humidity varies through wide ranges in different localities. The United States Weather Bureau shows the following mean percentages of humidities at different localities: Galveston, Tex., .85; New York City, .73; Salt Lake City, Utah, .53; Yuma, Ariz., .42; and El Paso, Tex., .39. It is somewhat curious that both the maximum and minimum values are found in Texas.

Effect of temperature and pressure on the moisture carrying capacity of air

The amount of moisture in a given amount of air at 100 per cent humidity depends on the pressure and the temperature. Considering pressure alone, the law states that the vapor carrying capacity varies inversely as the absolute pressure. In other words, if a cubic foot of free air, approximately 15 lb. absolute pressure at 100 per cent humidity is compressed to 60 lbs. gage pressure (75 lb. absolute) or five atmospheres, without change in temperature, it will be able to hold only one-fifth of the original moisture content in suspension and the remaining four-fifths will be precipitated as fog which will ultimately settle to the bottom of the container and form water.

To look at this from another angle, it is apparent that when the one cubic foot of free air is compressed to five atmospheres, its volume is reduced to one-fifth of the original volume. In other words, the space occupied is reduced in the same ratio as the ability to carry moisture in the form of vapor. This means that a given space can accommodate a given amount of water vapor regardless of the pressure of the air in that space, the temperatures remaining the same.

Changes in temperature, however, have a very pronounced effect on the amount of vapor that can be carried in suspension. The following table, which will be found in most hand books, gives the weight of water vapor per cubic foot of space at 100 per cent saturation and for each 1,000 cu. ft. of space at different temperatures:

Weight of water at different temperatures

Temperatures, degrees F.	Lbs. of water per cu. ft.	Lbs. of water per 1,000 cu. ft.
120	.00488	4.88
115	.00425	4.25
110	.00372	3.72
105	.00324	3.24
100	.00282	2.82
90	.00211	2.11
80	.00155	1.55
70	.00114	1.14
60	.000813	.813
50	.000585	.585
40	.000399	.399
30	.000271	.271
20	.000114	.114

This table may seem to be somewhat abstract for purposes of visualizing the actual amount of water that may be held in suspension in the atmosphere at 100 per cent humidity. A pint of water weighs 1.05 lb. so as a convenient point of comparison the reader will note that 1,000 cu. ft. of free air at 100 per cent humidity contains approximately this amount at normal room temperature of 70 deg. F.; in other words, the air in a room 10 ft. square with a 10-ft. ceiling can and does contain as much as a pint of water without causing any feeling of dampness whatever.

The tables will also show that within the normal range of temperatures, the amount of water vapor that can be held in suspension in this way is approximately doubled for each 20 deg. F. increase in temperature. This is only an approximate relation, but it affords a convenient means for easy analysis of the proposition within the limits of ordinary temperatures during compression and expansion.

Effect of increased temperatures

All are familiar with the fact that the temperature of air is increased during compression. We have then both the factors of temperature and pressure changes to consider when analyzing what happens to the moisture contained in the air drawn into the compressor suction, and as it passes from the compressor discharge out into the compressed air system. For example, assume an atmospheric temperature of 60 deg. F. and, for simplicity, a humidity of 100 per cent. This humidity is often obtained and is sometimes exceeded on wet days or where the compressor suction is exposed to drip or steam leaks. Assume also that the compressor is working against 75 lb. main reservoir pressure, which is approximately six atmospheres. The theoretical temperature due to compression is about 420 deg. F. This temperature will not actually be obtained, because of radiation from the cylinder walls. But as a conservative value, we can say that the air will be at least 200 deg. F. when it leaves the compressor discharge and enters the system.

The temerature between the inlet and discharge has therefore been raised at least 140 deg. F., or a total of seven steps of 20 deg. each. Considering that the moisture carrying capacity is doubled for each 20 deg. F. rise, its ability to carry moisture out of the compressor, as a result of the increased temperature, will be $2 \times 2 \times 2 \times 2 \times 2 \times 2 \times 2$, or 128 fold of what it was when it was

*Abstract of a paper read before the Manhattan Air Brake Club, New York, February 20, 1925.

drawn into the suction. Actually, the increased capacity due to this change in temperature is even greater than that obtained by this approximate method of calculation.

Effect of increased pressure

Offsetting this increased thirst of the air because of the heat, we have the effect of the increase in pressure. This effect is, however, only in proportion to the pressure increase which in this assumed case is six atmospheres, or six times the initial pressure. The net effect of the 128-fold increase and the six-fold decrease is the product of the two or more than a 20-fold increase. It will be apparent, therefore, that the air will not begin to deposit any of its moisture until considerable cooling has been effected. Under the assumed conditions, the precipitation will not start until somewhere along in the system where the temperature has dropped somewhat below 120 deg. F. Because at this point the temperature is still 60 deg. F. higher than the atmosphere, or three steps of 20 deg. F. each which produces $2 \times 2 \times 2$, or an eight-fold increase in moisture carrying capacity which still more than offsets the tendency of the increased pressure to reduce its capacity to one-sixth what it was in the beginning.

Five-sixths of the original moisture must be deposited somewhere between this point and the ultimate discharge from the system, assuming that the compressed air is finally cooled to the temperature of the atmosphere.

Collection of moisture in the brake system

The actual amounts of water that are involved in every-day air brake practice may be readily calculated. Even with a good tight train line the air lost from leakage alone in a 100-car train may run as high as 30 cu. ft. per min. If we assume that the average amount of air required for the train is 35 cu. ft. per min., or 2,100 cu. ft. per hour, under warm weather conditions with high humidity, we can see that about ½ gal. of water is being drawn into the compressor suction every hour and all but a small portion of it must be deposited in the main reservoir and elsewhere in the system. Fortunately, under cold weather conditions the atmosphere cannot carry as much moisture as in the summer, otherwise we would have much more trouble due to freezing of this condensation in the piping and the valve devices than is now experienced. The table shows that at freezing temperatures the amount of water is less than one-tenth of what it is at a temperature of 100 deg. F.

The radiating pipe on the locomotive is, of course, designed to provide as much cooling effect as possible on the locomotive so that the moisture may be deposited in the main reservoirs from which it can be drained. A recent survey of main reservoir piping on locomotives on various roads was recently made during which temperatures were taken at certain intervals of time during actual operation at various points in the piping to determine the efficiency of the cooling actually effected. In many cases it was found that the cooling pipe was located, either close to the firebox or in such a location that free circulation of atmospheric air around it was not afforded. This resulted in the air being reheated after leaving the first main reservoir, or possibly the second main reservoir and arriving at the brake valve, feed valve and other operating devices on the locomotive at a higher temperature than when in the reservoirs. This, of course, is a bad condition and increases the possibility of precipitation of moisture, with consequent damaging operating results in the valve devices on the locomotive and even in the train line.

It may be of interest to know the results of an investigation that was carried out by the Westinghouse Air Brake Company several years ago to determine to what extent water or condensation worked its way into the auxiliary reservoirs of freight brake equipment. During this investigation, which was carried out in the summer, more than 2,000 auxiliary reservoirs were examined. Water in varying amounts was found in 200 reservoirs or approximately 10 per cent of the total. The maximum amount in any reservoir was three gallons; another one had two gallons, and about 6 per cent out of the 10 per cent having any water at all had one pint or more. Practically all the dirt collectors on the cars examined either showed water or a rusty condition, indicating that they had held water at some recent time.

The length of radiating pipe

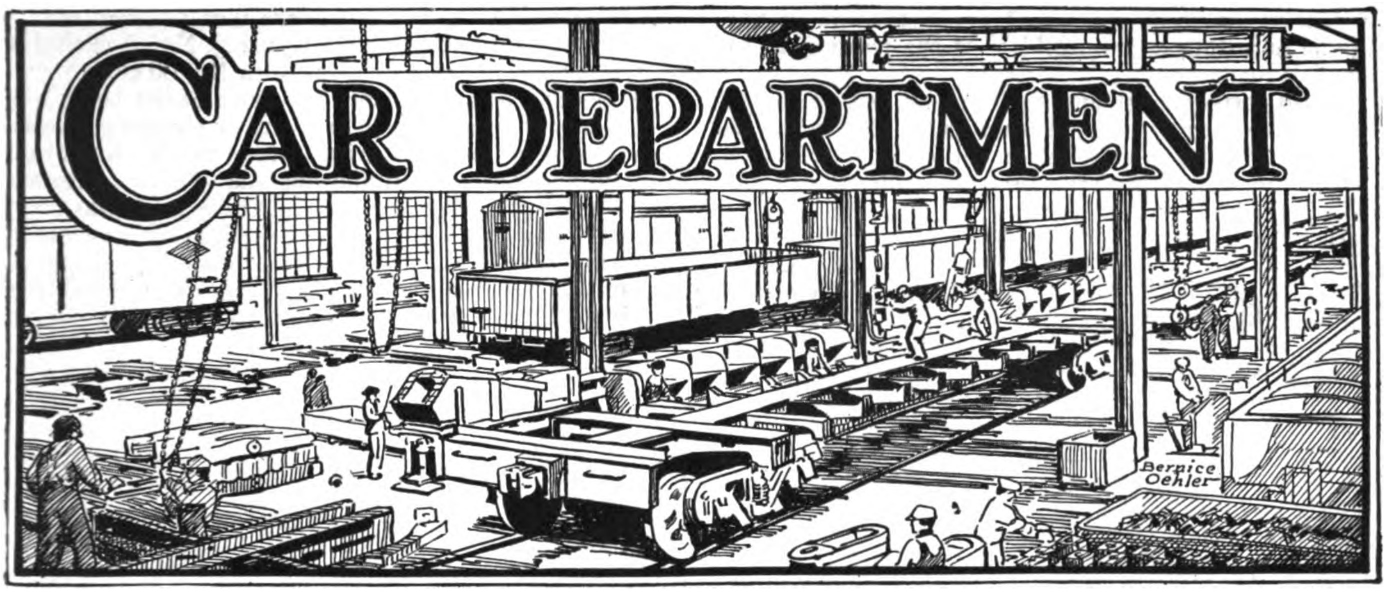
The Westinghouse Air Brake Company's recommendations as to length of radiating pipe for cooling purposes have for many years called for approximately 45 ft. between the compressor and the first main reservoir, and a like amount between the first and second main reservoirs. The Air Brake Association's recommended practice specifies as follows:

> Not less than 25 ft., nor more than 45 ft. of cooling pipe should be used between the air compressor and the first main reservoir. With two air compressors per locomotive, duplicate the amount of discharge pipe specified for one, these pipes to be connected to the main reservoir through a Y-fitting and a short two-inch extra strong nipple.
>
> The equalizing pipe between the main reservoirs should not be less than 1¼ in. in diameter and not less than 25 ft. nor more than 45 ft. long.
>
> The radiating pipe connected to the main reservoir should be located in the coolest possible place and placed so as to drain toward the reservoirs.

These recommendations allow considerable latitude. The reason for this is because it is practically out of the question to make any specific recommendation that will not be objectionable under certain circumstances. The atmospheric conditions in such localities as Florida and the Southwest differ widely from conditions in the Northern part of the country. The folly of attempting to specify an installation that will be equally well adapted to all conditions will be at once apparent. Under warm weather conditions, doubling or even tripling the lengths of pipe specified as a maximum by the Air Brake Association would not be sufficient to cool the air back to atmospheric temperature before reaching the brake valve. But under some extreme cold weather conditions, such an installation would without question permit the air to be cooled to freezing temperatures and below before even reaching the first main reservoir, with the result that the moisture would freeze and stop up the discharge to the main reservoir.

This condition has been obtained in steam road service and is quite a frequent occurrence in traction service. In order to avoid this and secure the desired results at all times would require an adjustable system which could be varied with changes in atmospheric temperatures, which is, of course, out of the question. The compromise to be sought is one that will produce a maximum of cooling with a minimum possibility of freezing.

It has been previously pointed out that the overall effect of compression of the air is to increase the thirst or moisture carrying ability of the air. Consequently, the effect of expansion is to cause a deposit of moisture. The effect produced as the air passes through the feed valve is well known to all air brake men. Drain cups, centrifugal dirt collectors with drain cocks, and reservoirs to catch condensation are commonly placed in the piping adjacent to the feed valve or under the brake valve and periodically drained of moisture collecting at this point.



The prevention of hot boxes*

A systematic record and analysis of the causes will suggest the proper remedy

By T. O. Quinn, Cleveland, Ohio

EPIDEMICS of hot boxes, no doubt, have been experienced by practically all roads handling any great volume of freight business, which has called for a large number of explanatory reports on the part of those in direct charge of car department work, these reports having been furnished generally, after a hurried investigation.

It is the writer's opinion that fully 75 per cent of the trouble caused by hot boxes is the direct result of the failure of the human factor to function properly, either through neglect or carelessness, and in some few cases through lack of proper methods and instructions. In order permanently to correct or eliminate such conditions, a thorough investigation from all angles is necessary before drawing any conclusions as to the principal cause for hot box epidemics, taking into consideration the human element involved and the possibility of the working force neglecting or overlooking some minor detail of the work assigned them. By the time the cause is located the organization is generally working to the entire satisfaction of all concerned, and can only be maintained at that point by the proper supervision of those engaged in hot box prevention work.

My experience leads me to believe that epidemics of hot boxes are caused mainly through improper lubrication and that in about three-fourths of the cases improper lubrication is due to the failure of the human element, and is not generally due to mechanical conditions. To lubricate properly the journals of railway freight equipment, considerable training of forces doing this class of work is required, as the "car knocker" is the principle cog in the machinery that causes, and through whom the cures are effected, where the hot box epidemics are concerned. Therefore the importance of his duty must be shown him in such a manner as to secure his interest in the work he is to do, if corrective measures are to be applied and satisfactory conditions maintained.

Methods to be followed to get the proper lubrications with our present lubricating system should consist of the packing and adjusting of journal box packing in the following manner, providing that the journal packing has been properly saturated with a good grade of car oil: first, in packing or repacking of a journal box complete, there should be inserted in the mouth or front of the journal box, a roll of journal packing, approximately 2½ in. in diameter and 10½ in. in length for journals 8 in. and 9 in. in length, and a roll approximately 3 in. in diameter and 12 in. in length for journals 10 in. and 11 in. in length, the rolls to have the ends square and uniform and to be held in a firm position by being tied with strands of waste or their wrappings, and then worked back under the journal to the extreme back of the box, leaving it in such a position that it does not extend above the center line of the journal. The rest of the packing is then placed firmly under the journal to prevent settling away from it, this being accomplished by placing the packing across the full width of the mouth of journal box, allowing the strands to hang down outside until packing is complete. Additional packing is applied on top of the overhanging strands, which form a binding for the entire mass and prevents the separation of the packing. The journal packing, when completed, should not extend above the center line of the journal at any point, neither should the front of the box be filled with packing, as this prevents proper inspection and does not lubricate the journal.

The attention to journal packing where repacking of

*A paper submitted in the competition on hot box prevention which closed March 1, 1924.

the box is not required, should consist of inspection, and the adjusting and reworking of the packing in the following manner:

Careful inspection should be made by close examination of the journal and contained parts of the journal box and defective mechanical conditions corrected. On a box where no mechanical defects exist and the journal shows any indication of heating, the journal packing should be loosened and pulled forward from the sides and worked back under the journal from the center, in order to break up the glazed surface of the packing from long contact with the journal and to raise the center portion of the packing in the box against the bottom of the journal. Where excessive packing or packing in a dry condition is encountered, it should be removed and in case insufficient packing remains, fresh saturated packing should be inserted and worked under the journal from the front and bottom portion of the box, raising the packing on each side to the center line of the journal.

Hot box epidemics, where they have been due to the lack of proper attention, have been corrected and satisfactory conditions maintained by following closely the above methods.

Sometimes it is difficult to determine the particular employee at fault or the one that is negligent in performing his work and some system is necessary whereby that person can be located and properly instructed. The method outlined below has been worked out and followed with success in a number of cases where hot box epidemics were caused through the failure of one or more men in the organization.

At the larger terminals where a large force of oilers is used, the men are divided into crews or gangs of four. One oiler takes care of the outside boxes on one side of each car in the train, and one oiler takes care of the inside boxes on the same side, the other two oilers handling the opposite side in the same manner, two men working always on the south or east side and the other two men always working on the north or west side. When oiling attention is completed the last man finishing a car on his side applies identification marks with chalk showing the station, symbol and date.

Hot box forms such as illustrated, are made out either by the inspector or the trainman whenever cars are set out or require attention en route. This form when filled out complete, contains all the information required to locate the oiler last giving the box attention at a terminal, prior to the departure of the train. The completed forms are made in duplicate and one copy forwarded to the car foreman at the originating point and one copy to the division car foreman or district master car builder, which enables the supervisors to deal at once with the party responsible, where the cause would indicate that failure was due to lack of attention.

Improper turning or truing of journals, resulting in hot boxes within a short time after application or change of wheels is one of the lesser causes of hot boxes. This arises in a number of cases from the use of a roller for applying the finish to journals. Where a roller has been used it has been found that the fine edges left from cutting or finishing tools are merely rolled into the journal only to be brought out when more than ordinary friction heat is produced, the result is a cut journal before the journal bearings become properly seated. The exact fitting of journal bearings is of minor importance where all other conditions are normal.

Where this condition was found the use of the roller was done away with entirely and journals for both freight and passenger service turned in the usual manner, a finishing cut being taken about 3/64-in. in width, particular attention being paid to see that collars and fillets are turned properly. The journals are then polished with a polishing stick and emery cloth, using No. 2 cloth for the first application and finishing with No. 00 cloth.

On another occasion a small epidemic of hot boxes was caused by car repairmen, in applying or changing wheels, preparing their journal bearings with a thin coating of oil prior to application, then allowing the bearing to remain near the ground while the balance of the work was completed on the car. In some cases the bearing was left in this position for an hour or more, with the natural result that the oil caught and retained all the foreign substances striking it. At the time the epidemic developed the season

This report must be made out promptly and sent to Division Master Car Builder for all hot boxes. Division Master Car Builder to forward one copy to Foreman at originating point.

Sample of the form used for reporting hot boxes

was extremely windy. When located, the matter was readily corrected by the exercise of more care in the handling of the journal bearings.

An increase in hot boxes generally follows a serious reduction in car department forces or when labor troubles are encountered, such as were experienced during 1922, but the result can hardly be called an epidemic. This condition is more generally due to a lack of attention and involves both the human and mechanical conditions.

The mechanical features resulting in the occasional hot box are generally understood and involve such defects as:

1.—Worn journal bearing, resulting in cracked bearings and improper bearing surface.

2.—Bent arch bars and truck out of line, resulting in the weight of the load being equally distributed on the journal bearing.

3.—Slid flat or shelled out wheels, causing the journal packing to settle away from the journal through the jar of the wheel, resulting in lack of lubrication and also distorting the contour of the brass.

4.—Improperly fitting journal wedge, resulting in uneven wear on the bearing.

5.—Missing journal box covers, permitting foreign substances of all kinds to enter the box and prevent proper lubrication of the journal.

By closely following the methods outlined hot box epidemics have been entirely eliminated and car failures per mile from this cause reduced to a minimum, resulting in increasing the mileage on the division where this method has been carried out to 585,113 miles per failure.

Reclamation of car journal packing

A description of the system used on B. & L. E. for the conservation of oil and waste

By G. Charles Hoey

Draftsman, mechanical department, Bessemer & Lake Erie, Greenville, Pa.

ONE of the most important jobs that the car department must do to obtain satisfactory car mileage is to provide for the proper lubrication of car journals. It is essential that the proper grade of oil and waste be supplied and the work of packing the

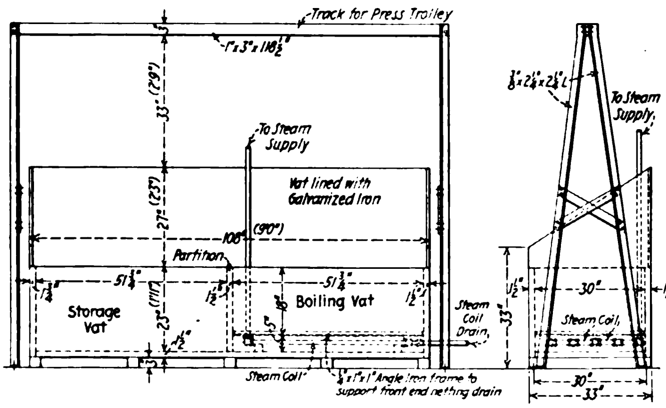

Fig. 2—Vat for boiling and storing reclaimed journal box packing

journal boxes be properly performed. It is has been noted that this particular phase of car repair work was emphasized in the papers submitted in the competition on the prevention of hot boxes which have been published during the past year in the *Railway Mechanical Engineer*. The reclamation of oil and waste is a question of prime importance in the work of car maintenance and in order to make it a real economy, it is essential that proper methods be used.

The oil and waste reclamation plant of the Bessemer & Lake Erie is located at its principal car repair shops, Greenville, Pa. All heavy repairs to steel and wooden freight cars and passenger equipment are performed at these shops. At the present time, the entire product of the oil and waste reclamation plant is used at the Greenville car shops which turns out an average of 25 cars a day.

The work of packing the journal boxes is left until the cars have gone through the repair shop and are spotted on the outbound track for stencilling, and testing of the air brakes. The journal box packing gang, consisting of three men, removes all of the packing from the journal boxes and transports it in low-side steel wheel-barrows to a steel storage bin located just outside the building, as shown in Fig. 1. A load of reclaimed waste is taken on the return trip and the boxes are repacked.

Reclaiming old waste and babbitt

Only one man is employed in the actual work of reclamation. Referring to the drawing of the floor plan, packing is removed from the storage tank to the picking table, which is placed in a convenient position for the attendant to work from the storage tank and thence to the two tanks for boiling and storing the reclaimed "dope." The top of the picking table consists of a screen made of front end netting on which the waste from the old pack-

ing is cleaned and fluffed up. All foreign material such as pin grease, babbitt and dirt, together with the packing unfit for further service is removed by picking or it falls through the screen into a bin underneath.

After the old packing has been cleaned and fluffed up, it is placed in the boiling vat, shown in Fig. 2. This vat is located in the corner of the building at the right of the entrance leading in from the storage tank. It is lined with galvanized iron and is separated from the storage vat by a 1½-in. partition. The packing is supported on a screen made of front end netting placed five inches above the bottom of the vat. Sufficient oil is placed in the vat to cover the "dope." Heat for boiling the oil is supplied by a steam-coil underneath the screen. Under ordinary conditions, a batch of reclaimed "dope," consisting of approximately three wheel-barrow loads, is allowed to remain in the boiling vat for about one hour. However, at times when the car shops are working under unusual business conditions, the "dope" is not allowed to boil more than

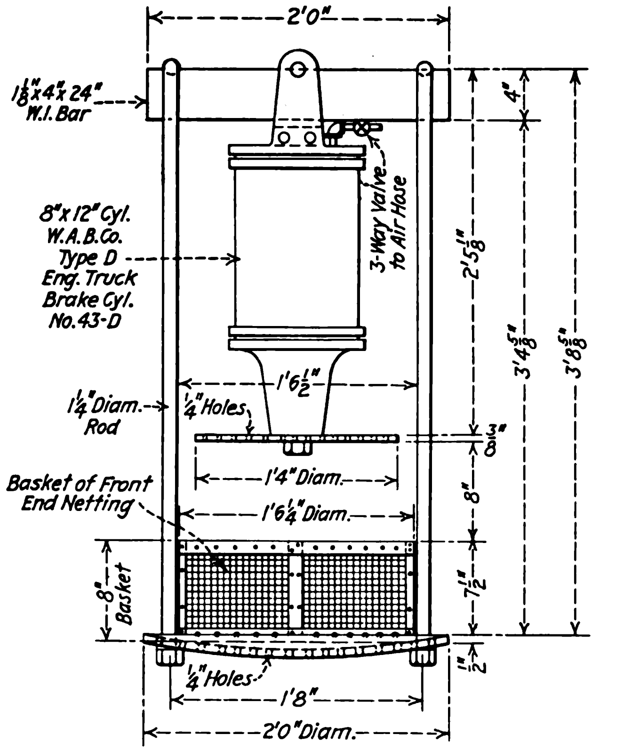

Fig. 3—Press for extracting the oil from the "dope" at the boiling vat

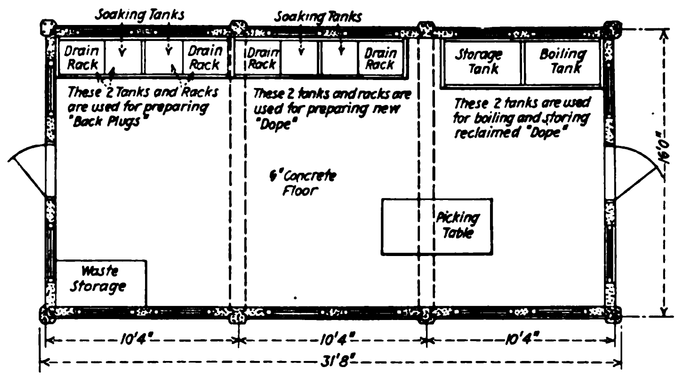
30 min. After the "dope" is boiled, it is pressed in the press shown in Fig. 3 and placed in the storage vat until removed by the journal box packing gang.

The press is carried over the boiling and storage vats on a monorail made of 1-in. by 3-in. flat iron supported on two ⅜-in. by 2¼-in. by 2¼-in. angles placed at the ends of the vats, as shown in Fig. 2. It consists essentially of a basket constructed of front end netting, 18¼ in. in diameter and 8 in. deep. The bottom of the basket is made of a ⅜-in. steel plate, dished as shown in Fig. 3, and is provided with a large number of ¼-in. holes to permit the oil to escape. The work of pressing is done by means of an 8-in. by 12-in. Westinghouse, type *D* engine truck brake cylinder. A ⅜-in. steel plate, 16-in. in diameter is secured to the end of the piston rod which has been turned down to a smaller diameter and threaded for a nut which holds the plate in position. Compressed air can be admitted to the cylinder from the shop air line by means of the three-way valve located at the top. The basket and air-cylinder are held in a frame which is swung from a trolley running on the monorail.

All of the dirt and foreign matter which has been removed during the process of picking is placed in a furnace and burned. The furnace is constructed of sheet iron with a screen made of front end netting, for supporting the material. Underneath the screen is a piece of sheet iron which slopes to the front of the furnace. As

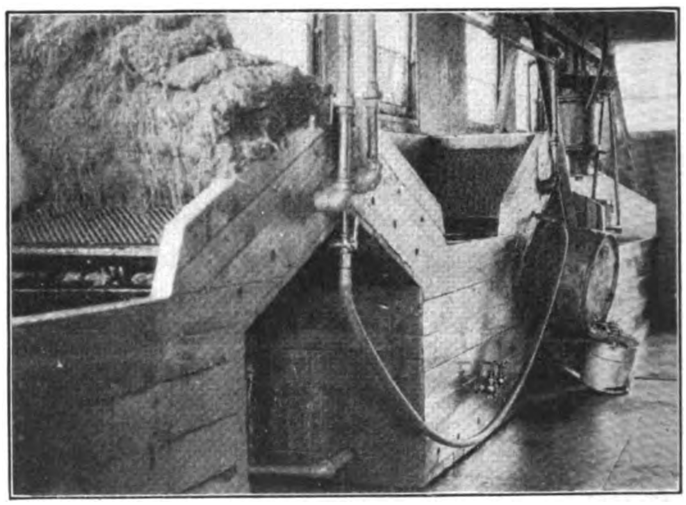


Floor plan of the plant for reclaiming oil and waste for journal box packing

the material burns, the babbitt metal drops through the screen and rolls down the sloping sheet.

Reclaiming the oil

In order to make the reclamation of oil a real economy, it is essential that it be done right. Many hot boxes are caused by foreign substances in reclaimed oil, which collect along the edge of the bearing until the accumulation is sufficient to wipe the oil off the journal. This material also works its way into the bearing, forming a carbon



An interior view of the packing reclamation plant showing the arrangement of the tanks and racks for preparing new "dope" and "back plugs"—The press and boiling vat is shown in the background

coating absolutely void of any anti-friction quality, which results in the gradual heating of the car journal. However, very little trouble of this nature has occurred on the road, due because of the process of filtration used in reclaiming the oil.

As excess oil accumulates in the boiling vat, it is removed and run through a filter. All foreign matter is removed by a process of slow heating, filtration and settling. The filtering apparatus consists of three steel barrels. The first barrel is equipped with a filter or

strainer and has a steam coil at the bottom. A pipe leading from near the top of the first barrel, carries the oil by gravity to the bottom of the second barrel. A similar piping arrangement connects the second barrel to the third barrel which is equipped with a steam coil, like the first, and a cock for removing the oil.

Oil from the boiling vat, which has accumulated from the boiling and pressing process is allowed to thicken and is poured through the filter into the first barrel where it is heated and agitated. As the barrel becomes full of oil, it escapes through the pipe to the second barrel, which serves as a settling tank. As the second barrel becomes full it flows in the same manner as from the first to the

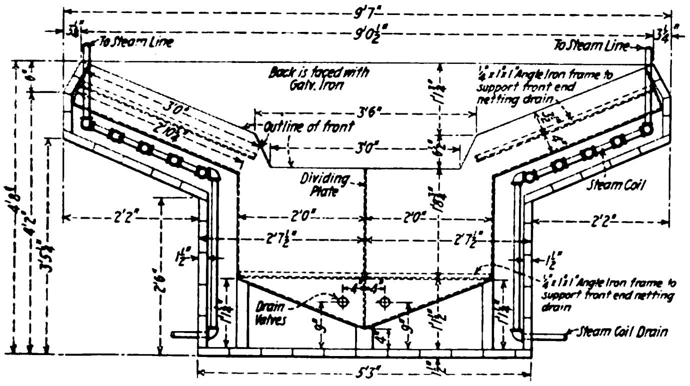


Fig. 4—Vat for soaking and draining new packing

third barrel where it is heated sufficiently to be drawn off and placed in storage.

Ordinary steel tubs are used for the handling of dope in the reclamation plant. All new "dope" and back plugs are soaked for not less than 16 hours in the double compartment vats shown in Fig. 4 and are then placed on the sloping drains as shown in the interior view of the plant, until it is needed by the journal box packing gang.

Practically the entire time of two men of this gang is devoted to repacking journal boxes. The time of the third man is used for packing journal boxes having new wheels.

This plant, which employs one man, supplemented by a gang of three men, maintains an average daily output sufficient for 25 cars. However, providing it is not necessary to use a large amount of new packing, which requires a longer time to soak, an output of 50 cars a day can be readily handled. Old packing is sometimes shipped in from outlying points to be reclaimed, but no special effort is made to collect all the old packing at such points. When a surplus does occur at any outlying point, it is shipped to the plant for reclamation. Old packing from locomotive journals and tender truck journals at the Greenville locomotive repair shops is also reclaimed at this plant and used for car journals.

The car department has entire supervision over this plant. "Dope" is taken from the storage bin as needed, no order or requisition form being used. The plant consumes approximately 12 barrels, containing 52 gal. each, of oil and three bales of waste, weighing 330 lb. each, in 15 working days. It is estimated that each car requires an average of 21 lb. of waste and 9½ gal. of oil.

The London & North Eastern Railway has announced that all passenger train rolling stock which it acquires henceforth will be built on the articulated principle. The company has recently received the first of 29 articulated trains which it has under order, each to consist of two five-coach articulated units. Savings in weight, increase in the comfort of travel and reductions in train length are the principal advantages afforded by articulation.

Decisions of the Arbitration Committee

(The Arbitration Committee of the A.R.A. Mechanical Division is called upon to render decisions on a large number of questions and controversies which are submitted from time to time. As these matters are of interest not only to railroad officers but also to car inspectors and others, the Railway Mechanical Engineer will print abstracts of decisions as rendered.)

Switching damage through hand brake failure

Barrett Company, tank car No. 4210, was damaged in switching service on the Chicago, Milwaukee & St. Paul lines. The handling line repaired the car and rendered a bill to the car owner. The handling line contended that the damage to the car occurred in fair usage while the car owner took the position that such extensive damage could not have occurred in ordinary handling, but must have been the result of undue impact occasioned through other than regular switching and that, under section *D*, Rule 32, the handling line was responsible and should issue authority for an offset bill. The Barrett Company in submitting its side of the case to the Arbitration Committee, stated that the tank shifted 5 ft. 6 in. to the B—end, breaking all anchor bolts and tank anchor bands. They claim that this was the result of unfair usage as the car was built in July, 1916, and equipped with center anchorage. The handling line stated that when the rider in charge of the car commenced to tighten the hand-brake, the clevis, which was on the end of the rod and connected with the floating lever, broke under the strain, making it impossible to set the hand brake. Upon inspection, it was found that the break in the clevice was new.

The Arbitration Committee rendered the following decision: "The evidence shows that the handling line provided rider protection and that every reasonable effort was made to protect the car. Therefore, the car owner is responsible."—*Case No.* 1923, *The Barrett Company vs. Chicago, Milwaukee & St. Paul.*

Depreciation on a destroyed car

On May 15, 1923, Chesapeake & Ohio box car No. 5399 was badly damaged in an accident on the St. Louis-San Francisco. The depreciation statement furnished by the owners shows that the car was built in July, 1914. The repairing line took exception to this date, as the underframe of the car was stencilled "rebuilt June 1910." A representative of the repairing line was sent to the office of the superintendent of the car department of the car owner and was informed that the original C. & O. car No. 5399 was built April 16, 1889, destroyed January 29, 1890, rebuilt June 29, 1899, and sold to a foreign company December, 1915. He was further advised that C. & O. car No. 85399 was built July 10, 1914; after the original car No. 5399 had been sold, car No. 85399 was changed to No. 5399 and that this was the car in question. The St. Louis-San Francisco contended that the depreciation should be figured from April, 1889.

The C. & O. stated that the car in question was built by the Central Locomotive and Car Works, July 10, 1914, and outshopped as car No. 85399, which number was changed to read No. 5399 on the owner's line August 8, 1916. The original car No. 5399 was built April 16, 1899, and was destroyed on the owner's line January 29, 1890, and rebuilt June 29, 1891, and then sold September, 1915. The car owner further stated that none of the

order of cars in which the car in question was included was delivered earlier than 1914. Therefore, the stencilling on the steel underframe showing the car rebuilt in 1910 was in error. The car owner concluded by stating that the settlement made for a car destroyed on a foreign line should be based on the original date built, according to Section D, Rule 112.

St. St. Louis-San Francisco claim that the fact that the underframe of the Chesapeake & Ohio car No. 5399 was stencilled rebuilt June, 1910, was positive evidence that the car was not entirely new when released by the builder July, 1914. Therefore, the depreciation should be figured from 1889.

The Arbitration Committee rendered the following decision: "Additional evidence submitted by the Chesapeake & Ohio substantiates their claim that the car body in question was built new in July, 1914. Therefore, the depreciation should be figured from that date."—*Case No. 1320, Chesapeake & Ohio vs. St. Louis-San Francisco.*

Exceptions taken to the cost of repairs for items listed on defect cards

On November 22, 1922, and June 27, 1923, the Kansas, Oklahoma & Gulf issued defect cards covering defects on T. A. R. X. car No. 2. On March 27, 1923, the Allied Refining Company rendered a bill for $358.51 for repairing the defects. The handling line objected to the bill on account of the repair card not being rendered in accordance with the A. R. A., Rule 7, Section 2, contending that it entitled it to a statement showing the actual material billed for. Exception was taken also to the charge of $58.00 for repairs to the tank head which it refused to pay according to paragraph 2 of Rule 4. The K., O. & G. also took exception to the charges made for replacing the dismantled underframe with another one, because Rule 94 does not cover this item. The Allied Refining Company stated that the defect card was issued several months subsequent to the date on which the damage actually occurred. The repairs were based on prices as covered by the particular code of rules in effect at the time of the accident. The car underframe was scrapped and charges were made against the defect card, according to Rule 94, for material only.

The Arbitration Committee rendered the following decision: "Defect card for delivering line defects should be dated not later than the first interchange of the car. Labor and material prices must conform to the rules in effect at the date of the defect card. With reference to the dismantled underframe, which was replaced with another one, the charge for labor and material should not exceed what would have been required for repairs or necessary renewals of the damaged parts in kind. With reference to the tank head, concerning the cost of repairs of which the car owner is not in possession of definite information, the Committee feels that the charge of $58.00 billed is not excessive."—*Case No. 1327, Kansas, Oklahoma & Gulf vs. Allied Refining Company.*

Another Rule 32 case

On May 17, the Philadelphia & Reading reported that N. O. T. & M. box car, No. 730, was damaged on its lines and requested the Gulf Coast lines to furnish a statement showing the depreciated value of the car. The matter was further investigated and it was found that the car came under the provisions of Rule 120 and accordingly, on May 29, an inspection certificate was furnished.

The Philadelphia & Reading stated that car No. 730, built during 1907, was the tenth car in a draft of 18 cars standing on the south end of a siding. Thirty-two cars were standing on the north end of the siding with a space of about eight car lengths between the two drafts. An engine crew backed eight cars against the draft of 18 cars and started to back a draft of 26 cars against the draft of 32 cars, and when the two drafts came together, car No. 730, the 18th car from the engine, buckled. No derailment resulted and no other cars were damaged in any manner whatever. The handling line further stated that the damage was the result of the weakened condition of the car, as the center sills, having no cover plates and being weakened by corrosion as the result of nearly 15 years service, naturally failed to stand the regular shock of switching.

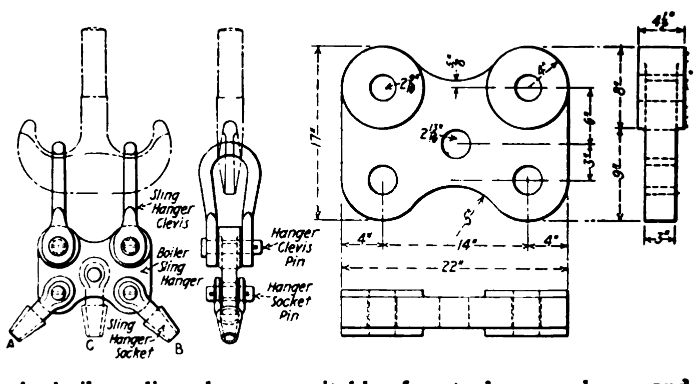
The car owner in making its contention, claimed that upon investigation by its representative, it was found that the damage to the car was due to handling and the failure of the flagman to get his signals to the engineman in order to avoid striking the second cut of cars. The car owner further pointed out that the assistant train master of the handling line recommended suspension and discipline for the members of the crew in their failure to perform their duties properly which resulted in damaging the car, thus inadvertently admitting its responsibility.

The Arbitration Committee in making their decision stated that: "According to the statements submitted by the train crew, signals were given with the intention of having the engineman stop, but the signals were not given in such manner as to be observed by the engineman. Therefore, under Section (d), Item 2, Rule 32, handling line is responsible."—*Case No. 1322, Philadelphia & Reading vs. Gulf Coast.*

Boiler sling hanger for wrecking service

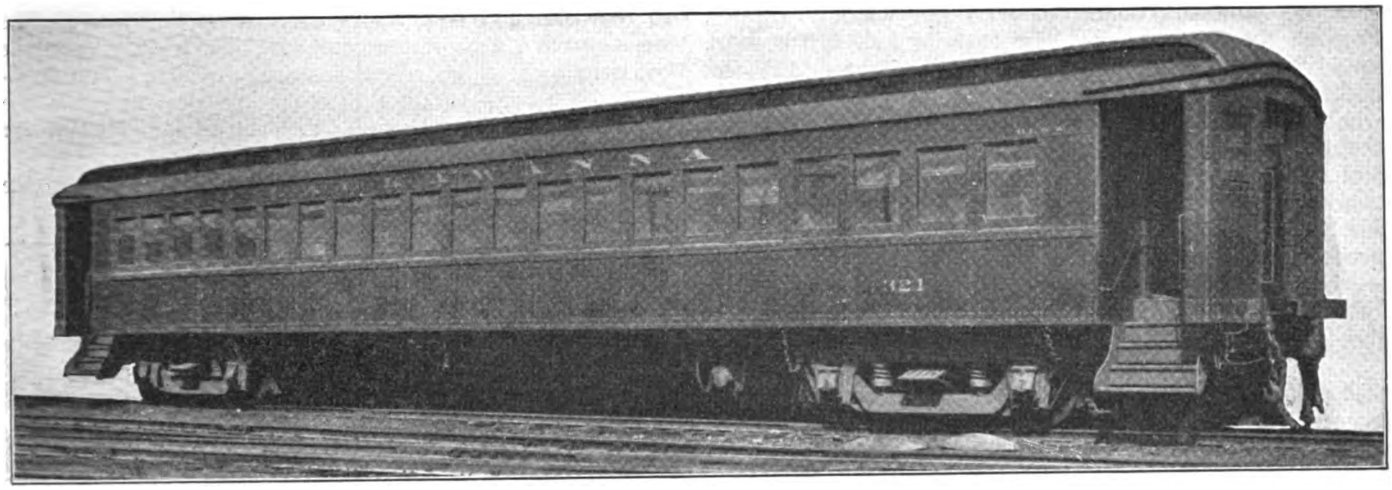
THE boiler sling hanger, shown in the drawing, was designed primarily to be included in the equipment for wreck cranes. It can, however, be used to advantage as part of the crane equipment in tank car shops and in locomotive erecting and boiler shops.

The hanger is forged from a solid piece of wrought



A boiler sling hanger suitable for tank car shops and locomotive erecting and boiler shops

steel and machined to the dimensions shown in the drawing. Referring to the side and end views of the assembly drawing, the calculated working load with the sling attached at *A* and *B* is 150,000 lb. The calculated working load, with a line attached at *C* only, is 125,000 lb. The three slings together are capable of handling any weight of locomotive, boiler or tank.

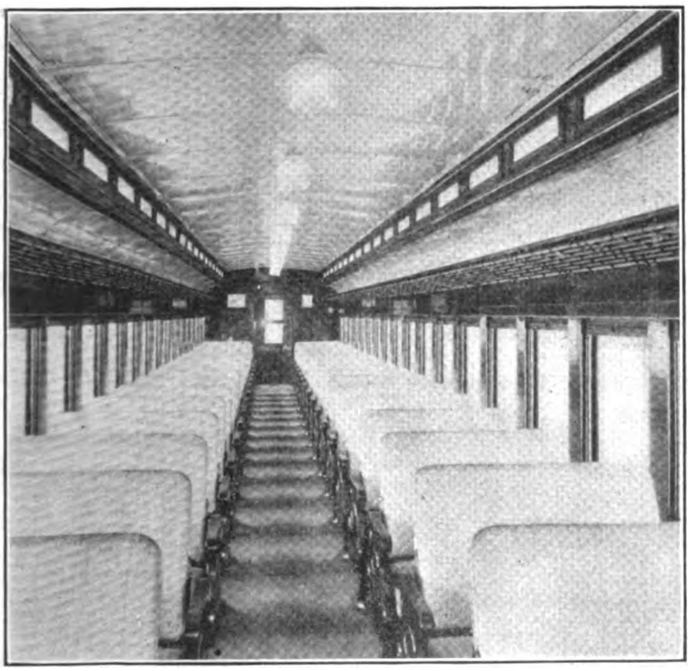


D. L. & W. Suburban Coach

Suburban cars for the D. L. & W.

All-steel construction with seating capacity of 82 passengers —Total light weight 106,000 lb.

THE Delaware, Lackawanna & Western has recently placed 50 new steel suburban coaches and 10 suburban combination passenger and baggage cars in service between Hoboken and outlying points in the New Jersey suburban district. The 50 coaches were built by the Pullman Car & Manufacturing Corporation and the 10 combination cars were built by the Bethlehem Shipbuilding Corporation, Ltd.



The coaches have seating accommodations for 82 pasengers

Several important details in the design of the cars are so carried out that they may be easily transferred to and arranged for operation in multiple unit service should the Lackawanna, at some future date, decide to electrify its suburban territory.

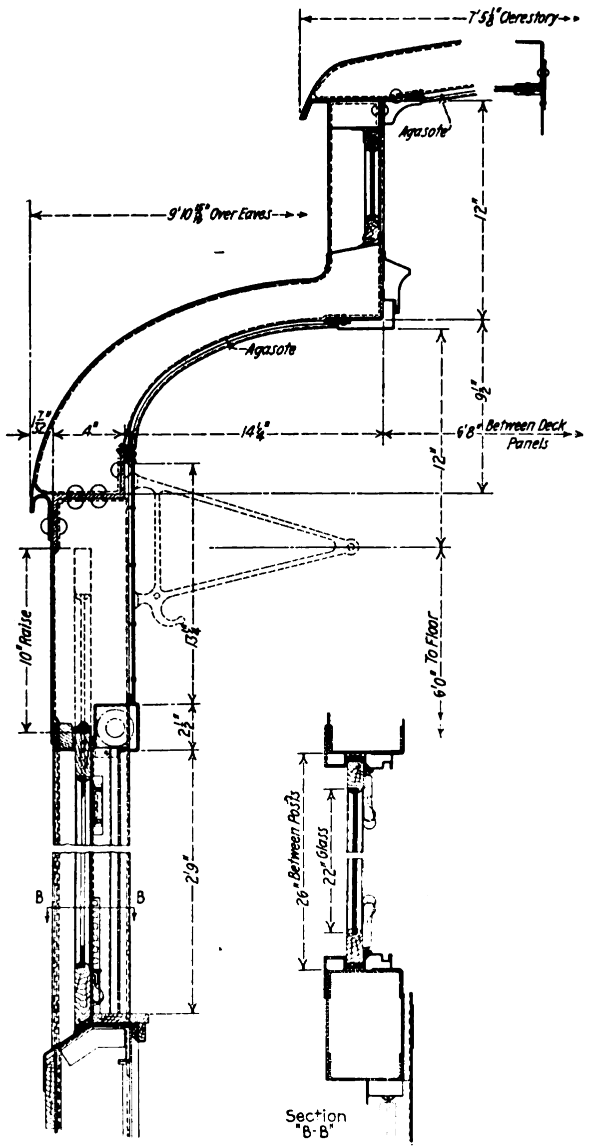
The cars are of steel construction throughout with steel interior finish. The underframe and superstructure details have been so designed as to provide the maximum possible strength consistent with weight limitations. The framing has been designed with a view to providing a car as nearly anti-telescoping as possible. The underframe consists of center sills of the box girder type made up of two 10-in., 23.6-lb. ship channels with 5/16-in. top and bottom cover plates. The center sills extend in one length between the buffer end sills. The side sills are 6-in. by 4-in. by ½-in. angles. The body bolsters are built up of ¼-in. pressed steel pans with bottom cover plates 7/16 in. thick and top cover plates of 5/16-in. steel. The cross bearers are pressed steel pans of ¼-in. plate and extend from side sill to side sill. Floor pans, pressed from ⅛-in. steel plate, extending from center sills to side sills serve as floor supports and provide additional transverse reinforcement to the frame. The bottom floor plates are supported on 5-in. by 3/16-in. floor stringers riveted to the cross members the full length of the body underframe. In addition to the buffing shocks, the underframe is designed to carry the weight of any electrical apparatus which may later be suspended beneath the car.

Details of body construction

The side posts consist of two 4-in. by ⅛-in. pressed steel channel sections placed flange to flange and the corner posts are built up of a 4-in. by 3-in. by 5/16-in. angle and a 4-in., 8.2-lb. Z-bar. The roof framing consists of pressed steel carlines, ⅛ in. thick. The carlines for the lower deck are continuous from the top of the side posts to the under side of the upper deck carlines to which they are riveted and, in fact, form the side posts for the side walls of the clerestory. The carlines are supported by a 4-in. 8.2-lb. Z-bar plate riveted to the side posts.

The side walls are of steel inside and out, except for an interior lining of ⅜-in. Agasote below the window sills to a point 10 in. above the floor. The exterior side sheets have vertical splice plates running from the bottom of the car side to the letter board between the window

openings and, in connection with the window frames, forming the post covers. The exterior belt rail is 4 in. by ½ in. and the letter board is of ⅛-in. steel 12½ in. high, with inside splices and welded joints. The single window frames with welded joints, in addition to forming the sash guides, also act as belt rail caps, side post covers and letter board stiffeners. There are 21 single sash windows on each side of the car. Wood sashes of ⅞-in. Mexican mahogany are fitted in such a manner as to provide unobstructed vision when raised. The window sills are of the same material as the sashes. O. M. Edwards window fixtures are used. The headlining on the lower deck is 3/16-in. Agasote and ¼-in. Agasote

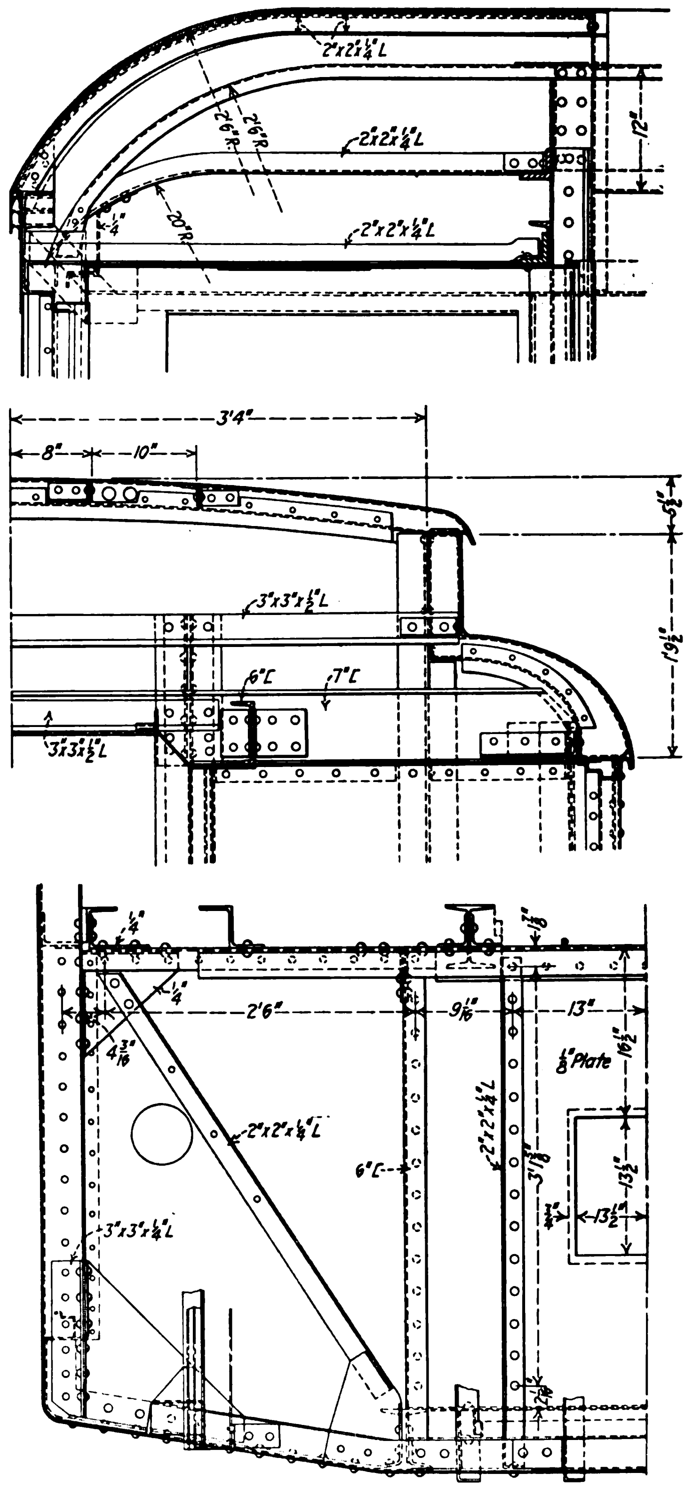


Sectional view of the side walls and roof

is used on the upper deck, all joints being covered with steel battens. The outside roof sheets are No. 14 gage on the upper deck and No. 16 gage on the lower. Swinging window sashes in the upper deck provide ventilation.

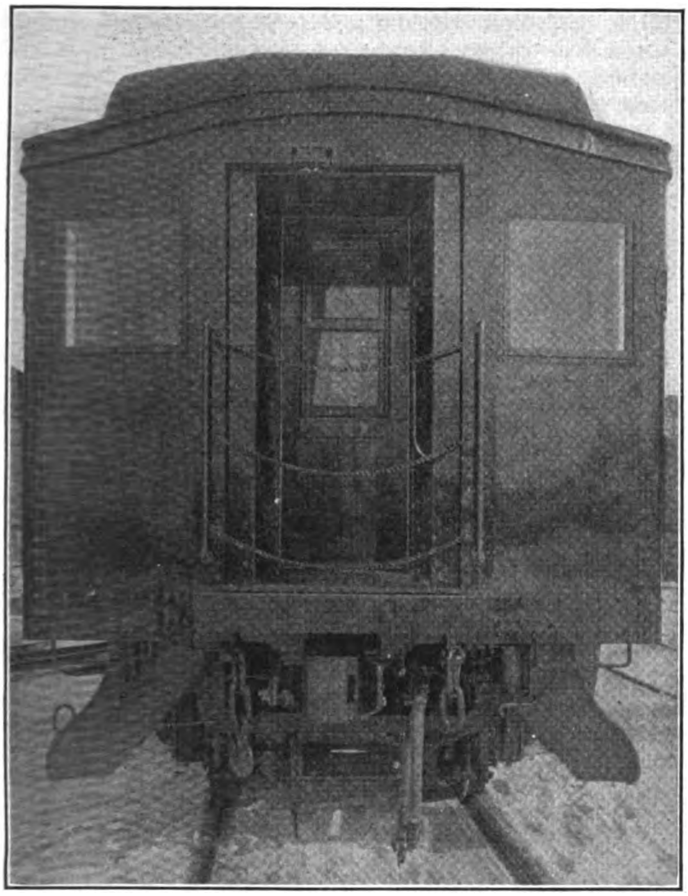
The platforms are of built-up steel construction, with cast steel buffer beams, pressed steel buffer wings and ¼-in. platform plate. The floor plate is riveted to the buffer beam, platform arms, center and body ends sills. Box type vestibule frames are provided with each end door post and the corresponding vestibule posts made of 6-in., 23.9-lb. H-beams. The floor and steps are covered with Feralun safety treads and the vestibules are arranged so that end and trap doors may be applied later. The steps provide a passageway 2 ft. 11 in. wide. Vestibule end windows with steel sashes are provided. The vestibule space and window location are designed for the possible future installation of electric control and air brake equipment.

The flooring consists of an under floor of steel plate



Longitudinal (at the top) and cross sections of the vestibule roof and plan of the bulkhead

supported on the underframe, over which is placed one course of ¾-in. 3-ply Salamander insulation. There is an air space between this insulation and the No. 24 gage galvanized steel Chanarch flooring which has ⅝-in. de-



End view of the car showing the box type vestibule with end windows

pressions. This flooring is secured to the floor supports in such a manner as to carry the load independent of the lower or deadening floor. Over the Chanarch is laid a ½-in. layer of Flexolith composition flooring. Around the sides and ends of the car the composition flooring is laid with a cove of about one inch radius to prevent water getting in behind the interior finish when the floor is washed. Next to the exterior side, end and roof sheets is placed a layer of 3-ply Salamander hair felt insulation. Back of the inside finish, below the window stools, one course of ½-in. Salamander is applied. This insulation is covered with cloth on each side and stitched. Insulation is used between the backs of all interior finish sheets and the faces of the framing members in order to break direct metallic connection through the side walls of the cars.

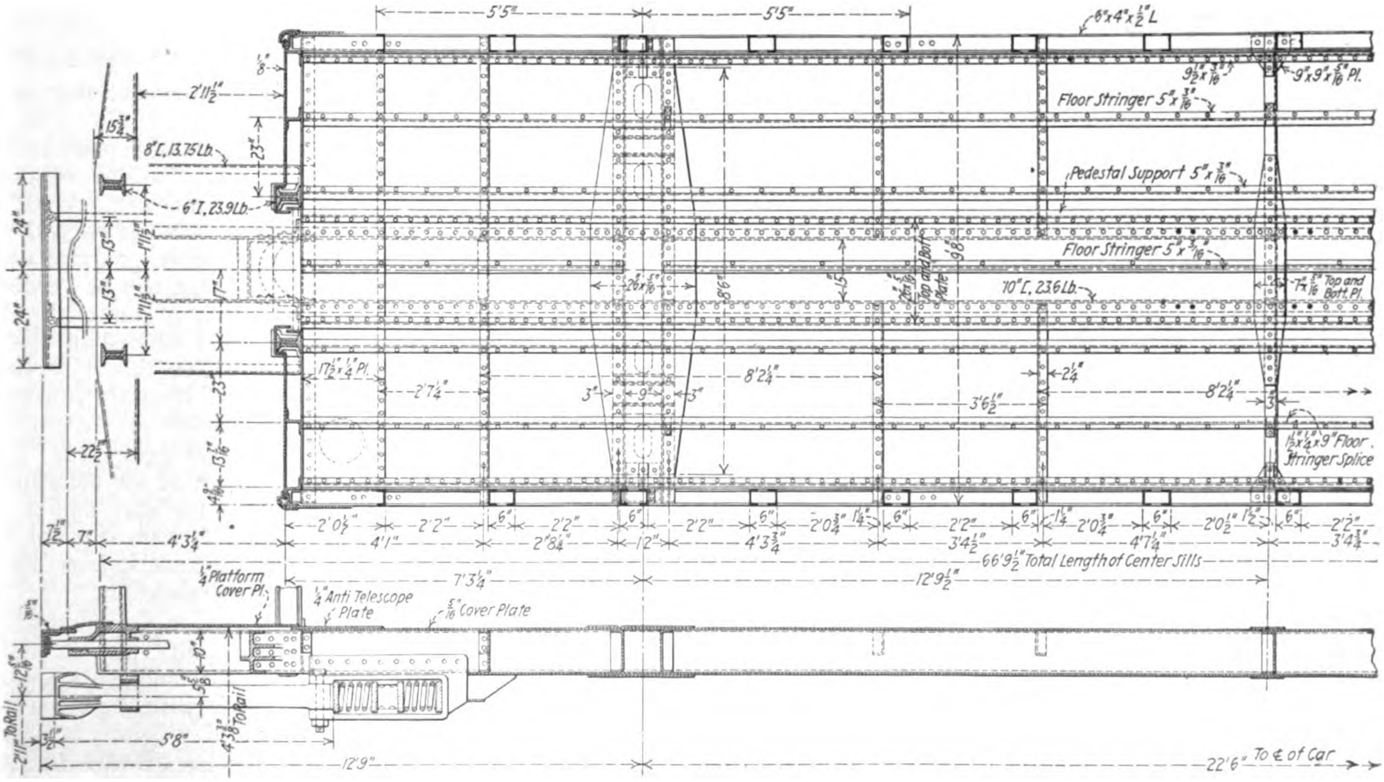
Interior lighting and fixtures

The interior lighting is provided by nine center fixtures fitted with Corona bowls and 50-watt, type "C" lamps. Four flush platform fixtures, one over each step, and one toilet fixture are provided with 25-watt type "C" lamps. The generating equipment consists of a Gould ball-bearing, 30/40-volt generator with body suspension, generator regulator and lamp regulator. A two-compartment switch and regulator panel locker is provided having automatic door-controlled panel lights. The storage battery equipment consists of 16 cells of lead plate battery having a capacity of 200 ampere-hours and housed in a steel battery box.

The latest type of Gold vapor heating system is used in the cars, designed to maintain a comfortable interior temperature. The heating equipment is installed in such a manner that it can be removed at any time without marring the interior and replaced by electric heaters.

The seats are of the Walkover type, manufactured by Hale & Kilburn, with twill rattan fabric cushions and backs and Mexican mahogany arm rests. Continuous steel basket racks are provided. A toilet compartment is built into one end of the car and is furnished with a dry porcelain hopper. Recessed into the toilet room is a water cooler accessible from the car body only.

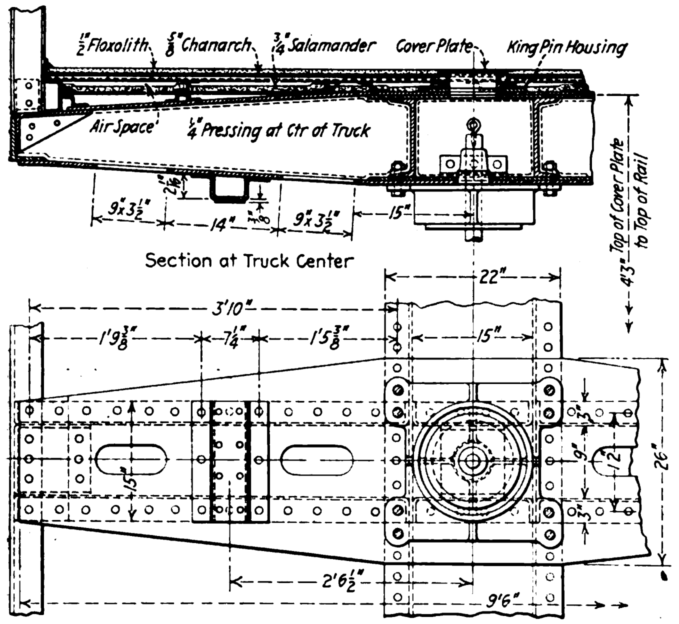
The metal interior finish is surfaced and two coats of light mahogany inside enamel applied. The headlinings



Underframe construction of the D. L. & W. suburban cars

are light in color and protected by three coats of finishing varnish. Gold leaf lettering is used both on the interior and the exterior of the car.

The cars are equipped with the Westinghouse UC air brake equipment arranged for clasp brakes and slack adjuster, to provide a braking power of 90 per cent of the light car weight with a brake cylinder pressure of 60 lb. All brake rigging is designed with ample strength for 105-lb. cylinder pressure. Miner friction draft gear and buffer attachments are used. The couplers are Gould long shank passenger type.



Construction of the body bolster

The trucks are of the four-wheel type with the Commonwealth Steel Company's one-piece cast steel truck frames, cast steel truck bolsters, 5-in. by 9-in. journals and 36-in. rolled steel wheels.

The light weight of these cars is approximately 106,000 lb. and, with a seating capacity of 82 persons, the weight per seated passenger is slightly less than 1,300 lb. The height is somewhat less than existing equipment and the roof structure is designed for the future application of a pantograph and headlights.

The 10 combination passenger and baggage cars mentioned in the first paragraph are of substantially the same design and equipment, having a baggage compartment with an inside length of 17 ft. 3 in. The passenger compartment has a seating capacity of 58 persons. The light weight of these cars is 106,700 lb. and the weight of the two trucks complete is 32,200 lb. Some of the more important dimensions of the coaches are given in the table.

Principle dimensions of D. L. & W. suburban coaches

Length over buffers	70 ft. 6 in.
Length over end sills	59 ft. 6½ in.
Length center to center of trucks	45 ft. 0 in.
Width over side sills	9 ft. 8 in.
Width at eaves	9 ft. 11 in.
Width over clerestory	7 ft. 5⅛ in.
Height from top of rail to top of roof	13 ft. 0 in.
Height from top of rail to bottoms of side sills	3 ft. 6 in.
Height from top of rail to center of drawbars	2 ft. 11 in.
Height from top of floor to ceiling in center of car	8 ft. 3 in.
Seating capacity—coaches	82 persons
Seating capacity—comb. baggage and passenger	58 persons

The maintenance of steel cars*

By J. A. Roberts

Chief A. R. A. clerk, Chesapeake & Ohio

THE subject of steel car maintenance is a vital one to coal-carrying roads that have to rely on foreign roads to maintain their steel cars while off of home lines.

The wooden coal car had been developed to carry 80,000 lb., when the first all-steel coal cars came into use, which were of 100,000 lb. capacity. Many railroads hesitated to adopt the steel car. Car repairers were not trained to remove riveted parts, straighten and reapply. Pneumatic and electric tools were practically unknown, making repairs slow and difficult and many were afraid that the car would rust out in three or four years. But, after a number of them were put in use and it was shown that the earnings from increased capacity of the car alone would pay for the car within three years, the situation then changed and the steel car was adopted by various railroads, until today, it is used on practically every railroad in the country.

The design of steel cars has been improved on to such an extent that some railroads now have such equipment with a carrying capacity up to 120 tons per car. Therefore, you can realize that with cars of this class, necessitating an enormous outlay of money, the equipment should receive every possible consideration in keeping it in first class condition, using facilities for mantenance that will hold the cost down to a minimum.

A record should be kept of the nature of repairs to be made to steel cars, indicating on forms similar to that illustrated, parts that will have to be renewed. With a record of this kind, you can determine what parts will be required for renewal in your heavy repair program and will enable you to order only material that will be needed, thereby keeping down a surplus stock of material. It has been found that steel car material carried in stock for any great length of time deteriorates almost as fast as the material in cars, therefore, it is important to carry in stock as little of this material as possible.

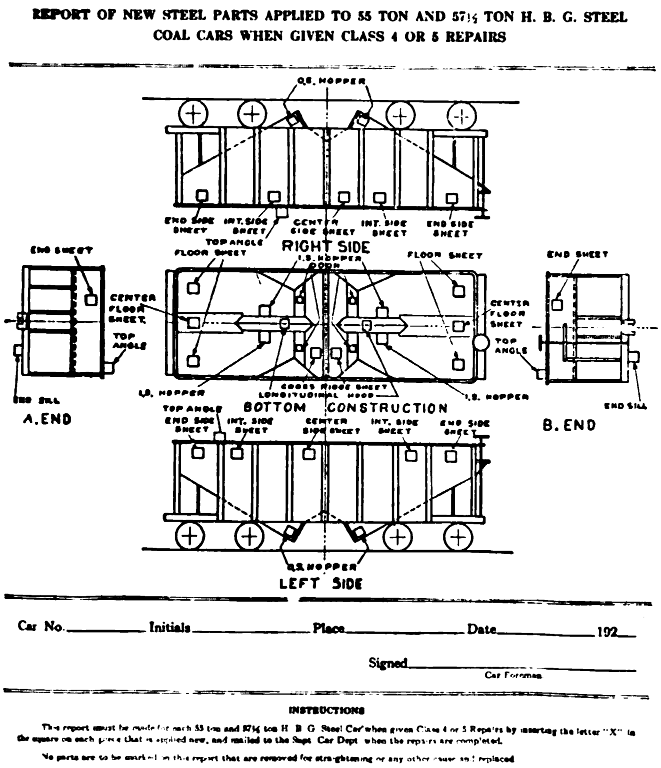
Concerning the deterioration of steel equipment: It has been found that at least 90 per cent of the deterioration of steel cars is on the inside of the cars and it is caused by sulphurous acid in coal. The cars can not be protected on the inside with paint, because it is scraped off in a very short time by mechanical abrasion.

This deterioration could be cut down to a minimum if the cars were used for transportation only, but in many cases, they are used for storage of coal and the sulphur that is found in coal forms a weak acid with the moisture or water in the coal, which, if allowed to stand in a car any length of time, causes the insides of cars to deteriorate quickly. On the other hand, if used for trans-

*Abstract of a paper presented at the annual convention of the Chief Interchange Car Inspectors' and Car Foremen's Association at Chicago, September 23, 24 and 25, 1924.

portation only, the coal is in motion, which will not allow the acids to accumulate in any one place, and the motion of coal will keep the metal smooth and free from corrosion. There is, however, some deterioration from corrosion on the outside of cars and it is good practice to scrape off all rust with steel scrapers and wire brushes and paint the cars as fast as they begin to show any amount of rust.

It has been claimed by manufacturers that copper-bearing steel subjected to sulphurous acid will not deteriorate as fast as ordinary steel and quite a few roads are purchasing cars built with copper-bearing steel. It is claimed



Sample form for recording repairs made to steel cars

that steel with .15 to .28 per cent copper will resist corrosion longer than ordinary steel and the American Railway Association, in its recommendations of specifications for steel shapes in Circular DV-282 Exhibit "D," recommends that when copper-bearing steel is specified, the copper content shall not be less than .20 per cent.

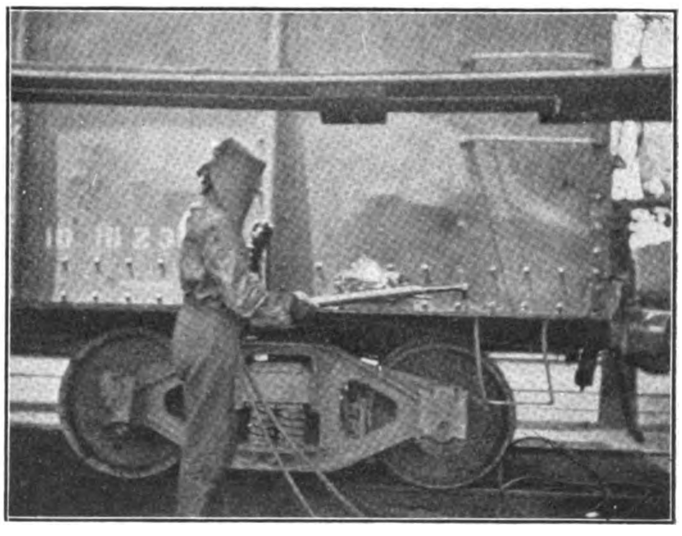
Method of repairing cars

In my opinion, the progressive plan of repairing steel cars should be installed in all principal shops. Roads having sufficient equipment should select cars of the same design and condition for repairs in sufficient numbers to fill out a repair track for as long a period as possible. A car requiring other or more extensive repairs will hold back the cars behind it. Cars of other designs will require more or less time for the different operations and interfere generally with the program. Place the cars on a track after the rivets have been burnt out by an electric burning outfit and specially assigned gangs detailed to do a certain class of work to these cars, until they are ready for the shipping tracks. The different operations will be as follows:

First—The cars are placed on a track equipped with the following electric rivet-burning apparatus—a motor generator set, supplying a direct current not exceeding 80 volts with the necessary capacity in amperes. This is governed by the number of cutting units used. Each cutting unit takes from 400 to 500 amperes. The generator should be located as close to the cutting tracks as possible, to prevent excessive voltage drop. The lead wires from the generator to the cutting stations should have ample cross-sectional area to prevent excessive power loss. In order to prevent the necessity for ladders or movable scaffold, a permanent scaffold should be located the entire length of each side of the burning track about six feet high and having a platform width of about two feet. The framework of this scaffold can be used in place of a pole line for carrying the supply wires, which should have plug-in stations approximately 35 ft. apart. The burning tool consists of a graphite stick held by a suitable handle with sufficient area to prevent excessive heat as a result of the heavy current carried. The rivets in the defective parts are burned out by this process and backed out with nine-inch hammers provided with suitable pneumatic tools. One operator can burn out from 1,000 to 1,500 rivets in eight hours and an operator with a pneumatic tool can back out from 1,500 to 1,800 in eight hours. Comparing this with the rivet-cutting gun, there can be a saving made of approximately 50 per cent in labor and this method does not damage the sheets to any extent, compared with what occurs in using the rivet-cutting guns. If a sheet is thin, the rivet-cutting gun will tear it. This does not occur while using the electric rivet-burning tool. It also practically eliminates accidents due to flying rivets and is a protection to operators.

Second—This operation consists of stripping the car of defective sheets and parts, which should be done before the car is placed on the repair track where it is to be reassembled. This is done in order to keep the working track free from scrap material, which, if allowed to accumulate, is a hazard and will hamper the workmen.

Third—The car is then set on the repair track, trucks



Cutting rivets with electric burning outfit

removed and car body set on tripods, or benches. After the entire line of cars have been jacked up and trucks removed, they are repaired by the following gangs:

Gang No. 1—This can consist of two car repairers and two helpers equipped with special tools. It repairs all trucks and removes and repairs all couplers.

Gang No. 2—One car repairer and one helper. This gang may start in at the same time as Gang No. 1 to straighten all bent parts on the car, set up all flanges and prepare the car for the fitting-up gang.

Gang No. 3—Four car repairers, two apprentices and two helpers. Operation 1—Fitting up all inside and outside hopper sheets, cross ridge sheets and longitudinal hoods. Operation 2—Fitting up all floor sheets, tie beams, side and end sheets. Opera-

tion 3—Fitting up all splices, end sills, body bolsters and all angles.

Gang No. 4—One car repairer and one helper whose duties will be to ream all holes.

Gang No. 5—Two car repairers, one apprentice and one helper. Operation 1—Riveting up all inside and outside hopper sheets, cross ridge sheets and longitudinal hoods. Operation 2—Riveting up all splices, end sills, body bolsters and draft lugs. Operation 3—Riveting up all floor sheets, side and end sheets and all angles.

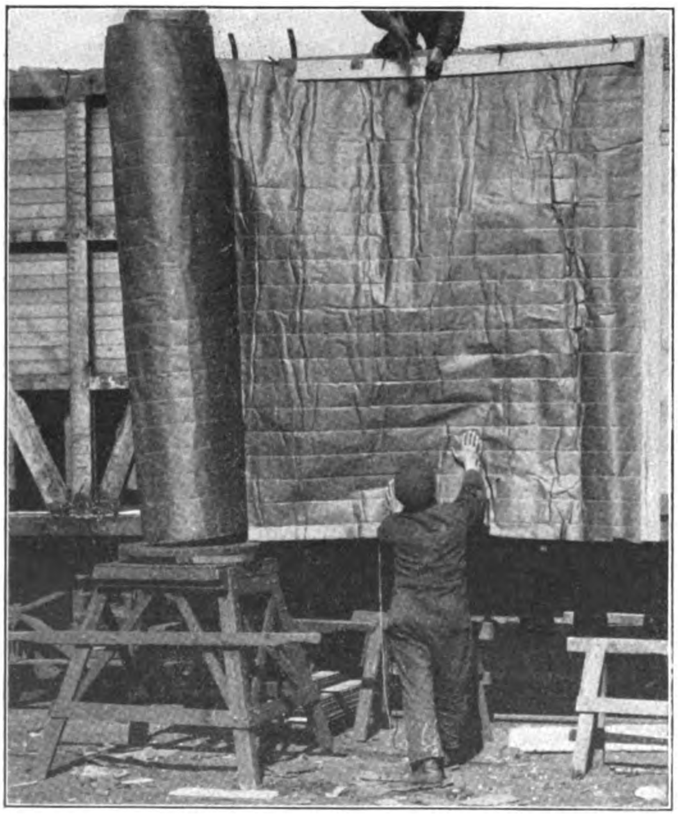
The cars are then painted and stencilled, air brakes tested and thoroughly inspected before being returned to service. Of course, the above gangs can consist of more men, as conditions may require.

Conclusion

If the car is properly repaired, it will give good service for at least 10 years before it will have to be shopped for heavy repairs, unless the car is in an accident, as the floor sheets and outside hopper sheets will last about 10 years before needing renewal, while the side and end sheets will last approximately 15 years before needing new sheets.

Applying insulation to refrigerator cars

THE carrier shown in the illustration has proved to be a time and labor saver in the job of applying insulating felt to the sides of refrigerator cars. It consists essentially of a table, provided with two handles, and a long vertical spindle, which revolves on male and female center plate castings. The table is built high enough so that the edge of the roll of felt comes even with the lower edge of the side sill. The spindle is made from a jack handle, fitted into the base on which the end of the roll of felt rests. The male center casting is bolted to the base of the spindle and it turns on the female center casting, which is bolted to the top of the table. The jack handle extends down through the king pin hole of the center casting about 18 in., so that the lower end will turn in a socket underneath the table top.



The carrier holds the roll of insulation felt in a vertical position so that two men can easily apply it

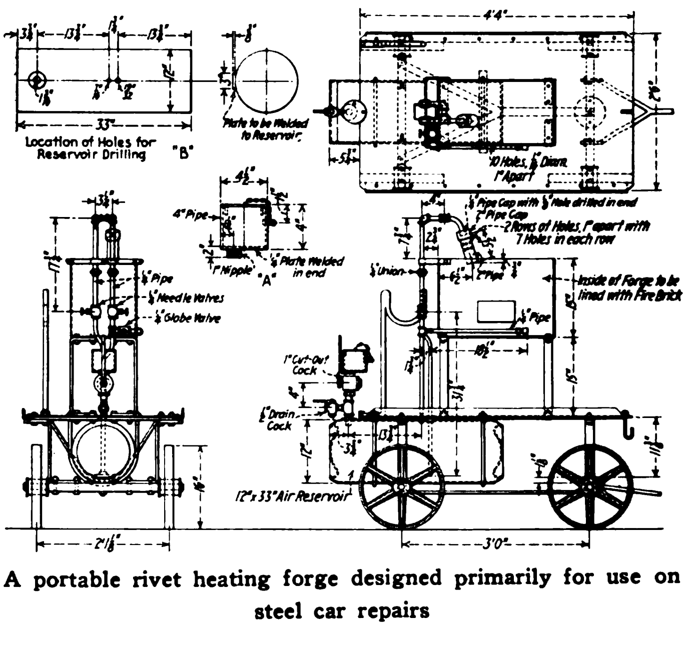
In order to place the felt on the carrier, the roll is laid on the ground, the spindle is removed from the table and thrust into the center of the roll. The table is tipped forward and the pivot end of the spindle is placed in the hole in the table top. The top end of the roll is then raised and as it approaches the vertical, the spindle slides into place in the lower socket.

The carrier is placed so that the felt will unroll on the side next to the car. The end of the felt is secured at the door post and the carrier is then moved along the side of the car and around the end to the other side as the mailing strips are applied.

A portable forge for heating rivets

THE portable rivet heating forge, shown in the drawing, was constructed in the shops of an eastern railroad. It has proved to be useful to the rivet gang engaged in steel car repair work when moving from station to station. The forge is supported on two brackets 15 in. above the bed of the wagon. This arrangement provides space for small tools and rivets underneath the forge, as well as additional carrying space in front of the forge for large tools. A hook over which the air hose can be looped while the forge is being moved is secured to the wagon bed between the forge and air inlet cock, as shown in the drawing.

The apparatus consists essentially of a flat topped



A portable rivet heating forge designed primarily for use on steel car repairs

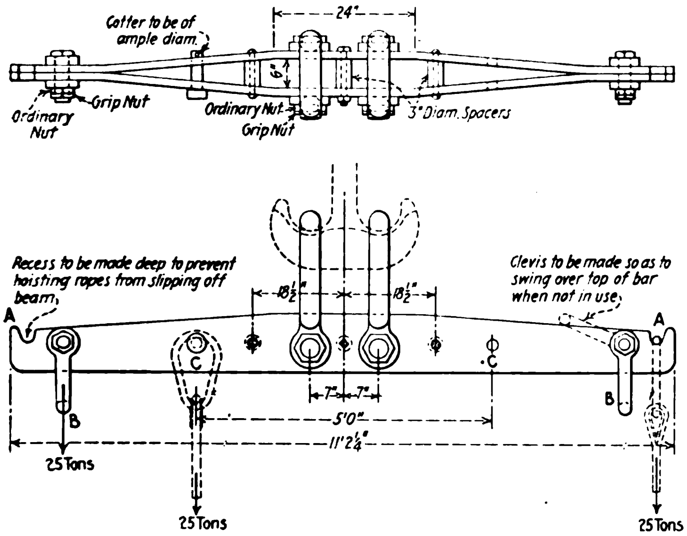
wagon, a 12-in. by 33-in. air reservoir *B*, an oil burner, and a furnace which is constructed of ¼-in. rolled steel and lined with fire brick. Referring to the side view of the forge in the drawing, the air reservoir is filled with fuel oil by means of a cup or funnel, a detailed drawing of which is shown at *A*, the lid is secured by a chain to prevent its being lost. Directly underneath the cup is a 1-in. cut-out cock and a 1-in. by 1-in. by ½-in. tee. This cock must be kept closed at all times, except when

refueling. The air hose is attached at the cock on the horizontal branch of the tee. Compressed air from the shop line is admitted to the oil reservoir as desired by opening or closing this cock. The pressure of the air exerted on top of the oil in the reservoir forces the oil up through a ¼-in. pipe, leading from a point near the bottom of the reservoir, to the burner. Air for atomizing the oil is taken from the top of the reservoir by a second ¼-in. pipe which is joined to the fuel oil pipe by a tee which is located about 15 in. above the bed of the wagon.

With the exception of the wheels, which are of gray iron, pipe fittings and burner, all of the various parts used in the construction of the apparatus are of forged or rolled steel. Two 2-in. by 2-in. by ¼-in. rolled steel angles from the sides of the wagon bed. The oil reservoir hangers are made of ½-in. round bar, bent U-shaped and threaded at the ends. The wagon tongue is forged from ½-in. by 1½-in. flat bar and is 37½ in. long. A hook is provided for holding the wagon tongue up out of the way when the forge is not being moved.

Hoisting beam for wreck cranes

It is essential that a variety of hoisting equipment necessary to meet the numerous conditions encountered in clearing up wrecks be provided on the wreck train. The hoisting beam, shown in the drawing, is included in the wreck crane equipment on an eastern railroad. It is not only suitable for wrecking service, but may be also included as a part of the crane equipment in the locomotive erecting shop. The beams are of wrought



Hoisting beam suitable for either wreck crane or locomotive erecting shop service

steel designed to carry a load of 50 tons with a factor of safety of five.

Any of the link or cable combinations, such as *AA, BB* or *CC,* may be used as desired. However, no combination, such as *AC* or *BC* on opposite sides of the fulcrum may be used on account of unbalancing the load on the beam. The two sections which compose the beam are held apart at the center by means of hollow spacers held in position by coupler yoke rivets. Care should be taken to make the recesses at the ends of the beam deep enough to prevent any possibility of the hoisting ropes slipping off the ends.

Convenient ladders for the coach cleaners

A LADDER is undoubtedly, the most important part of a coach cleaner's equipment. Possibly, the best type of ladder for this work is one having a step wide enough to support a part of the heel and ball of the foot. A step similar to the ones illustrated, provides a

This type of ladder provides a substantial support to work on —Note that the box is open at the top, making it convenient of access

more substantial footing for the cleaner and he feels safe while using both hands in his work. Furthermore a ladder with wide steps is not so tiresome to the feet as a rung ladder.

The coach cleaner's ladders, shown in the illustration,

Front and rear views of a coach cleaner's ladder, showing the side opening to the box and the pad on the back to prevent scratching

are examples of the kind used on the Delaware, Lackawanna & Western at its Hoboken, N. J., terminal and in the coach yard at East Buffalo, N. Y. They are not only built with wide steps, but boxes are also provided for holding cleaning materials. After the cleaner has once started to work, it is unnecessary for him to descend the ladder until the job is completed or the ladder has to be moved further along the car. Pads are placed on the back to prevent scratching the side of the car.

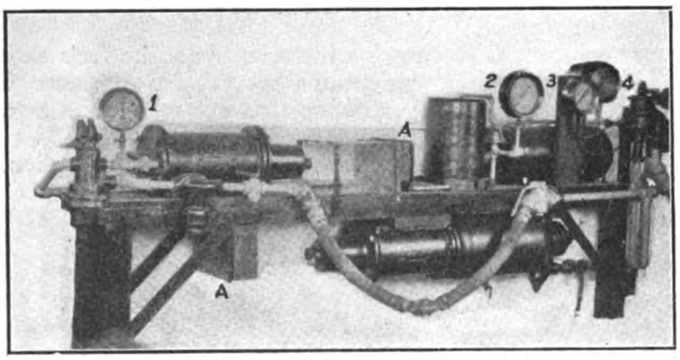
Air brake equipment at Rice Institute

By J. H. Pound

Assistant professor, mechanical engineering, Rice Institute, Houston, Tex.

During the past winter the mechanical engineering department at Rice Institute, Houston, Tex., constructed an arrangement of standard air brake equipment for the purpose of demonstrating the principles and routine operation to engineering students. On account of crowded laboratory conditions it was necessary to build the apparatus so that it would occupy a very small space.

This apparatus consists of a driver brake cylinder and detached auxiliary reservoir with a plain triple valve and double spring retaining valve, a standard combined freight car cylinder and auxiliary reservoir with a quick-action triple valve, and an engineman's brake valve complete with feed valve, equalizing reservoir, and duplex gage. The brake pipe contains the usual cut-out cocks, centrifugal dirt collector and hose connections. This equipment



Air brake apparatus constructed for purposes of demonstration to technical students

is mounted on a heavy wooden bench made of 4-in. by 12-in. timber, as shown in the illustration. Compressed air is supplied by a single stage, steam-driven locomotive type air compressor provided with a governor and main reservoir which had previously been installed in the laboratory.

When air is admitted into the brake cylinders, the thrust of the pistons is taken by the 8-in. steel angles *A* which are faced with hard wood and bolted securely to the bench. The pressure changes in the main reservoir and train pipe are recorded from the duplex gage. Gages *1* and *4* show the pressures in the driver brake cylinder and detached auxiliary reservoir during the various operations, which are performed both with and without the pressure retaining valve cut in. Gage *2* is connected to the auxiliary reservoir of the freight car cylinder and serves to show the difference in equalizing pressure existing with plain and with quick action triple valves after an emergency application. An emergency application is made by disengaging the hose coupling. The travel of the driver brake piston sleeve is protected with a wire guard.

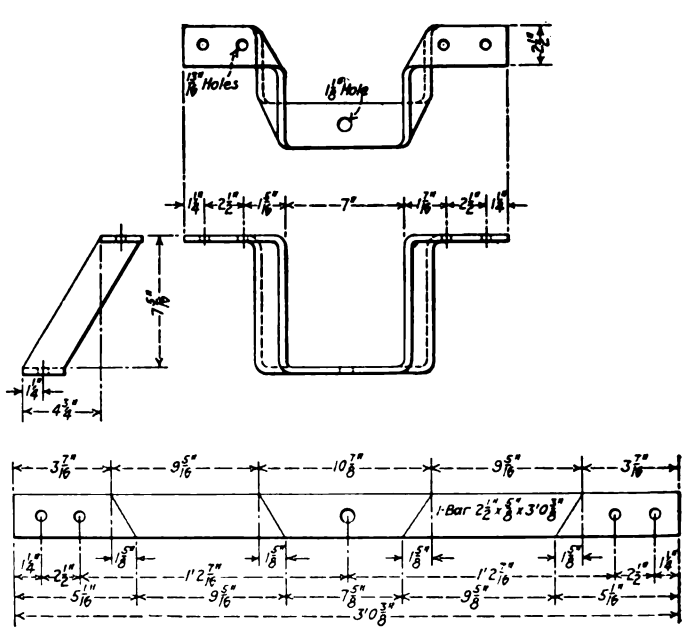
The instructor in demonstrating goes through certain operations which are briefly described on a mimeographed form supplied to each student. The readings of the gages during these operations are noted and recorded in blank spaces on the form opposite the description of the changes made in the brake valve positions. The student is required to write a description of the action of all the mechanisms involved in the operation he has witnessed. By means of this demonstration and a written report, the students get a much better idea of the operation of an automatic air brake system than they got by the old method of instruction.

This apparatus occupies a floor space approximately 17 in. by 9 ft. 8 in. It could probably be assembled at any school, from new parts, at a cost of between $200 and $225. Such equipment in a laboratory furnishes a means of demonstration of the possibilities of compressed air as a control medium which is useful even in engineering schools where special courses in railway mechanical engineering are not offered.

Forming brake shaft steps from cold stock

By Harry R. Taube

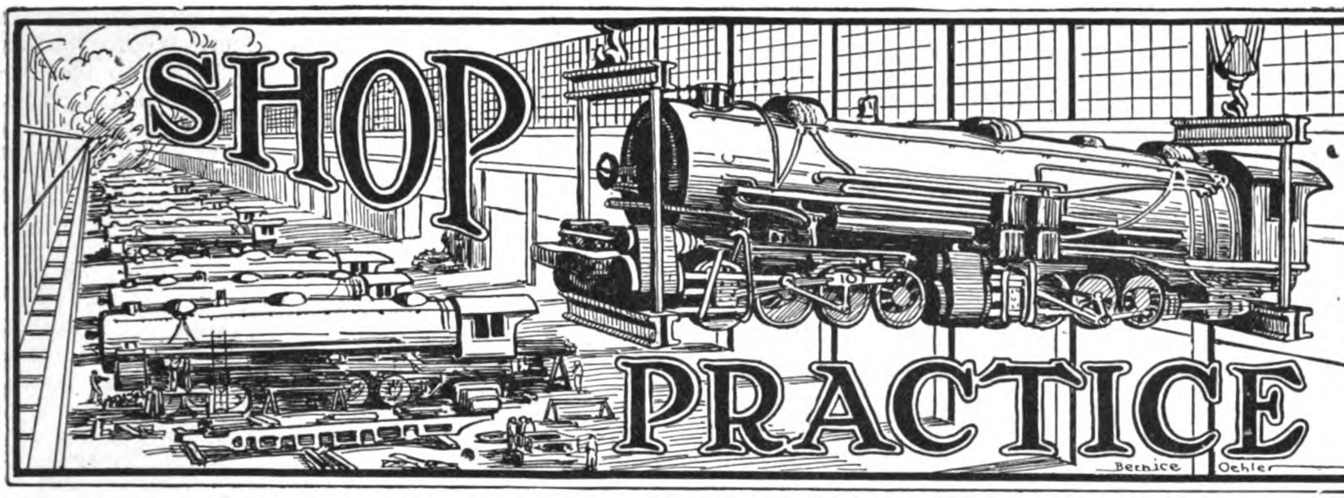
The accompanying illustration shows a method of cold forming brake shaft steps which has been developed in the Palatino shops of the American Steel Company at Havana, Cuba. The ordinary run of steel stock is used. In following the dimensions on the lay-out, it will be noted that the angles are laid obliquely,



Lay-out of stock for brake shaft steps preparatory to cold forming

as the purpose of this is to permit the offset to be formed by cold bending across the flat of the material rather than by hot bending edgewise.

This job can be done on a bulldozer in one set up. The ram forms the bottom of the bracket while two expanding toggles form the lugs. As the cost of fuel is high in Cuba, a considerable saving is effected by this method.



Case carburizing and hardening valve motion parts

The steel, carburizing agent, temperature and time element are essential factors

By J. E. Burns, Jr.
Member, research staff, E. F. Houghton & Co.

THE object of case carburizing and hardening valve motion parts is to secure a hard wearing surface on low carbon steel or iron, and the retention of toughness in the core of the metal used. The process can be roughly divided into two distinct operations, namely: the carburization or cementation of the surface by which the carbon content is sufficiently raised to insure the abrasive value and hardness desired, and to provide for a suitable heat treatment which will develop the desired physical characteristic of both the case and the core. The complete operation should not only result in obtaining a very hard case, but also non-brittleness in the core, thus producing link motion parts, which shall possess a minimum fragility and a maximum abrasive (hardness) value.

Essential factors in carburizing operations

The following four factors must be appreciated in detail if satisfactory valve motion parts are to be produced. They are the steel, the carburizing agent, the temperature and the time element.

The character of the steel or iron used for motion work is governed, in no small measure, by the fact that one of the essential factors is to eliminate brittleness in the core. It is an accepted engineering fact that the higher the carbon the greater the brittleness, particularly when the carbon content is .25 per cent or over. Furthermore, as practically all commercial carburizing practice is followed by one or more heat treatments for toughening and hardening, it follows that the use of steel with a high carbon content will also increase brittleness in quenching. For these reasons it is apparent that the carbon content in motion work should be low. On the other hand if the carbon content is too low, extreme difficulty is encountered in the machining operations. The low carbon results in a very mushy and rough surface, necessitating a greater depth of case than otherwise would be necessary to allow for the increased grinding tolerances necessary in order to secure a smooth surface after the hardening operation. For the above reasons the general American practice is to adopt a carbon content of approximately .10 to .20 per cent, .15 per cent being the desired amount.

From .30 to .35 per cent manganese is considered most desirable, as it is a well established fact that a higher manganese content renders the steel, as a whole, more sensitive to rapid cooling, while increasing the hardness of the case causes a corresponding and detrimental stiffening of the core.

The impurities, silicon, sulphur and phosphorus, should be just as low as is possible to secure in commercial steels as slag, blow holes, and segregations should be entirely absent.

Carburizing agent

Carburizing or cementation by its very nature demands the presence of free carbon in some form or another; either in a solid body or by the presence of a gas which will liberate free carbon by the process of decomposition. The mere presence of free carbon by contact with iron or steel will not satisfy the conditions for successful carburizing.

Science tells us that compounds evolving carbon monoxide or hydro-carbon gases alone have definite outstanding advantages, but for commercial endeavor they have many objectionable features. Combinations of compounds insuring the evolving of both these gases produce the most satisfactory medium for general commercial work, and such compounds are considered standards in many large industries.

Wood charcoal, which is sometimes used in the presence of a catalytic agent, has a definite tendency to develop

cemented zones of low and irregular carbon content. It also causes internal combustion in the carburizing pot, making it impossible to control the carburizing temperature. This is an objectionable condition as temperature, in the largest measure, controls the carbon content.

Animal charcoal such as charred leather, bone, horn, etc., are objectionable in themselves as carburizing agents. Grayson has produced incontrovertible evidence that sulphur will diffuse into iron or steel at temperatures used for carburizing with such substances as above mentioned, and that this sulphur combines with manganese and iron to form manganese and iron sulphides resulting in soft spots.

Referring to Fig. 1, it will be noticed that there appear on the edges large quantities of sulphide of manganese and also sulphide of iron with ferrite crystals intermingled. This sulphur diffusion is serious in valve motion work, because it produces soft spots, and when present in smaller quantities, will have a tendency to cause chipping of the case, thus producing two objectionable effects which should be avoided if satisfactory service is to be expected. Hence, any compounds manufactured by reliable commercial firms are much more to be desired than questionable home-made products.

The compound yielding both hydro-carbon and carbon monoxide gases in fixed percentages will insure satisfactory results, all other factors being equal. It is the experience of manufacturers that it is impossible to manufacture a carburizing material which will give uniform results, unless the energizers are attached to the grains of the carbon, either by impregnating or binding. The most uniform results are obtained from a compound made of grains of charcoal leather and wood charcoal suitably impregnated with energizers and then baked. Such a compound, when first used, will char the binder which will hold the energizers to the grain, thereby producing continuous uniform results, during the life of the compound. Such a compound evolves both carbon monoxide and hydro-carbon gases and is preferable to all others for general railroad purposes.

Temperature and time factors

Carburizing gases, by diffusing into steel, precipitate free carbon. This carbon, under suitable condition, will be dissolved at once by the iron, forming a true steel. The solubility of this carbon depends upon the temperature. If a piece of steel desirable for motion work, containing from .10 to .20 per cent carbon, is heated, none of the Cementite, which is mechanically mixed with Ferrite (iron) to make the mixture Pearlite, is effected until the lower critical temperature (1,350 deg. F.) is reached. At this temperature, the iron of the Pearlite changes and dissolves the Cementite, the two forming a solid solution called Austenite. As the temperature is progressively raised, more of the excess iron is dissolved by the Austenite until the so-called Ac 3 range is reached. At this point the entire mass of steel consists of Austenite.

It is thus possible for carburization to take place at temperatures between the Ac 1 and the Ac 3 ranges (the lower and upper critical points). The carburizing action, however, must necessarily be not only slow, but also irregular and non-uniform. The minimum temperature used should not be lower than the upper critical range, approximately 1,625 deg. F. The recommended furnace temperature is 1,700 deg. F.

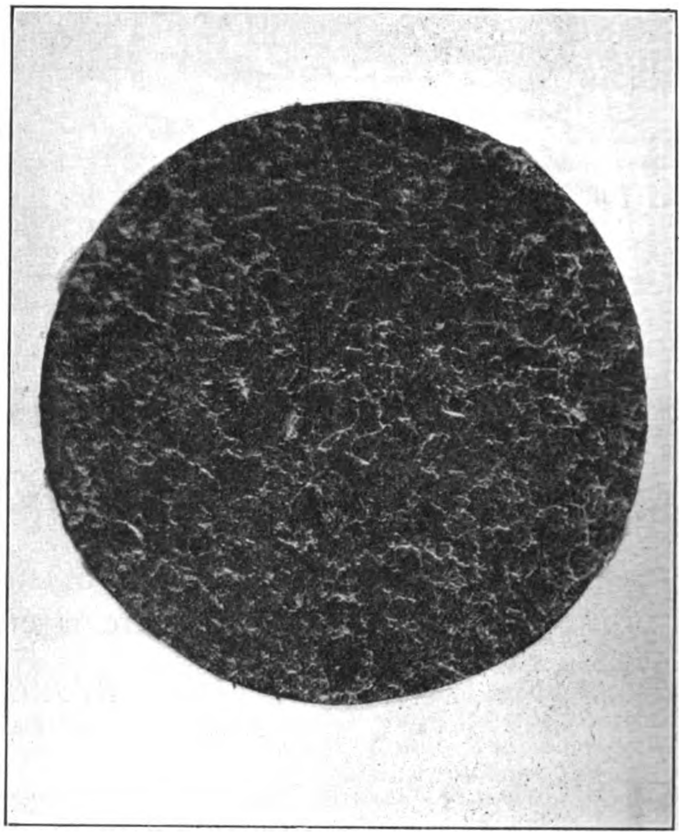


Fig. 1—Hypereutectoid case showing improperly deoxidized or abnormal steel—The small, curly, but numerous ridges of excess cementite indicate that the steel is of poor quality

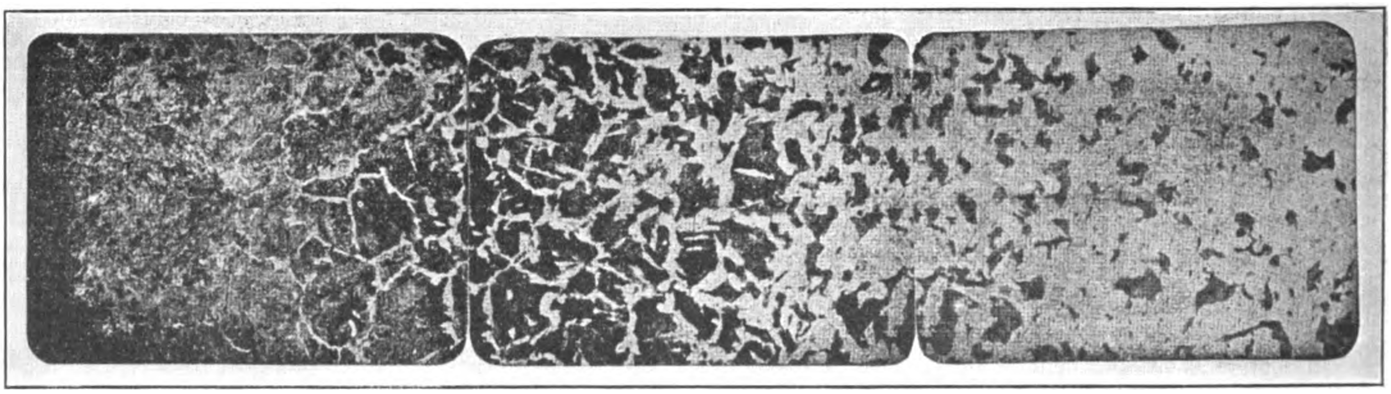

Fig. 2—At the left is shown a carbonized case of 90-point carbon—Remaining sections show graduation of the carbon from the case into the core

All commercial carburizing processes must provide a depth of case which will satisfy the requirements. Thus

valve motion parts should have sufficient depth to allow for any grinding and the low allowable limit for serviceable use.

Depth of penetration is regulated by the time factor

With a definite depth in view, economic considerations require that the velocity of penetration shall be definitely known in relation to the factors of time, temperature and carburizing agent. It is generally understood that the depth of penetration and carbon content increases with the temperature and time elements. A properly carburized valve motion part should show a gradual decrease in carbon content from about one per cent on the surface to that of the initial content in the core of from .10 to .20 per cent. This structure is shown in Fig. 2.

The case should develop traces of hyper-eutectoid structure (.95 to 1.00 per cent carbon). This will insure the proper development of the desired hardness without danger of enfoliation (chipping of the case). Fig. 3 shows the development of this granular formation.

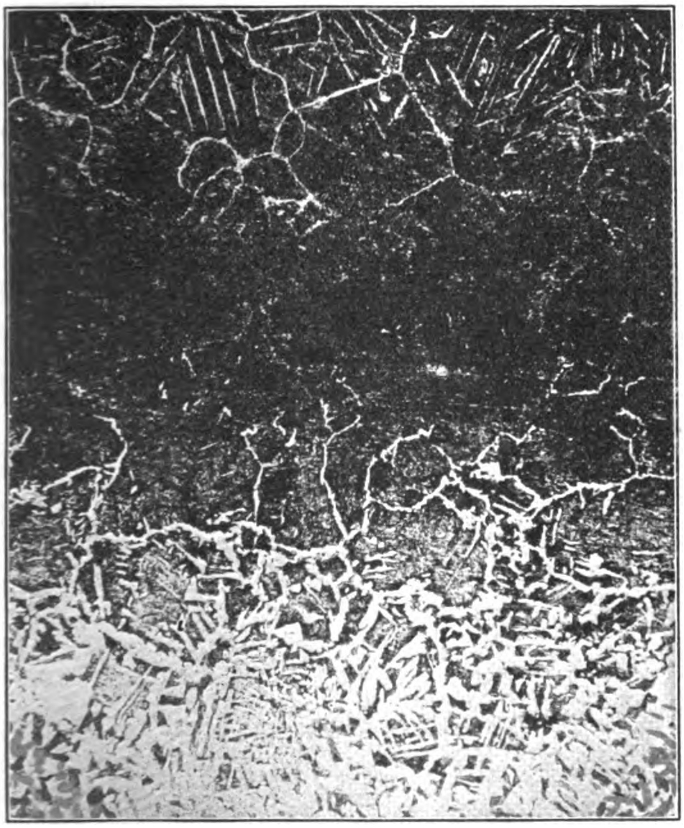

Fig. 3—Hypereutectoid case of normal steel showing, at the bottom, a network of cementite around the grains of lamellar pearlite—The network at the top indicates traces of the hypereutectoid structure—The dark area in the middle is the eutectoid zone

The hyper-eutectoid structure starts to develop at the point of saturation and at temperatures about 1,700 deg. F. The eutectoid zone is the saturated condition and hypo-eutectoid is indicative of non-saturation, which is shown in Fig. 2. Both the hyper-eutectoid and the eutectoid zones will develop maximum hardness. The hypo-eutectoid zone (lower than .90 per cent carbon) cannot insure this condition. Low carburizing temperatures invariably develop the hypo-eutectoid structure and are often the direct cause of soft work. Valve motion work should be carburized at a furnace temperature of 100 deg. above the Ac range (1,700 deg. F.). A desirable compound will insure the development of the eutectoid range with traces of hyper-eutectoid structure.

Chipping of the case

Enfoliation is a condition where flasking, chipping, and often peeling of the case is noted. Microscopic and chemical investigations indicate definitely that this line or plane of weakness characterizes the separation of the hyper-eutectoid zone from that of the hypo-eutectoid. In order to avoid this condition, it is necessary that the temperature factor be controlled, insuring no excess of carbon being developed (hyper-eutectoid) beyond the traces previously mentioned. Hence, it would be unsafe to use temperatures over 1,700 to 1,725 deg. F.

It has also been pointed out in an article dealing with the heat treatment of spring steel which appeared in the February issue of the *Railway Mechanical Engineer,* that temperatures materially above the Ac 3 range cause an increase in the grain growth with decrease in toughness. This is indicated by the following table compiled by Guillet:

Temperature, deg. F.	Impact-test Kilograms-meters
1470	26
1560	28
1650	15
1740	12
1830	7
1920	3
2010	4

It is thus obvious that any heating over a protracted period at temperatures above the upper critical range (Ac 3) greatly lowers the resistance of steel to impact or shock.

Carburizing boxes

The selection or design of a box or container for carburizing should be given the utmost consideration. In the attempt to secure a uniform case much thought and research has been given to the selection of steel, carburizing agent, and the degree and duration of heating. All this, in many instances, has proved unavailing.

It must be remembered that the inside of a box requires considerable time to acquire the furnace temperature, and in a large box such as is used for valve motion parts, the material in the center lags behind the indicated furnace temperature several hours or its temperature equivalent of several hundred degrees. No manipulation of the furnace can change this effect. It can only be remedied by altering the dimensions of the box itself.

Here, then, lies one explanation of many failures of valve motion work. The box should not be larger than is absolutely necessary for motion work and should be narrower in at least one dimension than in the others so that the heat has a chance to penetrate quickly from at least two sides and reach all the contents at about the same time. The box should not be made too deep in proportion to the other dimensions, that that bushings and pins can be packed in the same box. The design of the box should follow the outline of the link in rectangular form, allowing approximately 3 in. on all sides for clearance and packing.

For railroad work, suitable boxes can be made from boiler plate, electrically welded or suitably riveted. Cast iron boxes are not satisfactory as their life is comparatively short. The cover should fit as close as is practical and legs should be provided to insure radiation of the heat from the bottom of the box.

Carefulness in packing is fundamental for good practice and uniformity of results, just as much as carefulness in heating or treatment. The method of packing should be such as will insure as nearly as possible the even heating and uniform carburizing of all parts of motion work in the same box. Heavy pieces such as links do not

require the same amount of care as the smaller pieces.

The first step in the general operation of packing is to cover the bottom of the box with compound to a depth of 1½ to 2 in. The link should then be placed firmly on the bed so that the compound and work are in close contact with each other. The bushings and pins should be placed at such points in the box as will prevent contact with each other or with the sides of the box and should be separated by at least 1½ or 2 in. of compound. An insufficient amount of compound will cause non-uniformity of results; a little too much is more advisable than too little.

The top layer should have at least 2 in. of compound sprinkled over it. When the box is fully packed, the cover is placed on the box and the edges carefully sealed with fire clay. The box is now ready for the heating operation.

Furnace design

There are a number of furnaces satisfactory for carburizing work but it is not the intention to recommend any particular make but to confine this discussion to the general design. Three main points are to be considered:

1—The furnace should have a capacity of attaining the maximum temperature necessary.

2—It must obtain a thoroughly uniform heat application at any of the intervening temperatures and be capable of maintaining that temperature with little or no variation.

3—The atmosphere in the furnace should be non-oxidizing so as to protect the box and work where reheating operations are performed.

Under-fired furnaces, developing indirect combustion, are most generally used and have proved very dependable.

Thermal temperature

Link motion work that has undergone the carburizing process previously described, requires a subsequent heat treatment. As one of the essential aims of carburizing valve motion work is to produce a hard abrasive surface, and as carburized links and parts, when slowly cooled from the carburizing temperature, are lacking in this quality, it is evident that a hardening process is necessary. Where the carburizing temperature has not exceeded 1,700 deg. F., the grain growth in the links and the pins is not of sufficient importance, in consideration of their cross section area, to warrant the expense of a double treatment. We will, therefore, confine our discussion to the heat treatment of the case. Bushings, due to their comparatively small cross section, should be double heat treated and will be discussed separately.

When the carburizing process is completed, the links should be allowed to cool in the box, then replaced in the furnace and heated about 1,450 to 1,500 deg. F., and quenched into running cold water if maximum results are desired. Owing to the design of the link itself and the necessity for having a hard abrasive surface in the slotted area, it is necessary that some means be provided to insure a constant flow of water within this area during the quenching operation. If the link is immersed into the quenching tank without this precaution, vapor pockets are invariably created, causing a slow radiation of heat, which in turn prevents the developing of Martensite or the hardening constituent of steel. Soft links, where complaints have led to investigation, in a great number of cases have been attributed to this one cause.

It has been a more or less common practice to quench the links direct from the carburizing temperature. Satisfactory hardness can be secured, but at the expense of the grain growth in the case, which has a marked tendency to cause chipping. If the consideration of chipping is not of serious importance, considerable time and expense can be eliminated by the direct quenching method and a satisfactory, serviceable link secured.

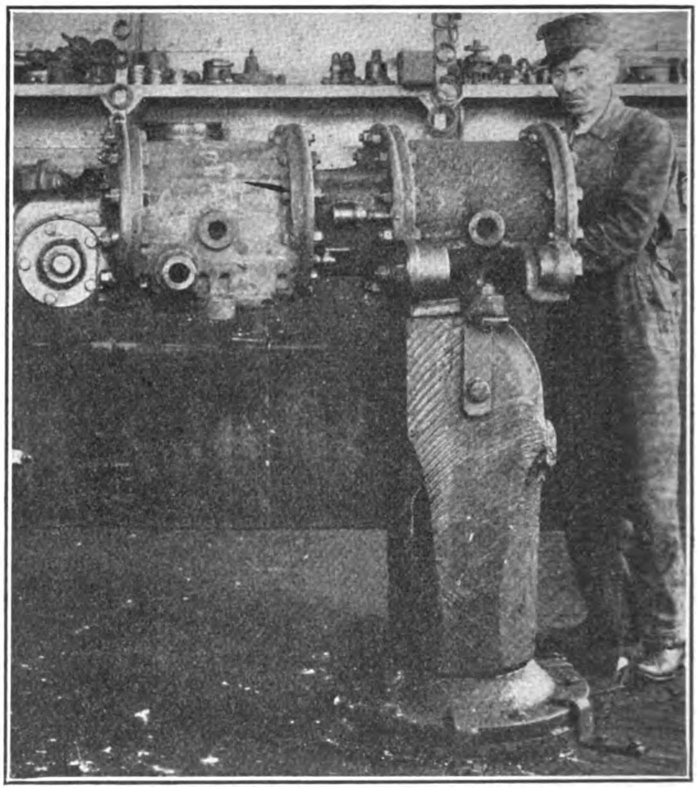
Pins may be processed in the same manner, provided failure of the pin is not indicated by fracture. If pins are rendered unserviceable from this cause, a double heat treatment will materially increase the fatigue resisting characteristics.

This double treatment is as follows: After carburizing, reheat the parts to 1,600 to 1,625 deg. F., quench in oil, and then reheat to 1,425 to 1,450 deg. F. and then quench in water. This treatment will develop the maximum physical characteristics possible. If abrasive value or hardness is the most necessary requisite, a direct quench from the carburizing temperature will serve.

Bushings at all times should be double heat treated as follows: After carburizing, reheat to 1,600 to 1,625 deg. F. and quench in oil; then reheat to 1,425 to 1,450 deg. F. and quench in water. This will insure a tough bushing with a maximum hardness and abrasive value.

Handy bench for repairing air pumps

An improved type of bench for repairing air pumps is described in the June 15, 1924, issue of the Mechanical Department Bulletin of the Kansas City Southern. It was designed by Charles Mays of the Shreveport, La., shops. Formerly an ordinary repair bench was used for air pumps undergoing repairs, which

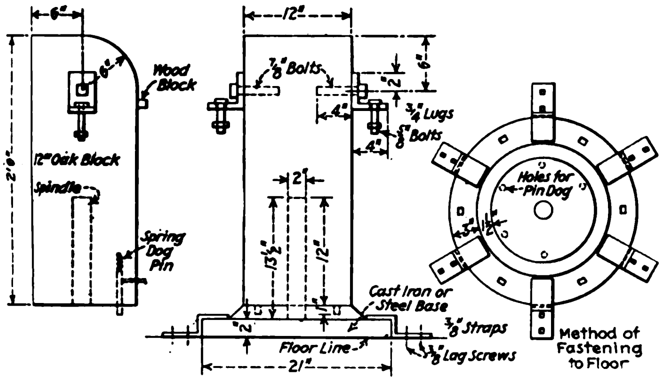


An air pump bench that may be rotated to any position desired and which permits the mechanic to work underneath

made it somewhat inconvenient to perform the work. It also required the assistance of a helper to place the pump on the bench and get into a convenient position for the mechanic to work on.

In order to eliminate this difficulty the bench shown in the sketch has been devised. It consists essentially of an

oak block 12 in. square by 2 ft. 6 in. high which is pivoted on a cast iron or cast steel base. The base is secured to the floor by means of ⅜-in. lag screws. Brackets for holding the pumps are bolted to the block 6 in. down from the top by means of ⅞-in. bolts, and ⅝-in. bolts are used to secure the lugs of the air pump to the brackets,



Sketch of bench for repairing air pumps

as shown in the illustration. The pump may be swung down to a vertical position from the horizontal position shown.

Pumps are placed on the bench by means of an air hoist. A saving of nearly 25 per cent over the former method has been accomplished by the use of this bench for repairing air pumps.

Welding locomotive frames with bronze

By J. H. Chancey

Blacksmith foreman, Georgia Railroad, Augusta, Ga.

SEVERAL inquiries have been made by those interested in the subject of bronze welding for locomotive frames. Inasmuch as there are now on the Georgia Railroad, nine frames welded by the Tobin bronze acetylene process, which have been in continuous freight and passenger service from three to nine months, our experience may be of value.

When the subject of welding frames with the bronze method was first suggested by a demonstrator, the writer was reluctant to attempt it. However, after being assured that it was possible to weld the bronze to steel or iron so that the bronze would break before tearing loose at its welded surface, this method of welding locomotive frames began on the Georgia Railroad.

In relating our experience to a number of persons, such a lack of confidence and disapproval was manifested that it was decided to test the process out in our own way, and so authority was given for the tests to be made. The results of these tests are given below.

Test No. 1—Two pieces of Tennessee bloom iron, 4¼ in. by 4¼ in. by 12 in. long, were welded together by the acetylene process, using ¼-in. Tobin Bronze filler. This test piece was then placed in a wheel press in such a position as to allow the press ram to bear directly against the center of the weld. The test piece started bending at 75 tons pressure and bent 2 in. out of center at 100 tons pressure. The pressure was released at 100 tons and the test piece was reversed and the pressure reapplied. It started bending at approximately 100 tons, bent 1¾ in. out of line and cracked one-half way through the center of the weld at 125 tons pressure.

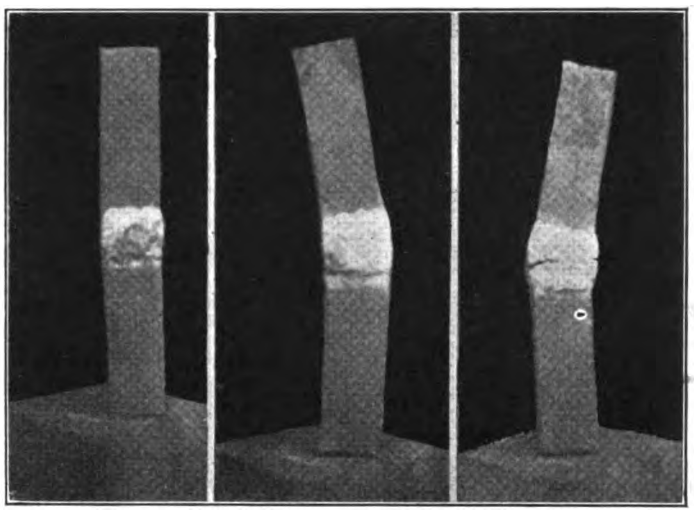
Test No. 2—Two pieces of material of the same grade and of the same dimensions were welded by the acetylene process with ¼-in. Norway iron filler. The piece was tested in the same manner and it started bending at approximately 70 tons pressure and bent 2 in. out of line at 100 tons. The pressure was released at 100 tons, and on the reverse pressure it started bending at 95 tons; bent 1½ in. out of line and cracked one-half way through the center of the weld at 110 tons pressure.

Test No. 3—Two pieces of material of the same grade and of the same dimensions were welded by the acetylene process with No. 1 patented steel ¼-in. filler. Using the same method of testing, the piece started bending at approximately 80 tons pressure, bent 1½ in. out of center and broke entirely through the center of the weld at 100 tons pressure.

Test No. 4—Two pieces of the same grade and of the same dimensions were welded by the electric process with 3/16-in. filler and when tested, started bending at 85 tons pressure, bent 1¼ in. out of line and broke in two pieces at 100 tons pressure.

From these tests the reader will note that the bronze weld surpassed all others by a margin of 15 tons, and the writer is thoroughly convinced that the bronze weld for locomotive frames is superior to autogenous welds with any other material he has thus far used.

In making these test welds, full access was afforded for



The results of testing a Tobin bronze weld

the testing of expansion and contraction, and it was found that the bronze weld contracted only 3/64-in. after entirely cooling off. Therefore, the bronze weld eliminates the frame problems we are confronted with, where it is almost out of the question to get the required expansion, other than by electric welding. Still another feature in favor of the bronze weld is that it can be completed in approximately one-half the time required in using any other filler, which necessarily results in quite a saving.

The following precautions should be taken when making a bronze weld. Cut the vee to a sufficient angle to give the necessary torch play, taking pains, of course, not to get it too large. Use as small a vee as possible so as to obtain a quicker, better job with less expense for material, labor, etc. Chip the welding surface of the frame as clean as possible, and last, but not least, get the best obtainable operators on the job.

On October 15, 1924, we welded a 4-in. by 5-in. top rail in front of a main driver without removing any parts and also allowed for no expansion. This job was completed in 30 min. after the torch was applied, using No. 10 tips. The entire cost of this operation, including labor and material, amounted to approximately ten dollars.

Repairing driving boxes in the average size shop*

By H. H. Henson
Machine shop foreman, Southern, Chattanooga, Tenn.

THIS is the most important key job in the railway locomotive shop. All of the different parts are usually ready to be assembled on the locomotive except the driving boxes. The machinist cannot lay off the shoes and wedges until he gets the driving box sizes. After the driving boxes are ready for the locomotive, everything moves along rapidly. Every machine shop foreman has some different idea of performing the different operations involved in this work. Some still cling to the old method of many years back.

The shop in which the writer is employed is not the largest on the system, but probably our method of handling driving boxes, may be of interest to some foremen in locomotive shops of a similar size. The practice adhered to in this shop is to keep one full set of driving boxes machined all over, ready to be bored for each class of locomotive which we have, besides extra boxes for the drop-pit repairs. This method insures a full set of boxes for the engine that is first due out of the shop. Boxes are always on hand ready to bore as soon as the wheels are dropped on locomotives in for light repairs.

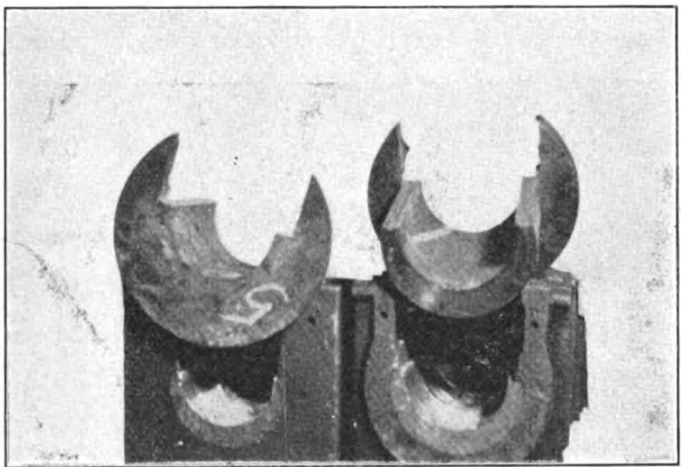


Fig. 1—Flanged driving box brasses

As soon as the locomotives in the erecting shop are stripped, all boxes are cleaned with oil and waste or sent to the lye vat. After passing through the cleaning process repair work is started at once on the set of boxes so as to have them ready for the next locomotive of that same class. The boxes are first examined to see if any have to be replaced on account of defects. The lead man of the box gang checks up the box sizes to see if any are undersize, and if he finds any, a record is taken after which they are sent to the electric welder to have slabs welded on, thus building the box up to conform to the standard size.

Method of applying brasses

Instead of pouring on the brass hub liner into the counterbore of box, as is done in some railroad shops, a brass is used that has the flange or hub liner cast in one piece which gives much better satisfaction than the old type. The driving box is prepared for this brass by counterboring the hub side of the box 3/8 in. deep, and making the diameter to suit the size of the box. These brasses are very easily handled, as they require no special chuck or mandrel to machine them. They are machined on a 36-in. Niles heavy duty engine lathe. The lathe hand can turn the brasses to fit the crown in the driving box, as fast as the shaper hand can lay off and machine the sides of the brass preparatory to pressing them in the box. Fig. 1 shows one of the flanged type brasses in the rough casting, ready to be machined. This is done by placing only the flanged section in the ordinary lathe chuck.

After the brass has been machined and pressed in the driving box, it is then ready to have the shoe and wedge sides faced on the planer in the usual way. After the planing operation, there is drilled in the top or crown of the box and brass a hole, 1 1/4 in. or larger, depending upon the size of the driving box. This hole is then reamed with a taper reamer from the inside of the box, and a taper brass pin driven in with a sledge hammer. Oil holes are drilled through the face of the hub on the box into the oil cellars in the top of the driving box, to lubricate the hub-liner.

The boxes are now ready for the vertical boring mill, on which the hub sides of the flanges are faced to the required thickness for the lateral motion between the wheel centers and the hub sides of the boxes. The boxes are held on the boring mill table by means of a two-jaw universal chuck. The boxes are then taken to the heavy duty Niles horizontal boring mill to be set up, and bored as in Fig. 2. It will be noted that an expanding double-cutter boring tool is used which bores the box in 30 to 45 minutes, depending on the size of the journal. Only two cuts are taken, a roughing and finishing cut. The cutters are made of high speed steel, 1/2 in. by 1 1/2 in. in size and lengths to suit. Two boxes are set up on the mill to start with. They are laid off by the lead man of the driving box gang, and when one box is completed the

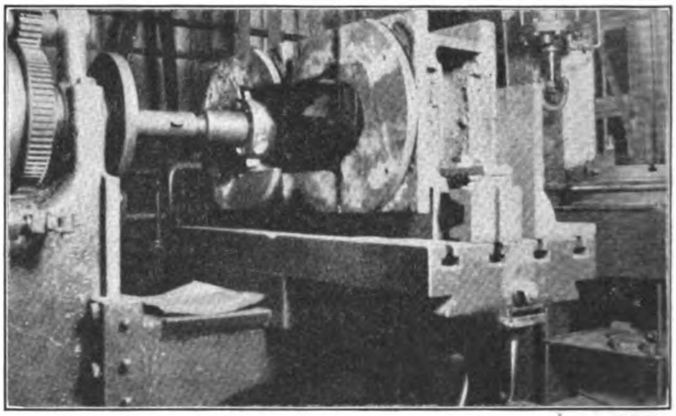

Fig. 2—Method of boring driving boxes in a horizontal boring machine

*One of the papers presented in the driving box competition which closed April 1, 1924.

boring mill man shifts the table over to the other and begins boring. While the heavy roughing cut is being taken, he hoists up another box and fastens it to the table. This keeps the tool almost continually busy.

Manner in which the boxes are bored

The front, intermediate, and back boxes are bored 1/32-in. larger than the journal while the main boxes are bored to a snug running fit. The front, intermediate and back boxes have a recess cut in the crown of the brass, as shown in Fig. 3, and are also undercut 1/32-in. deep, and about 1 in. back from the edge of the fillet, or shoulder at point *A*. Grease or journal compound grooves are cut 3/16-in. deep, by 3/16-in. wide, extending from the undercut edge of the brass to the recess

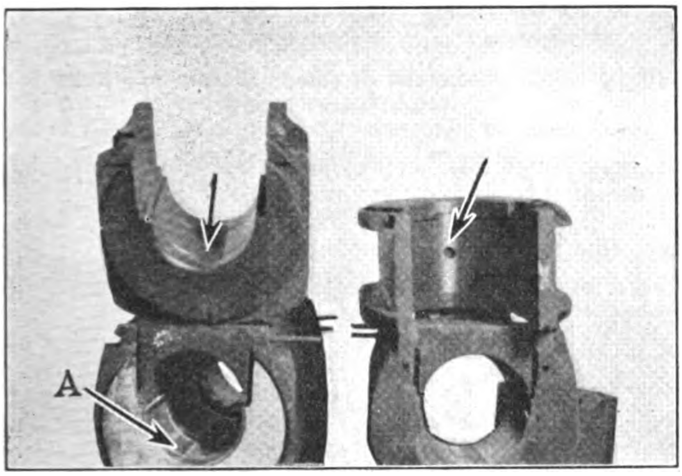

Fig. 3—Arrows indicate the location of the recesses in the driving box brass—Point A shows the location of the undercut

in the crown of the brass. This is to give the journal compound a good starting place to feed through, or circulate around the journal, as new brasses must have plenty of lubricant to start with in order to obtain the proper amount of mileage from the locomotive before it has to have its brasses recrowned or renewed. It is safe to say that 50 per cent of the success with journals regarding pounds and mileage, is due to the quality of the brass that is used in the box. It is very essential that driving box brasses should be cast of the very best material.

The machining of the main driving box requires just a little different operation at point *A*, Fig. 3. The brass is undercut 1/32-in. deep, and only ⅜ in. back of the fillet, instead of 1 in., as in the other boxes. The purpose for this difference is to have a snug job on the main boxes, as they pound soon enough. On the switch engines, the grease grooves are cut entirely around the bore of the brass because they back up as much as they go ahead. The Franklin No. 4 lubricator is used on switch engines with ⅜-in. perforations in the grease cellar as this type of locomotive never moves fast enough to warm the journal compound so that it will feed freely. On freight and passenger locomotives the Franklin No. 4 lubricator is used also, but it has 3/16-in. perforated cellars, instead of the ⅜-in. size.

Cutting the compound grooves on freight and passenger locomotives differs somewhat from the practice for switch engines. They are cut 3/16-in. wide, but only one groove is cut in the brass on the shoe side, and two on the wedge side. The reason for this is that road engines move ahead much more than they move backwards.

Fig. 4 shows the method employed for machining the circle on the rough box preparatory to fitting the brass. Four of the average size boxes or two of the heavy Mountain and Santa Fe type locomotive boxes are set up at one time on the table of a Morton draw cut shaper.

The hub liner problem looms up at this point of the article for its criticism. Many schemes have been tried and found wanting. Even Henry Ford is experimenting along this line, by testing hub liners of steel, case-hardened and ground, on Detroit, Toledo & Ironton locomotives. Of course, every mechanical supervisor has tried some kind of a hub liner, and when it is all summed up, they all get about the same results. The hub liners used at this point are made from steel boiler plate, electrically welded to the driving wheel center or hub. This method is inexpensive, and requires very little machine work, as the liners are laid off on sheet metal in circles to within ¼ in. of size, cut out with the acetylene torch, turned on the outside diameter and bored, separated in only one place, heated on the side opposite to the cut, applied to the journal, and then welded to the wheel center.

Other factors to consider

Good machine tools are among the most important factors in obtaining efficiency and production in a locomotive shop. The foreman comes in at this point for a little criticism. He has to be a "live wire," a good leader and instructor, and also must have the confidence of his men, to get the best results. The only way to gain the

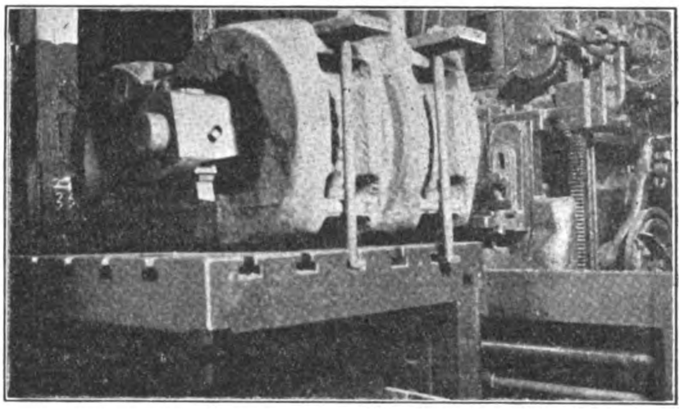

Fig. 4—Method of machining circles on the rough box preparatory to fitting the brass

confidence of his men is to show that he is a first-class mechanic and up-to-date in his methods.

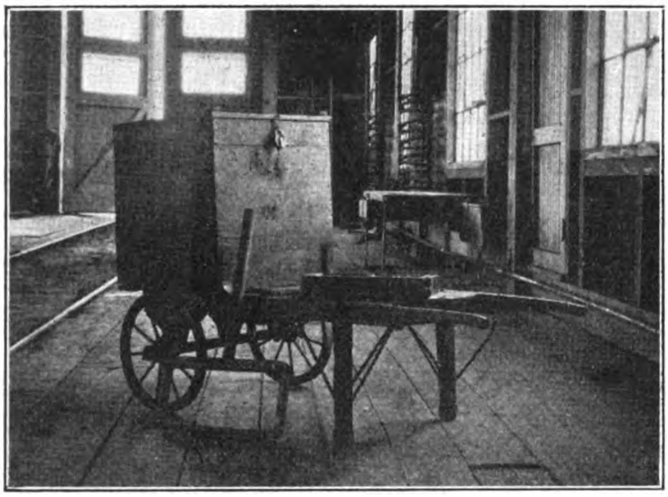
The tool room should not be neglected, as it makes for efficiency and production when it furnishes the proper tools and fixtures to work with. When you have machine tools that cannot produce, change them so they will give the desired results. When a machine tool will drive all the high speed tool bits will stand, then it is certain that the machine is giving production.

The cars in use by the British railways have always been very diminutive from an American standpoint, and now that the 120-ton coal car is coming into use on this continent, so at least one British road is adopting larger cars for its coal traffic. The road is the Great Western, and the new cars which it has placed in service are of 20 long tons' capacity, replacing cars of 8, 10 and 12 long tons. Apparently the chief obstacle in the way of adopting larger cars in England, aside from the severe limitations of clearance, is the habit and equipment of the shippers. Shippers equipped to handle 12-ton cars may find changes in methods and perhaps additional capital expenditures necessary in order to utilize the larger cars. Therefore, in order to offer some inducement to shippers, the railway is offering a 5 per cent rebate to all shippers using the larger cars loaded to capacity.

Portable tool box for valve motion mechanics

THERE can be found in railroad shops many types of portable tool boxes but the one shown in the illustration and used at the Billerica shops of the Boston & Maine has its own unique advantages. This tool box is particularly designed to meet the requirements of the mechanic who sets and squares up valve motion.

For this specialized job the mechanic must have a certain set of tools among which are such items as, trams, scribers, dividers, etc., which must be properly taken care of. This he can readily do by placing them under lock and key in the box shown. At the end of his day's work



Combination portable tool box, material wagon and ladder for locomotive mechanics

he can leave the box set wherever he may be in the shop and come back in the morning and find it there with the tools intact.

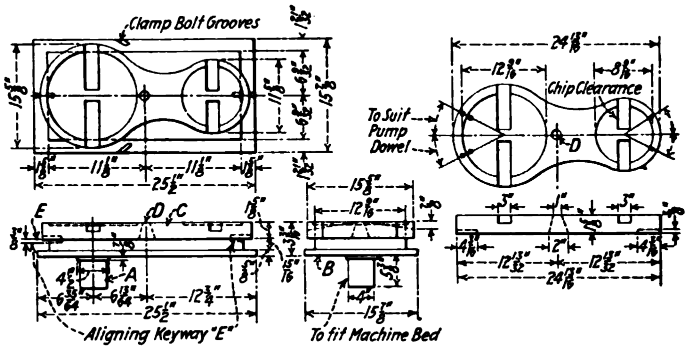
It will be noticed that the box covers only half of the top of the wheel-barrow. The remaining part is used to haul valve motion parts to the locomotive and is also convenient for the machinist to stand on so that he can readily reach the highest point of the valve motion.

Boring jig for air pump cylinders

STEAM and air cylinders can be bored complete in 10 min. on a Bullard vertical turret lathe or boring mill by using the jig here illustrated. The jig is placed on the bed of the boring mill with the lug *A* fitted into the center hole of the bed. It is then secured to the bed by bolts which enter the bolt grooves on the bottom plate *B* of the jig shown in the sketch. This completes all the work necessary to align the air pump cylinders to the boring spindle or tool. Both the top and bottom plates have dowel holes drilled at different radii so as to fit the dowels on different sized pumps.

The pump is placed on the jig, either end up, with the dowel pins on the cylinders inserted in the dowel holes. This places the center line of one cylinder equidistant from the boring bar and it is then ready for boring.

After one cylinder has been bored, the keys *E* are pulled out, which allows the pump and top plate *C* to turn on the pin *D*, bringing the other cylinder into position for boring. The keys *E* are then replaced in the keyways and the job is completed. Pump cylinders have been refinished on this jig, placed on an old boring mill, quicker than on machines built especially to do the work. Grinding a badly worn pump cylinder usually takes from one to three hours, but it has been found that much time



Jig for holding steam and air pump cylinders on a Bullard vertical turret lathe

can be saved if the pump cylinders are rough bored by the use of this jig and then ground.

This jig was designed by W. L. Lauer, general foreman, Illinois Central, Memphis, Tenn.

Securing small hubs or levers to shafts

CERTAIN minor locomotive parts such as bell yoke bearing shafts, cylinder cock levers and stoker mechanisms, in common with numerous machine parts not from locomotives, are positioned and secured by a taper pin or rivet as shown in Fig. 1 of the sketch. This method has the advantage of being simple and requiring a minimum of time in completing the assembly of the parts, but often causes trouble owing to the tendency of

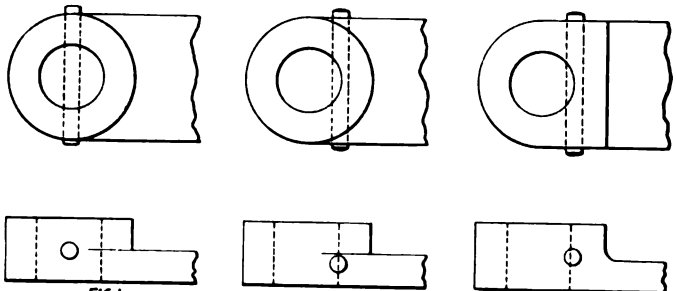


FIG. 1 FIG. 2 FIG. 3

The additional metal allowed by the arrangement shown in the last two figures tends to eliminate breakage

the pin or rivet to shear or occasionally the shaft to break on account of its reduced cross section.

The same size pin applied through the side of the shaft as shown in Fig. 2 presents a greater cross section to either a rotating or end movement of the shaft. Another advantage is that the work cannot be assembled with the shaft a half turn from its proper position as sometimes happens when the pin is located as in Fig. 1. As the parts thus assembled are not usually intended to be interchangeable with similar parts, no disadvantage occurs due to the changed position of the pin.

If the hub is forged or cast as in Fig. 3 the additional metal serves to reinforce the pin bearing and lessens the chances of hub breakage which exists in Fig. 1.

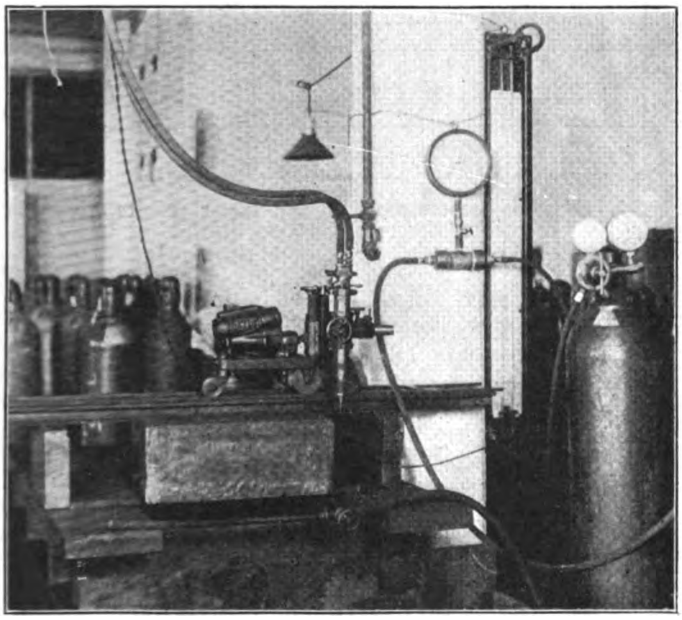
Economies effected by the use of high purity oxygen*

Consumption of the gas and the cutting time substantially reduced—Drag of cut improved

By John J. Crowe † and George L. Walker ‡

UNTIL a comparatively recent date, all oxygen was produced by chemical or electro-chemical means, and some of the older users of oxyacetylene torches will tell you that the oxygen produced for welding and cutting was very expensive and that it was about as impure as it was expensive when judged by our present standards. Today most of the oxygen used in oxy-acetylene welding and cutting is manufactured by the liquid air process.

The atmospheric air is liquified by compressing and cooling, and the oxygen is obtained by what amounts to a distillation process. The boiling temperature of oxygen at atmospheric pressure being —296.5 deg. F., whereas the boiling point of nitrogen is approximately 24 deg. F. lower or —320.8 deg. F.



Radiograph controlled cutting torch

The discovery of the principle of the oxyacetylene torch was first announced by the famous French physicist Henri LeChatelier in 1895 in a paper read before the Academie de Sciences, on the temperatures of flames. He stated at that time that the temperature of the oxyacetylene flame was 1,000 deg. C. higher than the oxyhydrogen flame, and we know today that the temperature approximately 3,480 deg. C. (6,300 deg. F.) exceeds that of any other know flame and closely approaches the temperature of the carbon arc. Practice application was made of the principle of the oxyacetylene flame by Fouché and Picard when they developed the first oxyacetylene torch in 1901.

The first torches were for welding, but it was not long before application was made of the principle of iron and steel combustion in an atmosphere rich in oxygen when raised to their ignition temperatures.

Oxygen purity

Until quite recently oxygen users were contented with oxygen of 97 to 98.5 per cent purity, but today, at least in the United States, such is not the case. By improving the apparatus and operation of liquid air plants it has been found possible to manufacture, commercially, oxygen of much higher purity. By stages the purity of oxygen has been increased until now it is possible to obtain, continuously by that method, oxygen with a guaranteed purity of 99.5 per cent, plus or minus a tolerance of 0.1 per cent.

The question naturally arises, what benefits are to be derived from small increments in purity as we approach the ultimate limit of 100 per cent oxygen. To answer this question the Air Reduction Sales Company has carried out two series of experiments extending over a period of several years, and it is the results of these experiments which are presented in this paper.

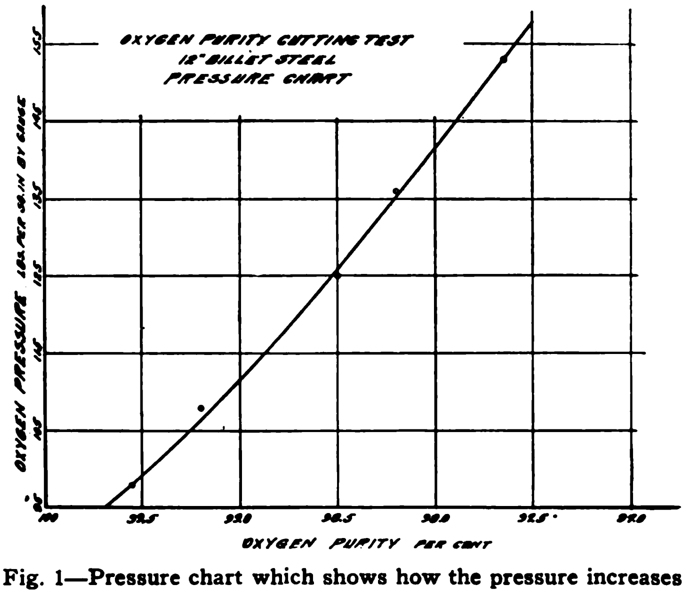


Fig. 1—Pressure chart which shows how the pressure increases as the purity of the oxygen decreases

Method of making tests

The experiments were made on steel plates and rolled steel billets, ranging in thickness from 3/8 in. to 12 in. To eliminate the human element or personal equation as far as possible, all the cutting done in the first series was done with a hand torch mounted on a radiograph geared

*Abstract of a paper presented at the February 16 meeting of the American Welding Society, New York City. Copyright, 1925, by the Air Reduction Sales Company, New York.

‡Associate engineer of the apparatus research and development department, Air Reduction Sales Company.

to give variable speeds from a few inches per minute up to 60 in. or more per min., and in the second test series the cutting was done with a machine torch mounted in the same manner.

The speed of the radiograph was checked with a stop watch. The pressure, where practicable, were measured with mercury manometers, and the higher pressures were measured with standard test gages, frequently calibrated and tested on a dead weight gage tester. The gas (oxygen and acetylene) consumptions were obtained by weighing the cylinders before and after using, on scales accurate to ¼ ounce, and these weights were checked up making up the loss in weight with shot and then weighing the shot on a separate balance. All the material was cooled to approximately the same temperature before cutting, and the experiments were carried out under laboratory conditions in which every possible variable was controlled as closely as possible.

Table I—Oxygen consumption of various purities required to cut metals of various thicknesses, using 100 cu. ft. of 99.5 per cent oxygen as a basis of comparison.

Average consumption		100.0	111.9	129.2	145.9	168.1
Difference for each ½ per cent decrease in oxygen purity.....			11.9	17.3	16.7	21.5

The laboratory was furnished with an ample supply of oxygen varying in purity from 98.5 per cent to 99.5 per cent by steps of approximately ¼ per cent for the first series and from 97.5 per cent to 99.5 per cent by ½ per cent steps for the second series. The actual purities were determined at the time of manufacture, and were carefully checked in the laboratory.

Previous experiments in which oxygen of various purities manufactured by the electrolytic process compared with a pressure that would make the cut without difficulty, and then to reduce the pressure by stages until the minimum pressure was found that would just make the cut.

Preliminary experiments were also made to determine the most economical size of tip and the speeds to use in making the final cuts. The curve shown is concave upwards but only slightly so, and this is typical of all curves plotted in this manner.

Taking Fig. 1 as an example it will be noted that the

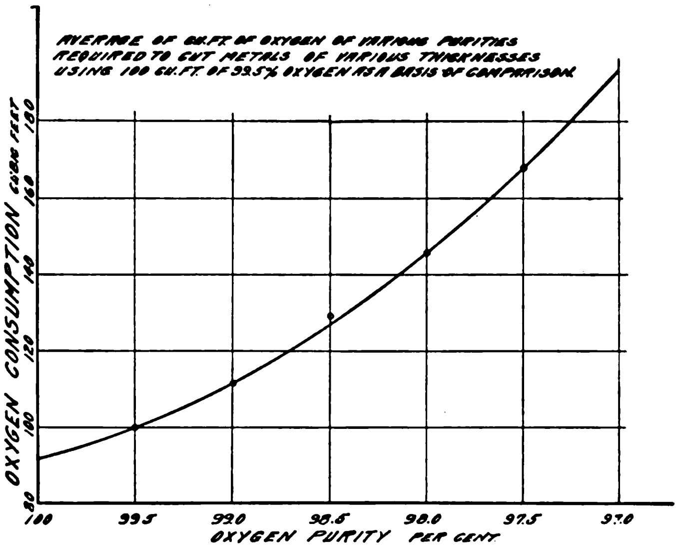

Fig. 2—Graphic presentation of the mean results given in Table I

pressure required to cut a billet 12 in. thick using oxygen of 99.5 per cent purity was 99 lb. per sq. in., whereas it required a pressure of 112 lb. when the oxygen purity was reduced 0.5 per cent and if the purity was dropped to 98.0 per cent the pressure required was increased to 142 lb.

As the cutting tip was the same for all cuts on the same thickness of metal the oxygen consumption for the same amount of cutting increases with the pressure required to make the cut.

Table II—Actual time required to make cuts of given lengths of metals of various thicknesses using oxygen of various purities and time expressed in percentages using time required with oxygen of 99.5 per cent purity as a standard.

Thickness of metal, in.	99.50 per cent: Time to make cut, min.	sec.	Per cent	99.25 per cent: Time to make cut, min.	sec.	Per cent	99.00 per cent: Time to make cut, min.	sec.	Per cent	98.75 per cent: Time to make cut, min.	sec.	Per cent	98.50 per cent: Time to make cut, min.	sec.	Per cent

Mean			100			105.3			112.9			120.7			131.0
Difference for ¼ per cent in oxygen purity						5.3 per cent			7.6 per cent			7.8 per cent			10.3 per cent
Difference for ½ per cent in oxygen purity						12.9 per cent						18.1 per cent			

with oxygen of the same purities manufactured by the liquid air process had shown no measurable difference.

Results of the tests

In the typical graph shown in Fig. 1 the minimum pressures required to cut a 12-in. billet have been plotted against the purity of the oxygen used. To determine these pressures a large number of preliminary cuts were made on each thickness of metal with oxygen of each purity. The method of procedure followed was to start

In order that the data obtained may be more easily compared they have been tabulated in Table I after reducing to a common basis, that is, the number of cubic feet of oxygen of the various purities required to cut metals of the various thicknesses, using 100 cu. ft. of 99.5 per cent oxygen as a standard of comparison. The mean of the results given in the table is shown graphically in Fig. 2.

It will be noted that 11.9 per cent more oxygen of 99.0 per cent purity is required to do the same amount of cutting as was done with oxygen of 99.5 per cent purity, and

when the oxygen purity was dropped from 99.5 per cent to 98.5 per cent the increase in consumption was 29.2 per cent. In other words, it required 129.2 cu. ft. of 98.5 per cent oxygen to make the same length of cut as was made with 100 cu. ft. of oxygen having a purity of 99.5 per cent.

The preceding data have shown how the oxygen consumption increases with a decrease in oxygen purity without reference to time. The results of time studies made in the first series of experiments on sizes up to 4⅜ in. thick are given in Table II. Owing to the large amount of material involved, these experiments were not extended to cover the larger sizes, all the cutting on the 6-in. and 12-in.

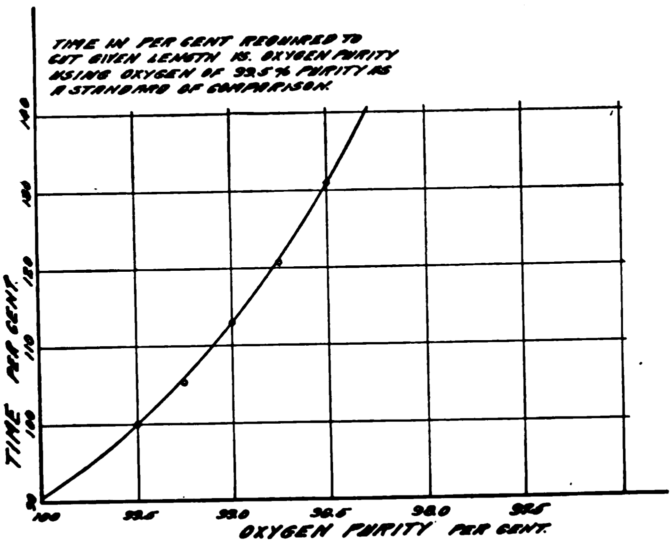

Fig. 3—Graphic presentation of the data given in Table II

billets being made at constant speed. The actual time to make the various cuts is shown in Table II and in order to compare the results they have all been reduced to a common basis and expressed in percentages using the time obtained with 99.5 per cent purity oxygen as a standard of comparison.

The loss in time expressed in percentages very closely approximates the waste in oxygen as the purity decreases, and the two go together, that is, as the oxygen purity decreases the time required to make a given cut goes up as shown in Table II, and the consumption of oxygen in making the cut goes up at the same time as shown in Table I. The average of the results expressed in percentages as shown in Table II is shown graphically in Fig. 3.

How pure oxygen effects drag

The characteristic drags obtained on the 12-in. billets with oxygen of four different purities are given in Fig. 4. For some work, such as straight line cutting, the amount of drag may not be of serious consequence but in the machine cutting of intricate shapes the drag must be maintained at a minimum as otherwise the underside of the shape cut will not register with the top side.

To decrease the drag to correspond with that obtained with the high purity oxygen (99.5 per cent) it would be necessary to increase greatly the pressures and it follows that the consumptions for the lower purities would be much greater than those shown in the curves and tables.

It was not the purpose of this investigation to enter into any considerable number of practical applications in cutting with high purity oxygen and the results obtained, but anyone interested can easily demonstrate the superior cutting properties of high purity oxygen by making simple and practical tests, if they will obtain oxygen of, say, 99.5 per cent purity and oxygen of 99.0 per cent purity or less and make cuts in the same steel plate or forging with both oxygens.

As a field check on the investigation made in the laboratory, a large number of oxygen cylinders analyzing 99.5 per cent and an equal number of oxygen cylinders analyzing 99.0 per cent were used for wrecking steel cars, and a careful study was made of the results obtained with the two oxygen purities. Ten cars were scrapped with each purity of oxygen, and to eliminate as far as possible the personal equation the operators were frequently changed from one oxygen purity to the other, and at no time were the operators informed as to the purity of the oxygen supplied them. Weather conditions were bad, the temperatures ranging from —30 deg. F. to —21 deg. F. and the cars were covered with snow. Working under these conditions and with operators some of whom had only a limited experience in oxyacetylene cutting, a saving of 10 per cent was shown in oxygen consumption and 11.2 per cent saving in time, both in favor of the oxygen having a purity of 99.5 per cent.

The following conclusions may now be arrived at.

First.—That small increases in oxygen purity greatly increase the efficiency of cutting operations, both as measured by oxygen consumption and by time required to complete a given amount of cutting.

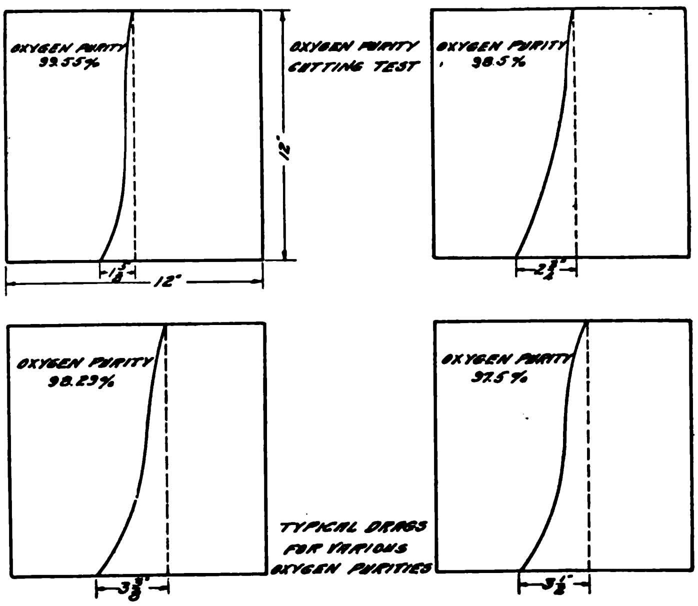

Fig. 4—Characteristic drags obtained on 12-in. billets with oxygen of four different purities

Second.—That the difference of effect of small increases in oxygen purity decreases as 100 per cent purity is approached, but the effect is of considerable magnitude for the interval of 99.0 per cent to 99.5 per cent oxygen purity showing a saving of approximately 12 per cent for oxygen consumption and an equivalent saving in time.

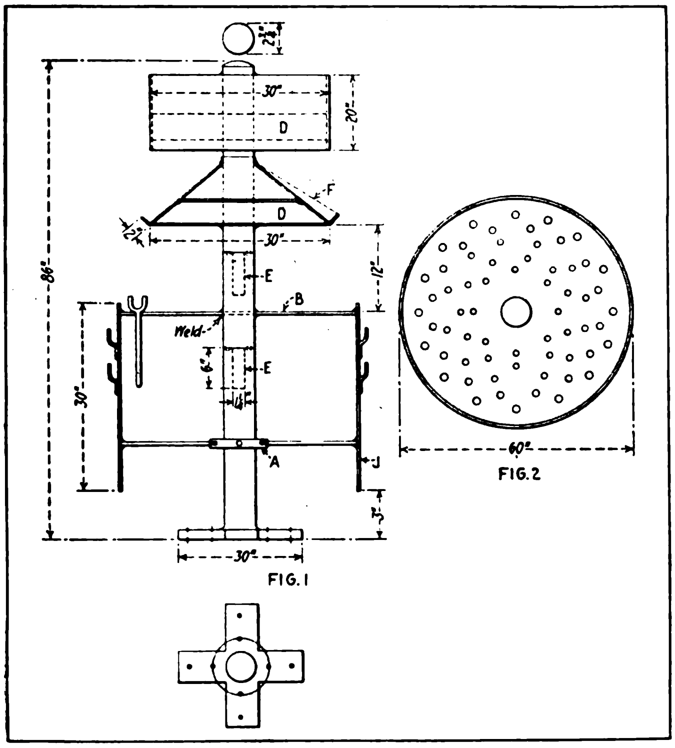
Third.—That decreases in consumption and time with small increases in oxygen purity found by the laboratory have been substantiated by practical applications made with oxygen of 99.5 per cent and 99.0 per cent purity.

The shops of the Pennsylvania Railroad at Sunbury, Pa., according to report, are soon to be closed. These shops, employing about 500 men, have been in operation since 1876. Reports say that the skilled workmen will be employed by the road at other places. The Sunbury shops are not equipped for repairing modern large locomotives.

A handy tool rack for the boiler shop

By Joseph Smith

PROVIDING the proper means for storing and distributing tools is quite as essential as having sufficient tools. Fig. 1 shows the elevation of a tool rack with a central shaft 2¾ in. in diameter in three sections, turned down and bored out as shown at *E* and



A boiler shop tool rack with two separately revolving containers

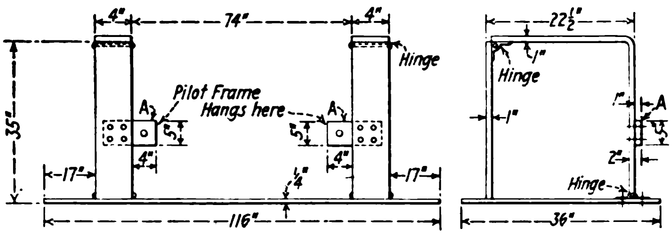
recessed as shown for ½-in. ball thrust bearings. The circular shell *J* is 60 in. in diameter and is made of ⅛-in. steel plate. The head, *B*, is constructed of ¼-in. steel plate welded to the shell *J* just a little below the top edge. The head, as shown in Fig. 2, has holes burned in at random to accommodate single ended wrenches, socket wrenches and various other tools. The brackets on the side of the shell are for double-ended box wrenches and similar tools. *A* is a wrought iron collar, bored for an easy fit around the shaft, and drilled and tapped out for four ⅞-in. rods. These rods are adjusted to the inside diameter of the shell and welded as shown, to support the bottom of the shell.

Front and end views of two shelves, made of ⅛-in. steel plate, are shown at the top of the drawing. These shelves are welded, as shown at *D*, and are used for storing small tools. They are made in one piece with a hole cut at the top to slip down over the shaft. The shelves are constructed with a 2-in. flange along the bottom edge to prevent the tools from sliding off. A taper flange is also welded on at each end, as shown by the dotted line *F*. These shelves may be used for staybolt taps, spindle taps and reamers.

The base is fastened to the floor by wood screws and is made of 4-in. by 1-in. flat iron. One piece is offset to fit over the other and both pieces are bored to fit the bottom of the shaft and welded. In assembling the shaft, a liberal supply of lubricant should be applied in the bore and at the ball bearings. An attendant can reach any tool by simply turning the rack.

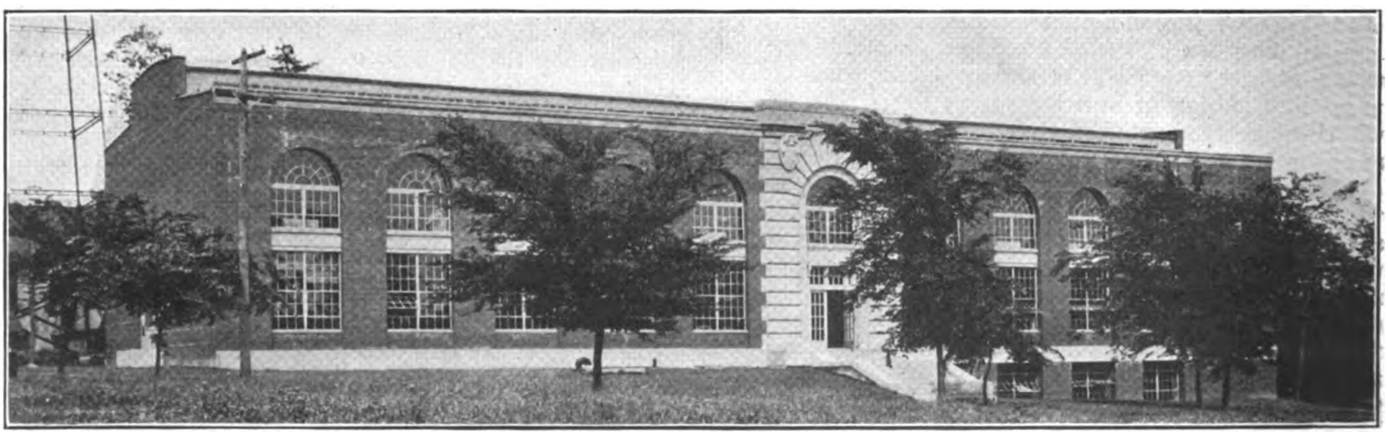
Jig for holding steel pilot frames when riveting

THE method of riveting together steel pilots as they rest on the floor always causes more or less trouble and inconvenience owing to the difficulty of placing them in different positions in order to rivet the various frame members. The difficulty was overcome by designing a jig, at the Grand Rapids, Mich., shops of the Pere Marquette, which swings on hinges enabling the workmen to place it in any position he may desire.

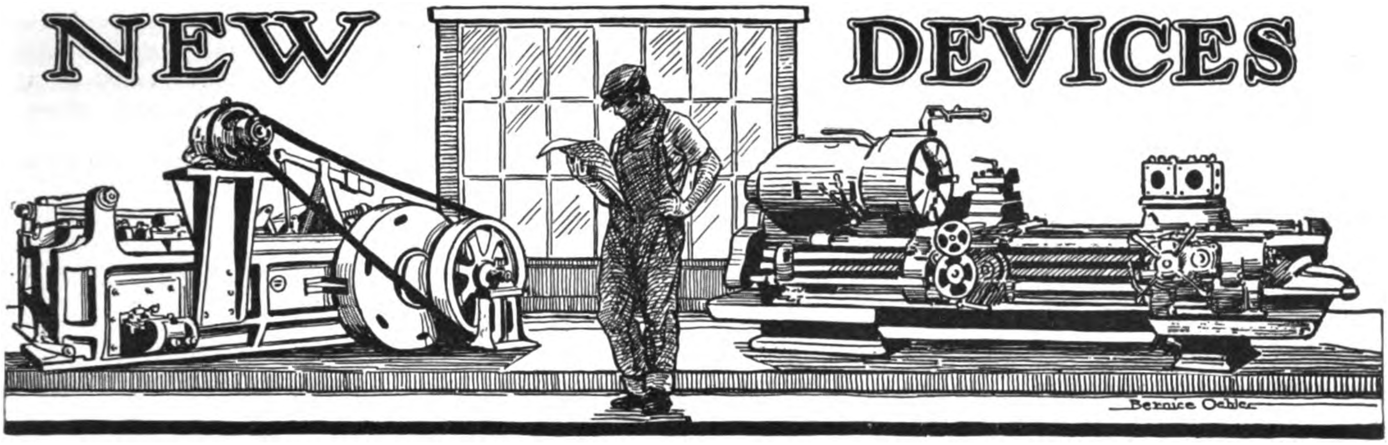


A pilot frame jig which swings on hinges

Referring to the illustration, the pilot frame is bolted to the lugs *A* thus holding it in the proper position for riveting. The hinges of the jig allow the pilot to be swung to all workable positions with very little effort, and a considerable saving of time.

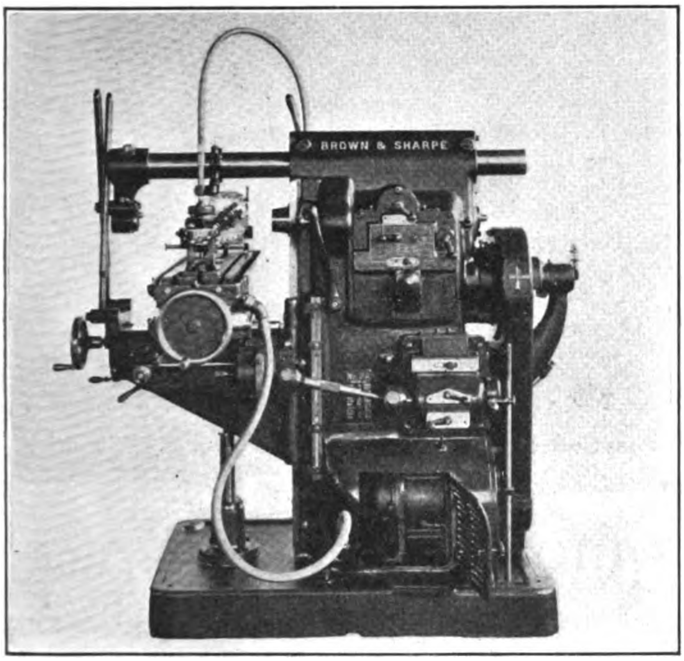


The mechanical engineering laboratory of The Pennsylvania State College



Milling machine with the motor in the base

A MILLING machine designed so that the motor is incorporated in the base has been placed on the market by the Brown & Sharpe Manufacturing Company, Providence, R. I. These machines, when equipped with a motor, are entirely self-contained, the motor being enclosed in an oil-tight compartment in the base.



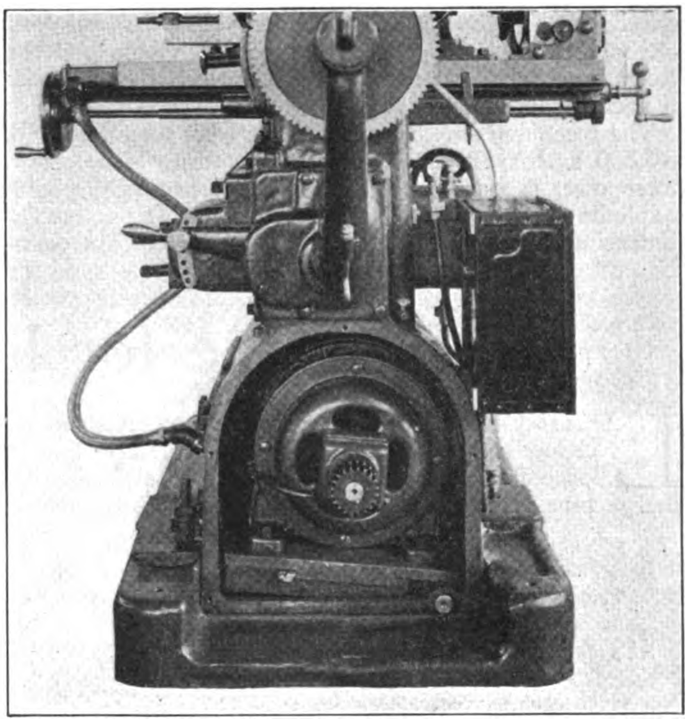
View of the right side showing the oiling arrangement for the motor bearings

The new design does not differ materially from the column and knee type except to include the construction necessary for this style of drive. The important change comprises a redesign of the lower part of the column to provide for the motor compartment which is cast with a solid top as a part of the column. Complete protection is furnished the motor from oil, cutting lubricant, chips and dirt. A tank for the cutting lubricant is located in the base, extending around the foot of the elevating screw. Strainers set in the top of the base provide for the prompt return of all oil to the reservoir.

Ample provisions have been made to insure a sufficient circulation of air by three ventilators located on the sides and rear of the compartment. They serve a two-fold purpose in that they also permit ready access to the motor for purposes of lubrication, repairs, adjustment and cleaning.

Oil wells fastened to the frame of the motor and readily accessible through the door on the right of the machine, are connected by tubes to the motor bearings. This permits quick and positive lubrication of these parts.

In order to facilitate installing and removing the motor and to provide for adjustment of the driving chain, a separate adjustable base is provided on which the motor is mounted. This base is hinged on the right side and has an angular adjustment regulated by means of the bolt on the left of the column outside the compartment. The bed of the motor is tongued and slides into a groove in the hinged base. When in position, the motor is held firmly in place by a gib inserted in the motor ways. The



Rear view with chains and guards removed, showing interior of the motor compartment

driven and driving sprockets as well as the driving chain are fully enclosed by a cast iron guard.

A distinctive feature of the machines is the ease with which the friction driving clutch can be adjusted. This clutch is mounted within the driving pulley or sprocket, on the main drive shaft. By removing the small plate on the side of the pulley, through an opening in the chain guard, the clutch can be readily adjusted without any further dismantling of the machine.

All parts of the machine are conveniently located for purposes of adjustment and operation. Complete access to the motor compartment is obtained by removing the chain guard, the chain and rear wall of the compartment.

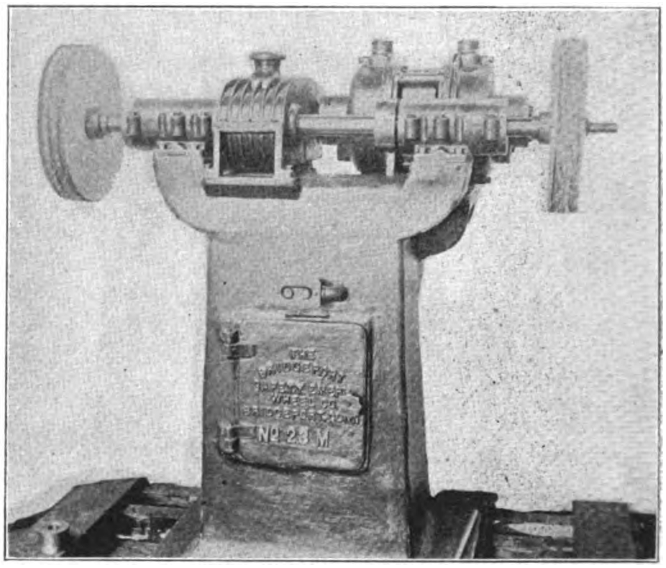
When used as a belt-driven machine the motor compartment is available for storage of tools and parts. The change from belt to motor drive can be easily and quickly accomplished. These machines are made in two styles of three sizes each; the Nos. 1A, 2A and 3A universal and the Nos. 1B, 2B and 3B plain milling machines.

Buffing lathe with chain drive

CONSIDERABLE difficulty has been experienced in the past by the Bridgeport Safety Emery Wheel Company, Bridgeport, Conn., in obtaining a suitable drive which would give the desired buffing speed when using 60-cycle, alternating current. In a newly designed motor-driven buffing lathe this difficulty is said to have been overcome by mounting the motor on the back of the machine and connecting it with a chain drive to the grinding wheel spindle. By using appropriate sizes of chain sprockets the buffing spindle can be brought within close range of the desired speed.

The machine pedestal is cast with a bracket on the back on which the driving motor is mounted. This brings the center of the motor shaft horizontally back of the buffing spindle and the two are connected with the silent chain drive. This chain runs in an oil-tight case with an oil bath in the bottom, which insures continual and positive lubrication. Both the motor spindle and the buffing spindle run in ball bearings. The buffing spindle has four sets of bearings, one at each end of each box, and the boxes have large oil reservoirs into which the balls dip at each revolution.

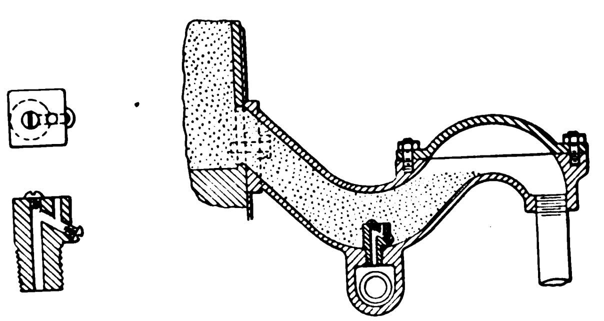
The machine is built in three sizes, each furnished with a 3,500 r.p.m., alternating current motor, which have a horsepower capacity of 2, 5 and 7½, respectively, giving a spindle speed of 2,400 and 2,500 r.p.m. The following dimensions are for the larger type of machine. The diameter of the spindle in the bearing is 2 in., length of the bearing 10½ in.; diameter of spindle where the wheel fits, 1½ in.; height from floor to the center of the spindle, 33 in.; net weight, 1,350 lb.



Motor-driven buffing lathe provided with a chain drive

Air nozzle for locomotive sanders

LOCOMOTIVE sanders of ordinary construction include a substantially straight air nozzle that is located in the lower portion of a pocket in the discharge pipe leading from the sand dome. It frequently happens that the duct in the air nozzle and the air chamber immediately beneath it become filled with sand. As a result of vibration, the sand becomes packed to such a degree as to prevent the compressed air, when turned on, from blowing through the sand discharge pipe, thus failing to serve its purpose.



Air nozzle designed to prevent the sand from packing in locomotive sanders

The air nozzle, shown in the illustration, has been designed in a manner which apparently overcomes this trouble. The air nozzle is seated in the bottom of the U-shaped portion of the trap immediately above the compressed air chamber and projects upwards into the passageway of the trap. The nozzle includes a rectangular metal body provided with an externally threaded shank that is screwed into the bottom of the trap. Formed through the body of the nozzle is an air duct the upper end of which is closed by means of a screw. There is formed in the upper portion of the body and immediately to one side of and parallel with the main air duct, a short duct extending a short distance down the body. These two air ducts are connected by a duct which is inclined at an angle of 45 deg. with respect to the horizontal. The lower end of this air passage is also closed with a screw plug. The three air ducts form a Z-shaped air passage, the inclined portion of which forms a trap between the

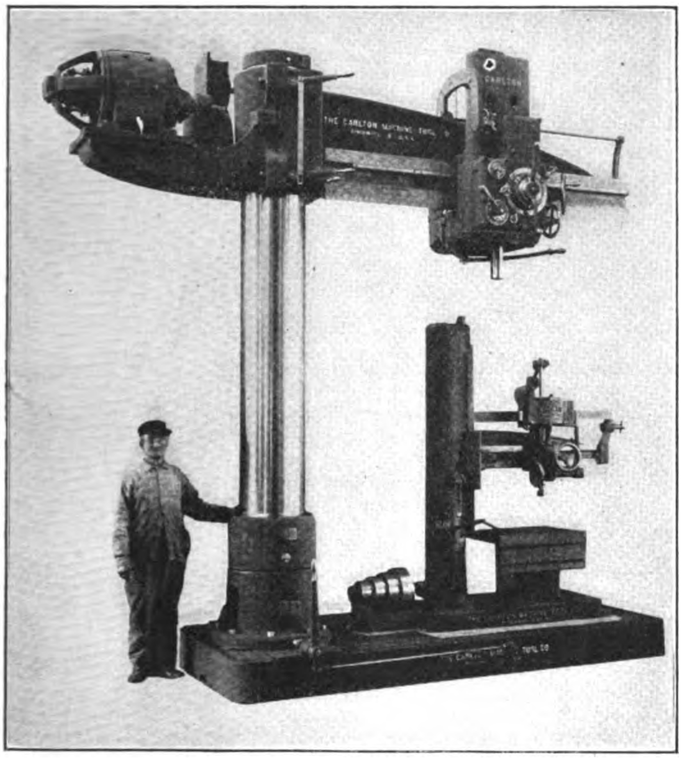
vertical portions that will receive and retain a relatively small amount of sand and consequently prevents the passage of any large amount of sand through the nozzle into the main air chamber. In this manner the sanders are prevented from becoming ineffective by the packing of sand within the air nozzles as it is only necessary to expel a relatively small amount of sand from the two smaller air ducts.

This device has been patented by John W. Simpson, Santa Barbara, Cal.

Ball bearing heavy duty radial drill

A RADIAL drill equipped throughout with ball bearings, constructed on the unit principle, having a concentrated and convenient control and a low-hung drive of the spindle, has been developed by the Carlton Machine Tool Company, Cincinnati, Ohio. Particular attention has been paid to lubricating the machine to increase production by reducing friction, wear, power losses, shutdowns and renewals.

The speed box is composed of several sub units. The driven shaft is provided with four keys running almost its entire length. The six gears which form the cone are made of alloy steel with four keyways multiple broached to fit on the shaft. The large gear on the end is made of cast iron which carries a pawl to drive the ratchet mounted on the shaft so that when the train of gears is disconnected, the pawl drops in the ratchet and keeps the gears in constant motion. The upper shaft, which carries the sliding tumbler gears, is also made from the solid bar. The ratchet teeth on the tumbler engage with a small segment on the front cover and are used only for engaging and disengaging the train of gears. The speed box is entirely closed with long levers extending to the front of the column for the convenience of the operator. The speed box contains a sight oil gage. There are 24 speeds in geometrical progression covering a range from 18½ to 800 r.p.m. when the speed box pulley is revolving at 500 r.p.m. A range of 24 to 1,000 r.p.m. may be obtained if desired by revolving the speed box pulley at 600 r.p.m. These high speeds are made possible by the fact that every bearing, shaft or sleeve is supported by ball bearings. There are 12 feeds mounted in the head, covering a range of .004 to .060 in. per revolution of the spindle.



Carlton 7-ft. heavy duty radial drill with the column lengthened to take 8 ft. 3 3/16 in. under the spindle

The stump knee has been designed as a complete unit in a housing. The horizontal shaft with bevel gears is mounted with ball bearings at each end. The bevel gear which carries the vertical shaft is mounted on a steel sleeve which is supported on each end with ball bearings. A sight oil gage indicates the amount of oil that these gears should run in.

The cap contains only three gears which are mounted on steel sleeves and supported on each end with ball bearings. These gears transmit the power from the center shaft to the outside vertical shaft. This unit runs in an oil bath which is controlled by a sight gage.

The arm knee elevator fits on the back of the arm and carries the bevel gears which transmit the power from the vertical to the horizontal shaft. These gears are also mounted in steel sleeves supported on each end with ball bearings. The power for raising and lowering the arm is taken from this unit. The tumbler gears are made up in a unit and mounted in the arm knee elevator. These gears tumble in mesh with the gear on the vertical shaft which is constantly in motion for raising and lowering the arm. This unit also runs in oil and has a sight oil level gage.

The head on the arm has two holes bored parallel, one for the weight and one for the spindle. Both the spindle sleeve and the counter-weight have generated teeth their full length and both balance on a pinion gear which is mounted in ball bearings. The head is designed with a low hung drive, with the train of gears underneath the arm which drives the spindle off its largest diameter down close to the work. In order to overcome wearing the head bell-mouthed, the large driving gear is mounted on a large semi-steel sleeve mounted on the head in two large ball bearings. The spindle does not revolve on this sleeve but simply slides up and down in a double keyway and when it reaches its maximum travel of 18 in. it still maintains 7 in. of bearing in the sleeve, which is mounted in large ball bearings 18 in. apart. A pump in the head supplies oil to the gears and bearings.

The only part which connects the transmission to the head is the driving gear in the transmission to the driven gear mounted on the spindle sleeve. The bottom part of the transmission sets in oil in the bottom of the head. This unit contains the reverse for both the gears and their clutches, one for the forward drive and the other for reverse for tapping. The multiple clutch in the unit has seven driving discs in the forward drive and the same number in the reverse.

The outer column of the machine hangs on two ball bearings mounted on the top of the inner column, a large thrust bearing to take the weight and a large radial bearing to take the radial load of the swinging arm, together with roller bearings mounted on the bottom of the column. The clamping mechanism for binding the inner and outer column consists of a pair of eccentric wedges of crescent shape, mounted between the two columns. The column

can be locked either by a hand lever or a foot treadle as shown on the front of the base.

The arm binding levers point toward the operator and are eccentric on the binding end so that the operator pulls down on the lever to bind the arm and pushes up to release it. There is a mechanism in the arm to prevent the operator from trying to raise it while it is clamped. When the arm reaches its maximum travel at the top of the column, it is stopped automatically by a plunger and if it should meet any obstruction while being lowered, it again stops automatically. This is accomplished by a stationary screw and revolving nut. The screw hangs on a friction bearing at the top of the column. The revolving nut is mounted in ball bearings in the arm. The weight of the arm on the screw creates the friction to keep the screw stationary, but when the arm strikes or rests on any obstruction, it releases the weight of the friction and allows the screw to turn with the nut. The power for rotating this nut is received from the rear shaft through a set of hardened tumbler gears.

The variable speed motor is mounted in the arm with an 11-point rheostat directly connected to the head which gives 24 speeds. Variation of speed is obtained by revolving the pilot wheel just above the levers on the head. This attachment is mounted on the head and slides along the spline shaft in the rear.

Hose dismantling and assembling machine

THERE appeared on page 780 of the December, 1921, issue of the *Railway Mechanical Engineer* a description of one of the first hose dismantling and assembling machines made by the Covington Machine Company, Inc., Covington, Va. Since the publication of this description considerable improvement has been made in the machine.

The machine is designed for the single purpose of dismantling and assembling air, signal and steam hose used in railroad work. It is a self-contained, air-operated machine which needs no special foundation and can be set up on the shop floor under a shed or in any location convenient to an air line with from 85 lb. to 100 lb. pressure.

The changes in the design start with the frame *A*, Fig.

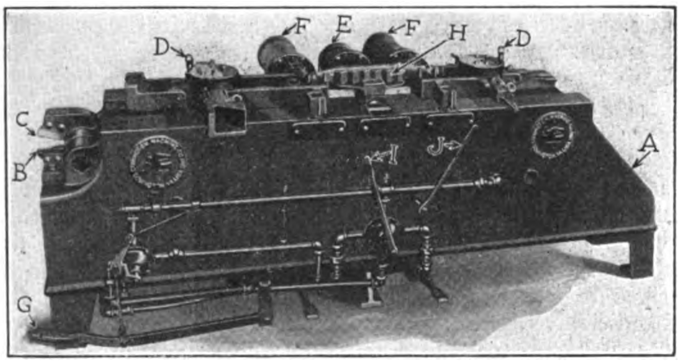


Fig. 1—Covington machine set to remove the couplings from both ends of the hose at one operation

1, which is made with cored openings in the top and out through the rear side, which allows the old metal parts when stripped from the hose to pass through the machine and drop into boxes. The knife block *B* and knife arm *C*, used for cutting the clamp bolts on the old hose, have been lowered below the top surface of the frame, allowing the sliding turret with the attached tools to pass over the top knife arm. Instead of a fixed sliding head, revolving turrets with all the dismantling and assembling tools mounted on them, have been mounted on the sliding crossheads. Thus, the tools are ready for instant use by simply removing the indexing pins *D* and revolving the turrets to bring the tools desired into working position.

A 6-in. clamping cylinder *E* has been mounted horizontally with the double pistons *F* for use when clamping old hose to be dismantled and holding new hose when assembling.

The methods of performing the various operations on the machine have been materially changed. The operations for stripping old hose are as follows: Referring to Fig. 1, the clamp bolts are first cut by the two knives *B* and *C* without injuring the hose clamps. The valve con-

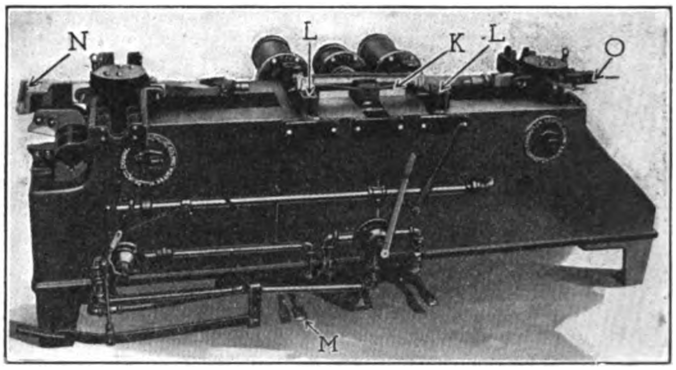

Fig. 2—Machine set for the first operation when assembling air or steam hose

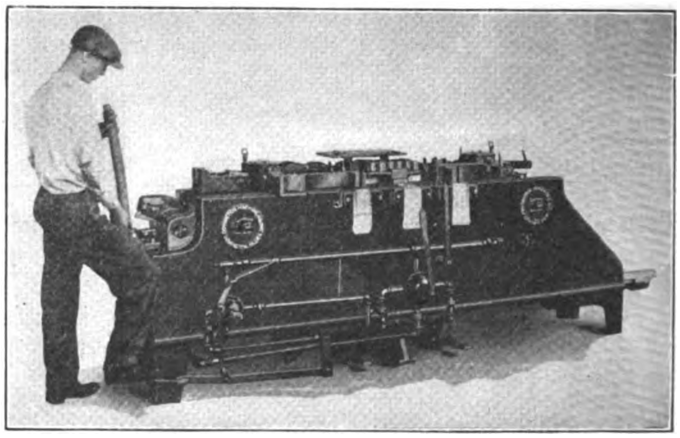
trolling this operation is operated by the foot treadle *G*, thus leaving both hands free to hold the hose.

The operator now moves to the front of the machine and throws lever *I* to the left which brings the turrets



Performing first operation of shearing the clamp bolts on the hose

carrying the pulling blocks toward the center of the machine. The hose is then dropped in between the clamping head *H* with the coupling end of the hose to the left in the puller block, the coupling being in the larger opening and the clamp in the smaller opening. The nipple end

rests in the right puller block with the nipple in the larger opening toward the turret center and the clamp in the other opening. The lever J is now thrown to the right, clamping the hose in the heads H. Lever I is then thrown to the right, which, by means of a series of air operated levers, moves the pulling blocks away from the center of the machine, stripping off the nipple, coupling and clamps which drop through the frame of the machine. Lever I is then moved back to the left releasing the hose. The nipple, or coupling ends of either air, steam, or signal hose are handled in the same way, with the tools mounted on the revolving turret head.

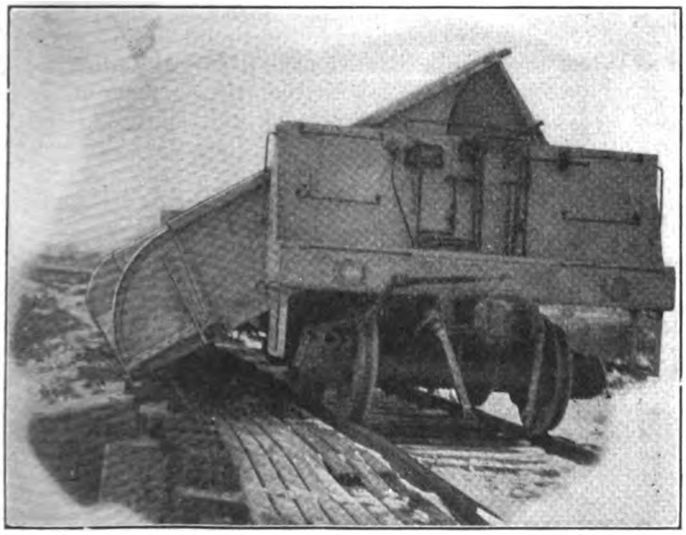
In assembling an air hose, a new hose is laid in the trough K, Fig. 2, with the fitting in each end and the two clamps loosely mounted. The heads L are brought toward the center of the machine by the operator stepping on treadle M, which squeezes the clamp around the hose while holding it in position. While holding the clamp in this position, the operator inserts a clamp bolt, puts on a nut and the hose is completely assembled. In assembling steam hose, the operation is exactly the same except that the assembler N is used for the coupling and the stem O for the nipple.

The speed of the machine depends on the operator's willingness to work. On test, one operator is said to have dismantled 240 standard air hose in 60 min., which is an average of one every 15 sec. The signal hose required a little longer time because of the small nipples, but 200 per hour were dismantled without trouble. The same operator assembled 55 standard air hose in 60 min. It required 60 min. to assemble 45 signal hose and 60 min. to assemble 35 steam hose.

Air dump car with traversing and tilting body

An air dump car with a capacity of 100,000 lb., a cubic capacity of 28 cu. yd. level full, or 43 cu. yd. with a normal crown load, has recently been placed on the market by the Differential Steel Car Company, Findlay, Ohio.

In dumping, the movement of the body is first a lateral movement across the underframe during which time the side folds down to the same plane as the floor. The body



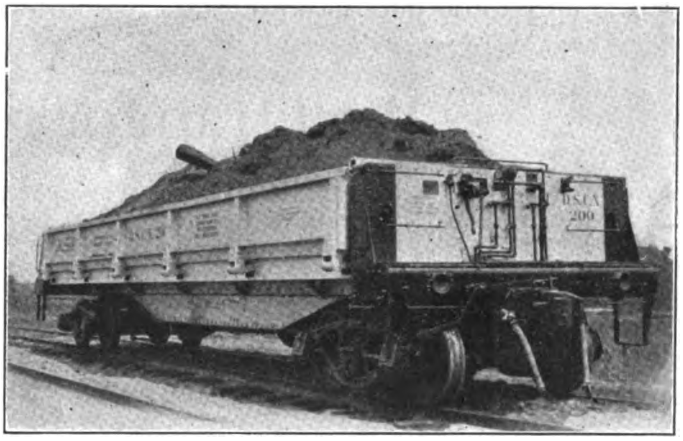
Differential dump car in the dumping position

then tilts and is balanced in all positions. The car is thus able to dump the material clear of the track. The dumping mechanism is so arranged that part of the load may be discharged without discharging the remainder, as it is easy to arrest the motion of the body at any desired angle and to bring the body back to the horizontal position. In this way material may be distributed when and where desired. It is equally as easy to dump to either side of the car as the air control lever governs the entire dumping operation which simply requires moving the control lever in the desired direction. There is no part of the car which offers any obstruction to the discharge of its load. This is particularly important in dumping large boulders where an obstructed opening would render discharge impossible. The floor of the car is perfectly smooth, with no projecting rivet heads or other obstructions which might impede the discharge of the load. The door is hinged in such a manner that there is always a sealed joint between the door and the floor. The door folds under the floor plate so that at no time is there a crack between the two.

The distance from the rail to the top of the sideboard is only 7 ft. This height may be further reduced for hand loading by the simple expedient of lowering the door, thus reducing the loading height to the floor level, which is about 4 ft. 6 in. above the rail. The operation of opening and closing the doors is executed by means of the air dumping mechanism. It is possible to operate the car on a pressure as low as 40 lb.

The dumping mechanism is provided with a mechanical interlock which keys the body to the underframe. This locking device operates as part of the dumping control. There is no chance of accidental dumping due to leaky valves or other causes.

The car is of all-steel construction, complies with A. R. A. standards, and is equipped with United States safety appliances. The body is supported on two lines of rollers



An air operated dump car with a traversing and tilting body

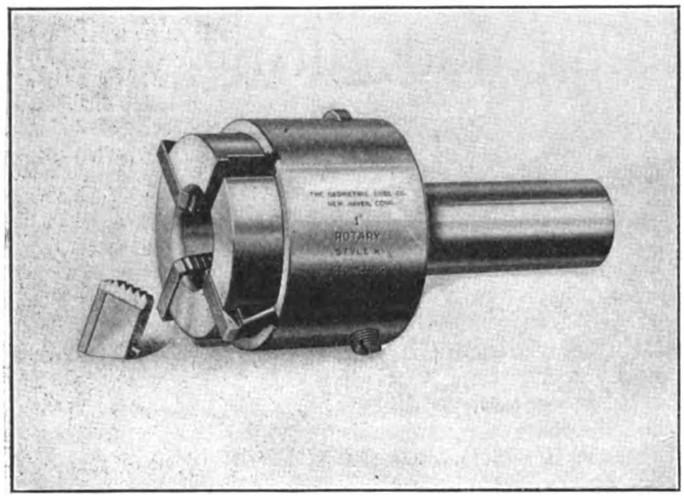
on 2-ft. centers and at 7-ft. intervals the full length of the car. These rollers operate in the raised sections of the floor. This method of support gives greater stability because the two lines of support are at about the same height as the center of gravity of the loaded body. It strengthens the floor of the car and renders the body much less likely to be damaged by heavy pieces of material being dropped into the car. These raised sections of the floor also serve as an excellent protection to the mechanism. The moving parts of the operating mechanism are

equipped with large bronze and graphite oilless bushings.

The car is dumped by means of a rugged air motor operating through a worm gear reduction, all enclosed in an oil-tight case. It is controlled by air and the control is so arranged that any number of cars may be dumped in a train from one car to either side in less than one minute. Any car may be locked so that it will not dump. An entire train may be dumped from the locomotive in either direction. The operator, standing on one of the cars of a train, can dump all cars ahead of him in one direction and all to the rear in the other. This control is universal so that any combination can be secured.

Rotary self-opening die head

The rotary self-opening die head shown in the illustration has been designed by the Geometric Tool Company, New Haven, Conn., with particular reference to the various types of multiple spindle automatics and other live spindle machines. Owing to its small diameter, it swings freely in the limited space afforded by many of the modern automatic screw machines.



Geometric Style K rotary self-opening die head

It is constructed in three units which are completely enclosed, thus keeping out dirt or chips from the mechanism. The opening and closing of the die head is effected by the forward and backward movement. It is designed so that the chasers project beyond the face of the die head, permitting threads to be cut to a shoulder without any adjustment, and also giving maximum chip clearance. All the working parts are ground, including the entire sliding surface of the slots in which the chasers are located.

The threading chasers, while in the cutting position, are rigidly supported on all sides and at the top; they are completely boxed in, except in the face, where the teeth are located. The wide slots in which the chasers fit allow them to be large in size, thus providing durability. The chasers can be instantly removed or replaced, for there is no removing of the face plate or screws in order to get the chasers in or out. This construction eliminates the necessity of lining up cam slots before the die head can be locked. Chasers for cutting left and right hand threads are interchangeable.

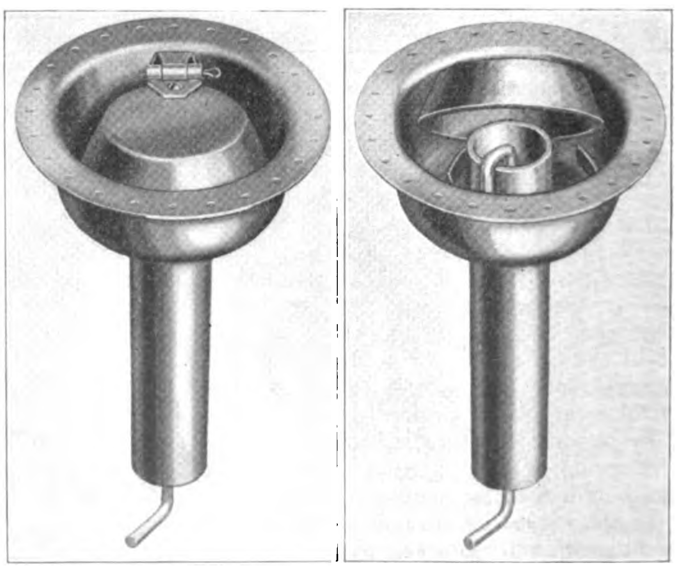
The die head is characterized by its simplicity in operation. When the spindle is advanced, a stop provided on the machine makes contact with the trip on the outside of the tool the moment the desired length of thread has been cut. This opens the die head. When the spindle is returned, the die head is closed by a yoke on the machine which makes contact with the rear of the die head closing sleeve.

This die head is known as Style *K* and is made to take the following stock sizes: 9/16 in., 1 in., 1¼ in. and 1½ in.

Well trap for refrigerator cars

A new well trap with permanently attached agitator has been developed for use in refrigerator cars by the Equipment Specialties Company, Chicago. The well trap itself is made of pressed steel and consists of a bowl and cap with a standard wrought iron overflow pipe, pressed into the bowl bottom flange and further secured by two ¼-in. hot driven rivets. The hinges are heavy and are well secured, being located where they can be readily inspected and the brass cotter pin easily applied. The drain is heavily galvanized and not likely to break owing to its pressed steel construction.

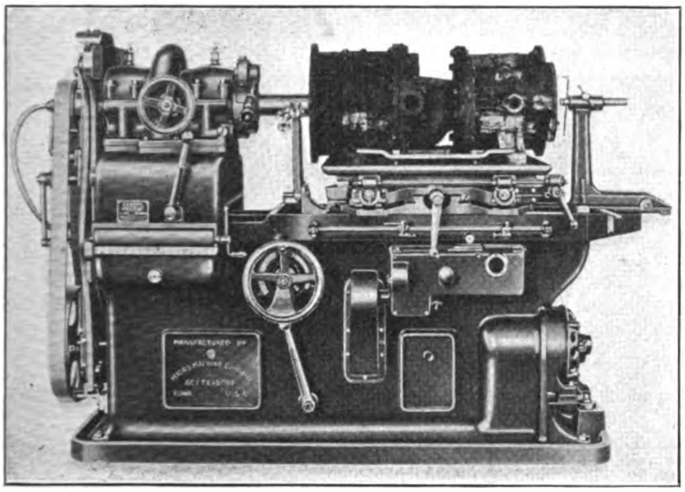
The agitator is a permanent part of the trap and is operated from the outside of the car. By its use the sediment or accumulation which collects in traps can be broken up and allowed to flow out of the overflow pipe, thus preventing the clogging of drains and flooding of car floors. The agitator reaches all parts of the bowl and is positive in effect. It also raises the flare-sided seal cap and further agitates the sediment. The cap of its own accord drops back into place and the water seal is again intact. Either a straight overflow pipe, or one with a 10-deg. offset from the vertical in order better to clear the journal box lid, can be provided.



Equipco well trap with cap closed and open to show the agitator

Internal grinder for railroad shops

THE illustrations show a new machine recently developed by the Micro Machine Company, Bettendorf, Iowa, and designed exclusively for grinding work in railroad shops. With suitable work-holding fixtures the machine will grind all bushing and pin holes in locomotive rods, running gear, air brake valve cylinders and similar parts. By means of a special swiveling table, air compressor cylinders can be ground



Micro internal grinder refinishing the worn cylinders of a cross compound air compressor

without unbolting them from the center castings and with the assurance when the job is done that the cylinders will be smooth, accurately round and without taper, and the axes in exact alinement, thus tending to prevent piston rod packing troubles and provide more efficient compressors. The standard range of the machine is 2½-in. to 10-in. holes, 13 in. deep. With special spindles, 1-in. to 15-in. holes, 19 in. or more in depth may be ground.

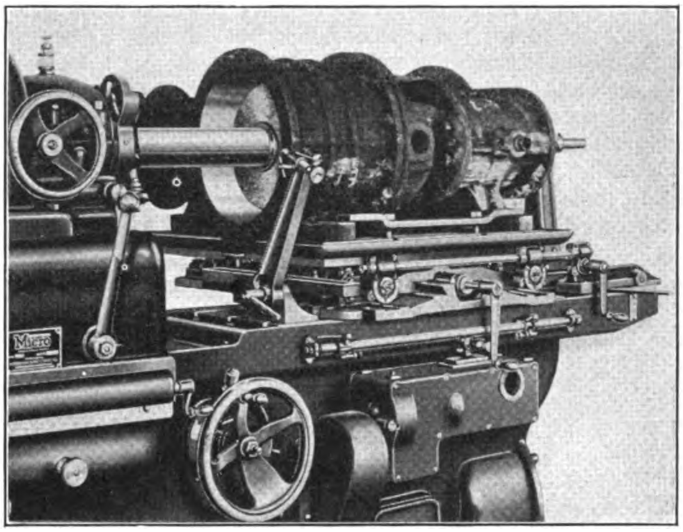
The Micro grinder has several new features of special interest. The driving motor and mechanism are a part of the machine, power being transmitted to the grinding spindle by a counterbalanced pantagraph arrangement which assures a constant speed of the grinding wheel without back lash of the belting and thus promotes more smooth, accurate work. By practically eliminating vibration from the source of power through to the finished job, maximum smoothness is assured.

An adjustable speed headstock is provided, enabling the correct relation between work speeds and wheel travel to be maintained. In determining the correct relation of these two variables, the builder conducted exhaustive experiments demonstrating that the orbital speed which is correct for a small hole is too rapid for a large hole and that, given the proper work travel, an unusual amount of stock (up to 1/32-in. in cast iron) may be removed in one cut regardless of the size of the hole. Orbital headstock speed control is one of the most important features of the new grinder.

The Micro grinder is equipped for wet grinding. During the operation, a cooling compound is forced through the center of the patented main spindle and centrifugal action throws it directly between the wall of the hole and the grinding wheel. By keeping the work cool distortion due to unequal expansion and contraction is prevented. The cooling compound then drains into a clarifier tank where all sediment and oil is removed assuring the delivery of clean grinding compound to the work.

Force feed lubrication is provided for both the headstock and the gear box. All oil holes are protected by filters to prevent dust and grit getting into the bearings, the lubrication being retained by special seals. There are five table feeds to take care of various depths of cut of the work. The eccentric feed can be made coarse or fine while the machine is in operation. For centering the work, rapid hand feed is provided.

The reverse gear box is an enclosed unit also provided with automatic force feed lubrication. The table change feed worm and gear box and all other running units are equipped with the Alemite system of lubrication. The drive for the machine consists of a 3-hp. motor located



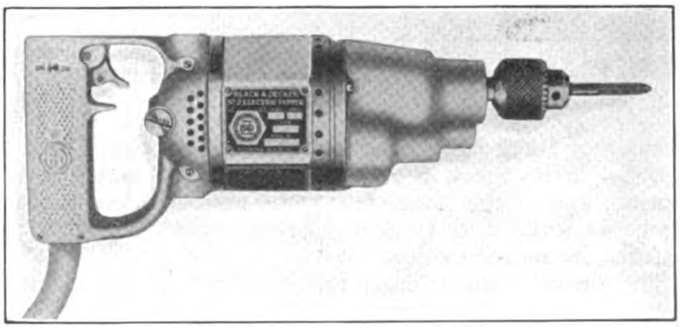
Close-up view showing compressor holder and swiveling table

in the rear end of the base and controlled by a friction clutch with a lever conveniently located near the operator on the front of the machine.

The Micro grinder is designed to combine precision and accuracy with a flexibility and ready change from one job to another which suits its demands.

Portable electric tapper

AN electric tapper with an automatic reverse is a recent addition made by the Black & Decker Company, Towson, Md., to its line of portable electric tools. It is similar in design and construction to the



Black & Decker electric tapper which has an automatic reverse

other electric tools made by the same company except that the mechanism in the gear case is so designed that

the tap is driven in at a speed of 350 r.p.m., by a slight backward pull on the machine, the tap chuck is automatically reversed and the tap backed out of the threaded hole at double the speed it is driven in, thus eliminating a reversing switch.

It is adapted to a wide range of work as it will tap holes in steel up to 1/4 in.; in cast iron, up to 3/8 in. and in brass or aluminum, up to 5/8 in. The machine weighs approximately 8 3/4 lb.

Melting furnace for soft metals used in railway shops

THE melting of soft metals for locomotive crossheads, driving boxes, etc., is an extensive practice in railway shops. A melting furnace adaptable to this class of work has been recently added to the line of gas furnaces and appliances manufactured by the Johnson Gas Appliance Company, Cedar Rapids, Iowa. It is fitted with a removable cast-iron melting pot with a capacity of 300 lb. of metal.

The pot has a removable lid and an outlet valve for drawing off the molten metal. The heating element

The Johnson 300 lb. capacity melting furnace

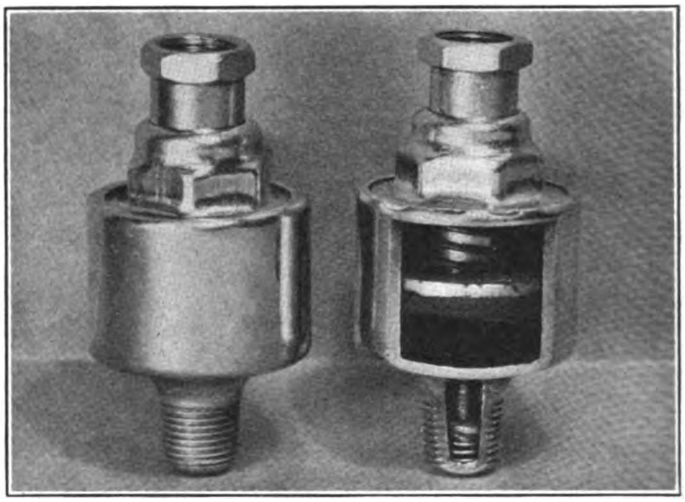
consists of three large direct-jet Bunsen burners. They are said to be equal to an air-blast outfit in rapidity of heating, and at the same time to be more economical in gas consumption and easier to operate which are desirable features for railway shops.

The furnace can be used for melting lead, tin, white metal, babbitt, solder scrap and all other low or medium fusion metals and alloys. It can also be used for cyanide hardening, oil tempering and the melting of various chemicals. The over-all height of the furnace is 31 in. and the weight complete is 185 lb. The gas consumption is 85 cu. ft. per hour.

National grease cup with an automatic feed

A GREASE cup designed to feed semi-liquid lubricants to shop machinery, elevators, shop trucks, etc., has been put on the market by the National Automatic Grease Cup Company, Chicago. This cup, which is substantially made, does not replace other lubricating systems, merely adding to them a reservoir containing sufficient semi-liquid grease or heavy oil for many hours of operation.

The cup does not require any special fitting for application as the top stem will accommodate any type of fitting. The position of this stem indicates when the cup is full or empty.



Automatic grease cup which is filled with a pressure gun

A uniform feed is obtained regardless of the pressure exerted by the spring on the main stem. The flow is controlled by a screw slot adjustment located in the lower shank of the cup. This slot is turned only in an anticlockwise direction. It is not necessary to remove any caps for filling as any type of pressure gun may be used for this purpose.

REPAIRING LOCOMOTIVE GUIDES.—An interesting exhibit was brought to the attention of railroad men at the National Railway Appliance Association's exhibition at the Coliseum, Chicago, recently. A new process for repairing locomotive guides was displayed, by means of which the General Electric Company claims to have eliminated all difficulties previously encountered in renewing these guides and keeping them up to I. C. C. standards.

The process used was electric arc welding automatically applied. The guides were placed in an ordinary lathe and the automatic welder was mounted on the tool post. When in operation, the guide remained stationary and the automatic welder traveled along with the carriage of the lathe, depositing electrode metal on the worn surface of the guide. The welding was applied on the side surface of the guide covering a width of 2 in., beginning on the inside and laying down adjacent beads, working to the outer edge. Two layers of beads were required to build up the worn spot, a total of 3/8 in. on each side. This was then machined away 1/8 in. on each side, leaving 1/4 in. finished built-up stock. The length of the built-up guide was 5 ft. A total of three hours was required for welding both sides using 150 amperes, 20 volts across the arc and 1/8 in. diameter electrode wire.

Figures obtained from a railroad now using this process indicate a saving of almost 50 per cent when automatic electric arc welding is used in preference to the oxy-acetylene process.

General News

Locomotive Inspection Bureau's February report

The Bureau of Locomotive Inspection in the month of February inspected 5,732 locomotives, of which 2,648, or 46 per cent, were found defective and 267 were ordered out of service, according to the Interstate Commerce Commission's monthly report to the President on the condition of railroad equipment. The Bureau of Safety during the same month inspected 96,249 freight cars, of which 3,803, or 3 per cent, were found defective, and 1,523 passenger cars, of which 27 were found defective. Twenty-two complaints, involving 50 violations of the safety appliance acts, were transmitted to various United States attorneys for prosecution.

Suit between Brown Instrument Company and Republic Flow Meters Company settled

The suit brought by the Brown Instrument Company in the Federal Court at Chicago against the Republic Flow Meters Company and certain individuals has been settled between the parties; also certain suits at law brought by the Republic Flow Meters Company and the same individuals in the same court against Richard P. Brown have been dismissed.

The officers of the Republic Flow Meters Company did not wish to be under the imputation of illegally using any of the original construction of the Brown instruments. It having been called to their attention that there were pending on behalf of the Brown Instrument Company patent applications covering some of these features, the Republic Flow Meters Company has changed the construction of its indicating and recording pyrometers for the purpose of avoiding infringement either of patents or of original design or construction of the Brown Instrument Company.

Wage statistics for 1924

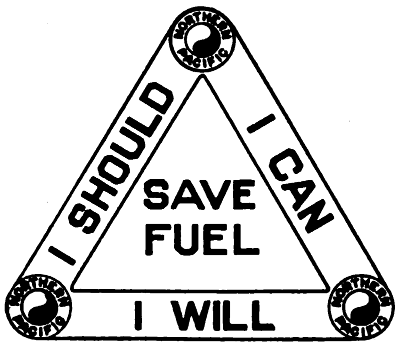
The Interstate Commerce Commission has issued a summary of railroad wage statistics for the twelve months ended with December, 1924, a consolidation of the monthly summaries heretofore issued, with certain minor changes.

The average number of employees reported for the year was 1,777,391, a decrease of 102,379, or 5.4 per cent, as compared with the preceding year. The total compensation was $2,867,564,802, a decrease of $175,596,361, or 5.8 per cent. Compared with the previous year, the average straight time hourly earnings for all employees reported on an hourly basis increased from 56.5 to 57.7 cents, and the average overtime hourly earnings increased from 76.8 to 80.4 cents. But owing to a reduction in the number of overtime hours worked, the percentage relation of overtime to total compensation decreased from 8.24 to 6.04.

The tables show, for employee groups: (1) the average annual compensation, the decrease in the average number of employees, and the increase or decrease in 1924, as compared with 1923; (2) the average straight time earnings per day or hour for the years 1924, 1923 and 1922, and last half of 1921; and (3) average earnings by districts for 1924. The reason for showing the last half of 1921 separately is that the present classification of employees became effective July 1, 1921. This is also the date of the general reduction in wages following the increases of 1920.

N. P. fuel economy slogan

"A scoop of coal dumped with the ashes in the clinker pit every time a fire is cleaned on a Northern Pacific locomotive would waste $15,000 a year. A single pound of coal wasted daily in each station stove would cost $7,000 a year. Savings in similar amounts may be effected with proper attention." So read the announcement of a fuel economy slogan contest open to every Northern Pacific employee, which ran from October 30 to December 10, 1924.



During the contest 2,100 slogans from nearly 450 participants were submitted. The winner of the first prize of $50 is J. J. Schmidt, chief yard clerk at the Fourth street yards, St. Paul, Minn. His slogan, accompanied by a triangular design about which the words are attractively grouped for display purposes, is shown in the illustration. B. M. Pederson, of the office of the auditor or freight receipts, St. Paul, was the winner of the second prize of $25. His slogan is "Coal, burn it as your own."

The slogan idea arose with the committee of the Northern Pacific representatives who attended the convention of the International Railway Fuel Association at Chicago last May. Practically every department on every division of the railroad was represented in the slogans submitted. The contest judges were C. L. Nichols, general manager; T. J. Cutler, mechanical superintendent, and M. M. Goodsill, assistant general passenger agent.

The first prize slogan will be used in the form of stickers and on envelopes, letter heads and engine equipment, including shovels. It will also be posted wherever coal is used on the railroad.

Figures as to installations and retirements prepared by Car Service Division, A. R. A., published in Form C. S. 56A-1. Figures cover only those roads reporting to the Car Service Division. They include equipment received from builders and railroad shops. Figures of installations and retirements alike include also equipment rebuilt to an extent sufficiently so that under the accounting rules it must be retired and entered in the equipment statement as new equipment.

Pere Marquette has correspondence course in efficient car handling

A correspondence course for the instruction of its employees in the principles of efficient car handling as established by the present car service and Per Diem rules was arranged by the Pere Marquette several months ago. The course is available to all employees regardless of their occupation and 282 have enrolled in it. Although some dropped out after a few lessons, a considerable number have consistently studied and reported on the lessons submitted.

The course consists of six lessons, each accompanied by a list of questions which are to be answered and returned before the succeeding lesson is released. The answers to these questions are carefully checked to determine whether the employee has correctly interpreted the facts as given in the lesson and all misunderstandings are corrected by letter. The subjects discussed in the six lessons are as follows: Lesson No. 1 covers the general theory of car distribution with tables showing the ratio of loaded and empty car miles to total car miles, the average number of cars on line per day and the average miles per car per day, with explanations of the various terms used and methods by which the comparative statements are arrived at. Lesson No. 2 quotes car service rules governing the handling of empty cars of connecting railroads and charts the junction points of the Pere Marquette with connecting lines. Lesson No. 3 explains the Pere Marquette's system of car distribution, directing attention to the geographical location of the lines, as well as to the different kinds of freight general office car records, manifest freight and car tracing, and handled in local territories. Lesson No. 4 explains the interchange report and the Per Diem rule. Lesson No. 5 discusses the Lesson No. 6 is devoted to car demurrage.

C. M. & St. P. military organization

The 609th Engineers' Battalion of the United States Army, the military railway organization on the Chicago, Milwaukee & St. Paul, now has its commissioned personnel up to full peace strength, with 18 officers for the four companies, a headquarters company, an operating company, a maintenance of way company and a mechanical company. The enlistment of additional men for the ranks is now in progress, seven men having been enrolled already. This is believed to be the first reserve organization of its kind to have its commissioned personnel up to full peace strength. Norman A. Ryan, division superintendent at Terre Haute, Ind., where the battalion headquarters is located, is the commanding officer of the unit. The organization of the commissioned personnel of the battalion is as follows:

609th engineers' battalion (C. M. & St. P. Ry.)

Name	Grade	Civilian Duty	Location
		Headquarters	
N. A. Ryan	Captain	Superintendent	Terre Haute, Ind.
I. C. Jordan	Captain	Staff of Vice-president	Chicago, Ill.
G. M. Hayden	Captain	Chief Dispatcher	Tacoma, Wash.
H. G. Bernard	1st Lieutenant	Dispatcher	Ottumwa, Iowa.
E. A. Lalk	1st Lieutenant	General Agent	Milwaukee, Wis.
J. G. Bruce	1st Lieutenant	Agent	Bozeman, Mont.
		Company A (M. of W.)	
C. F. Allen	Captain	Roadmaster	St. Maries, Idaho.
N. F. Podas	1st Lieutenant	Assistant Engineer	Minneapolis, Minn.
V. Hansen	1st Lieutenant	Chief Carpenter	Montevideo, Minn.
R. V. Cummings	2nd Lieutenant	Freight Department	Great Falls, Mont.
		Company B (Mechanical)	
E. Jones	Captain	Engineer	Spokane, Wash.
J. H. Hale	1st Lieutenant	General Foreman	Galewood, Ill.
H. Wallace	2nd Lieutenant	General Foreman	West Clinton, Ind.
R. C. Visger	2nd Lieutenant	Locomotive Engineer	Chicago, Ill.
		Company C (Operating)	
F. R. Doud	Captain	Chief Dispatcher	Bellingham, Wash.
E. Kiesele	1st Lieutenant	General Yardmaster	Dubuque, Iowa.
C. G. Ellis	2nd Lieutenant	Locomotive Engineer	Milwaukee, Wis.
C. G. Gepner	2nd Lieutenant	Night Chief Dispatcher	Terre Haute, Ind.

C. M. & St. P. in receivership

On March 18 a receivership for the Chicago, Milwaukee & St. Paul was established by Judge James H. Wilkerson, United States District Court, at Chicago, who appointed as receivers H. E. Byram, president of the C. M. & St. P.; Mark W. Potter, who recently retired from the Interstate Commerce Commission, and Edward Brundage, former attorney general of the State of Illinois. It was decided by the board of directors that in all probability the road would be unable to meet the $48,000,000 maturities due on its bonds on June 1. The causes contributing to the company's present difficulties are considered to be as follows:

1. The competition of the Panama Canal, which, by reason of the low freight rates between the Atlantic seaboard and the Pacific Coast, and also to the Far East, via the canal, has been heavily felt by all transcontinental lines, and particularly by the Chicago, Milwaukee & St. Paul because of the large percentage of its investment in the Puget Sound extension.

2. The depressed agricultural and business conditions of the past few years in the Northwest, where a large part of the company's traffic originates. Passenger earnings, which were $31,034,000 it 1920, were only $21,768,000 in 1924, due largely to motor vehicle competition.

3. The large increases in the cost of labor and materials and in taxes, which have not been offset by corresponding increases in rates or in volume of traffic.

4. The lack, for a number of years, of surplus earnings to apply toward necessary improvements, betterments, etc., the consequences of which are that the current position of the company is unfavorable, and that its equipment has suffered deterioration and is insufficient in amount.

Court decisions

Non-compliance with labor board decision held not a conspiracy.—The Supreme Court of the United States has affirmed the decree of the Circuit Court of Appeals, Third Circuit, 1 Fed. (2nd) 171, affirming the decree of the Federal District Court for eastern Pennsylvania, 296 Fed. 220, dismissing the bill of the Pennsylvania Railroad System and Allied Lines Federation No. 90 against the Pennsylvania. The issues involved the construction and application of Title III of the Transportation Act of 1920, and the controversy was a continuation of that considered in Pennsylvania v. Labor Board, 261 U. S. 72.

The bill in the present case was filed to enjoin what was charged to be a conspiracy by the Pennsylvania and its officers to defeat the provisions of the Act and deprive the employees of the rights with which the provisions of Title III of the Act intended to vest them in their dealings with the company; averring that in the effort to deprive them of their proper representation and maintain the plan of the company, the company resorted to coercion with threats of discharge, and further violated their rights by preventing a large number of employees who were furloughed from casting their votes in the election.

The whole issue in the case, the Supreme Court said, "is whether Title III in pointing out what Congress wished the parties to the dispute to do was intended by Congress to be a positive, obligatory law. * * * The Supreme Court has decided that there is nothing compulsory in the provisions of the statute as against either the company or the employees upon the basis of which either acquired additional rights against the other which can be enforced in a court of law.

"What the complainants are seeking to do," the court said, "is to enforce by mandatory injunction a compliance with a decision of the Board not based on the legal rights of the parties, but on its judgment as to what legal rights the disputants should surrender, or abate in the public interest and in the interest of each other, to maintain harmonious relations between them necessary to the continuance of interstate commerce, and to avoid severing those

Freight car repair situation

December	66,615	1,288,635	1,355,250
January, 1925	69,084	1,358,308	1,427,392

Data from **Car Service Division** reports.

relations as they would have the strict legal right to do. Such a remedy by injunction in a court it was not the intention of Congress to provide."

The complainants also sought damages on behalf of the members of Federation No. 90. First, for employees on furlough when notified to return on the scale of wages made effective by the company July 1, 1921, who refused to return except on the old scale prevailing September 1, 1920, and who sought wages though they did not work. Second, employees who worked under the company scale for a year and then struck, who claimed the difference between the old and new scales. Third, those who did not strike, but accepted wages on the new scale, who claimed the difference between the two scales till the filing of the bill.

The court did not find it necessary to consider these claims on their merits. "Even if the Federation No. 90 and its members as representatives in a class suit in equity could recover such claims as damages incidental to granting the main equitable relief prayed for, the denial of the prayer for the equitable relief and the dismissal of the main part of the bill carries with it such incidental claims without prejudice to their prosecution at law by individual claimants as they may be advised."—Pennsylvania System and Allied Lines Federation No. 90 v. Pennsylvania. Decided March 2, 1925. Opinion by Chief Justice Taft.

Meetings and Conventions

American Railway Association headquarters for London Congress

The American Railway Association will have headquarters for its delegates to the International Railway Congress to be held in London on June 22 to July 12 at the Hotel Cecil, the Strand, London. Representatives of railways which are members of the association are invited to make use of the facilities at the headquarters, which will include translations into and from the French, stenographic service, assistance with bookings and the like.

American Welding Society

The annual meeting of the American Welding Society will be held on April 22, 23 and 24 at 29 West Thirty-ninth street, New York. The tentative program for this meeting is as follows:

Wednesday, April 22.

9:00 a.m.—Resistance Welding Committee meeting.
11:00 a.m.—Gas Welding Committee meeting.
2:00 p.m.—Electric Arc Welding Committee meeting.
8:00 p.m.—Educational Committee meeting.

Thursday, April 23.

9:30 a.m.—Business session American Welding Society.
1:45 p.m.—Inspection trip to Bay Way plant, Standard Oil Company.
7:00 p.m.—Annual dinner, Park Avenue Hotel.

Friday, April 24.

9:30 a.m.—Technical session.

Symposium.

1.—Methods of inspecting welds.
2.—Testing the skill of operators.

12:00 m. —Luncheon Engineers' Club.
12:45 p.m.—Technical session continued.
2:00 p.m.—American Bureau of Welding.
3:30 p.m.—Board of directors, American Welding Society.

Annual meeting of the Mechanical Division, American Railway Association

The annual meeting of the Mechanical Division, American Railway Association, will be held at the Drake Hotel, Chicago, June 16, 17 and 18, 1925. This meeting is to be strictly a business meeting and is confined to members authorized to represent and vote for the railroads, and members of committees. There is no objection to any railroad sending such representative members as they may desire. The business to be taken up will be the consideration of and acting upon reports of the various committees. In addition, two or three individual papers on important subjects will be presented and discussed. All voting representative members of the railroads are urged to be present, in order that proper consideration may be given to all committee reports and subjects coming before the Mechanical Division and proper action taken.

Wood Preservers' Association

On account of the growth of the work of the American Wood Preservers' Association, the office of secretary has been divorced from that of secretary-manager of the Service Bureau and E. J. Stocking has been appointed secretary with office at 111 West Washington street, Chicago. P. R. Hicks continues as secretary-manager of the Service Bureau of the association with office at 10 South La Salle street, Chicago, devoting his full time to the work of that organization. The Executive Committee of the Wood Preservers' Association has also reconsidered the action taken at the annual convention relative to the location of the next meeting and has selected Cleveland for the convention which will be held on January 26-28, 1926.

The following list gives names of secretaries, dates of next or regular meetings and places of meeting of mechanical associations and railroad clubs.

Air-Brake Association.—F. M. Nellis, Room 3014, 165 Broadway, New York City. Next meeting May 26-29, inclusive, Alexandria Hotel, Los Angeles, Cal.

American Railroad Master Tinners', Coppersmiths' and Pipefitters' Association.—C. Borcherdt, 202 North Hamlin ave., Chicago.

American Railway Association, Division V.—Mechanical.—V. R. Hawthorne, 431 South Dearborn St., Chicago. Business meeting to be held in Chicago June 16, 17 and 18. No exhibit of railway supplies and machinery will be held.

Division V.—Equipment Painting Section.—V. R. Hawthorne, Chicago. Next meeting September, 1925.

Division VI.—Purchases and Stores.—W. J. Farrell, 30 Vesey St., New York. Next meeting May 19, 20 and 21, at St. Louis, Mo.

American Railway Tool Foremen's Association.—G. G. Macina, 11402 Calumet Ave., Chicago. Annual convention August, 1925, Hotel Sherman, Chicago.

American Society of Mechanical Engineers.—Calvin W. Rice, 29 W. Thirty-ninth St., New York. Railroad Division. A. F. Steubing, Bradford Corp., 25 West Forty-third street, New York. Spring meeting May 18 to 21, inclusive, Milwaukee, Wis.

American Society for Steel Treating.—W. H. Eiseman, 4600 Prospect Ave., Cleveland, Ohio.

American Society for Testing Materials.—C. L. Warwick, 1315 Spruce St., Philadelphia, Pa. Annual meeting, June 22-26, Chalfonte-Haddon Hall, Atlantic City, N. J..

Association of Railway Electrical Engineers—Joseph A. Andreucetti, C. & N. W., Room 411, C. & N. W. Station, Chicago, Ill. Annual meeting October 20-24, Hotel Sherman, Chicago.

Canadian Railway Club.—C. R. Crook, 129 Charron St., Montreal, Que. Regular meetings second Tuesday in each month, except June, July and August, at Windsor Hotel, Montreal, Que.

Car Foremen's Association of Chicago.—Aaron Kline, 626 N. Pine Ave., Chicago, Ill. Meeting second Monday in month, except June, July and August, Great Northern Hotel, Chicago, Ill.

Car Foremen's Association of St. Louis.—R. E. Giger, 721 North 23rd street, E. St. Louis, Ill. Meetings, first Tuesday in month, except June, July and August, at the American Hotel Annex, St. Louis.

Central Railway Club.—H. D. Vought, 26 Cortlandt St., New York, N. Y. Regular meetings second Thursday each month, Hotel Statler, Buffalo, N. Y. Next meeting April 9. Paper on billing in transit, mixing in transit and reconsigning will be presented by W. B. Errington, local freight agent, Nickel Plate, Buffalo.

Chief Interchange Car Inspectors' and Car Foremen's Association.—A. S. Sternberg, Belt Railway, Clearing Station, Chicago.

Cincinnati Railway Club.—W. C. Cooder, Union Central Building, Cincinnati, Ohio. Meetings second Tuesday, February, May, September and November.

Cleveland Steam Railway Club.—F. L. Frericks, 14416 Adler Ave., Cleveland, Ohio. Meeting first Monday each month at Hotel Cleveland, Public Square, Cleveland. Next meeting April 6. Paper on Oxy-acetylene process will be presented by G. C. Harcke. A film "Oxygen the Wonder Worker," will also be shown.

International Railroad Master Blacksmiths' Association.—W. J. Mayer, Michigan Central, 2347 Clark Ave., Detroit, Mich. Next convention, Hotel Winton, Cleveland, Ohio, August 18, 19 and 20.

International Railway Fuel Association.—J. B. Hutchinson, 6000 Michigan Ave., Chicago, Ill. Next annual convention May 26-29, Hotel Sherman, Chicago.

International Railway General Foremen's Association.—William Hall, 1061 W. Wabasha Ave., Winona, Minn. Annual convention September 8-11, Hotel Sherman, Chicago.

Master Boiler Makers' Association.—Harry D. Vought, 26 Cortlandt St., New York, N. Y. Next convention May 19-25, Hotel Sherman, Chicago.

New England Railroad Club.—W. E. Cade, Jr., 683 Atlantic Ave., Boston, Mass. Regular meeting second Tuesday in month, except June, July, August and September. Copley-Plaza Hotel, Boston, Mass. Next meeting April 14. A paper on purchases and stores will be presented by C. D. Young, Pennsylvania railroad.

New York Railroad Club.—H. D. Vought, 26 Cortlandt St., New York. Next meeting April 17. Prof. W. M. Daniels, Yale University, will speak on what branches of transportation technical schools and universities attempt to teach. Entertainment by B. & O. Glee Club.

Niagara Frontier Car Men's Association.—George A. J. Hochgreb, 623 Brisbane Building, Buffalo, N. Y. Regular meetings, January, March, May, September and October.

Pacific Railway Club.—W. S. Wollner, 64 Pine St., San Francisco, Cal. Next meeting April 9. Paper on Manufacture of Pure Iron, by T. Faw, California Corrugated Culvert Company, and a paper on the Reclamation of Railway Springs, by F. H. Pelle. E. F. Houghton Company, will be presented; also motion pictures illustrating the manufacture of pure iron.

Railway Club of Greenville.—F. D. Castor, clerk, maintenance of way department, Bessemer & Lake Erie, Greenville, Pa. Meeting last Friday of each month, except June, July and August.

Railway Club of Pittsburgh.—J. D. Conway, 515 Grandview Ave., Pittsburgh, Pa. Regular meeting fourth Thursday in month, except June, July and August. Fort Pitt Hotel, Pittsburgh, Pa.

St. Louis Railway Club.—B. W. Frauenthal, Union Station, St. Louis, Mo. Regular meetings second Friday in each month, except June, July and August.

Southeastern Carmen's Interchange Association.—J. E. Rubley, Southern railway shops, Atlanta, Ga.

Traveling Engineer's Association.—W. O. Thompson, 1177 East Ninety-eighth St., Cleveland, Ohio. Annual meeting September 15-18, 1925, Chicago.

Western Railway Club.—Bruce V. Crandall, 189 West Madison St., Chicago. Annual meeting May 23, Edgewater Beach Hotel, Chicago.

Supply Trade Notes

The Lehon Company, Chicago, has moved its New York office from 95 Liberty street to 60 Broadway.

The General Piston Ring Company, Indianapolis, Ind., has moved its plant and offices to Tipton, Ind.

The Hubbard Steel Foundry Company, East Chicago, Ill., is constructing a machine shop, 150 by 120 ft.

C. C. Fredericks, vice-president and general manager of the W. N. Matthews Corporation of St. Louis, Mo., has resigned.

C. R. Naylor, sales agent of Symington Company at 2108 Straus building, Chicago, has been appointed manager western sales.

The Standard Stoker Company has removed its New York City office from 5054 Grand Central Terminal to 350 Madison avenue.

The Jordan Machine Company, Minneapolis, Minn., will construct a one-story and basement machine shop addition 70 by 120 ft.

R. M. Taylor, assistant general manager of the Thomson Electric Welding Company, has resigned to go with Congoleum-Nairn, Inc.

The Woodman Railway Supply Company, Railway Exchange building, Chicago, has been incorporated to take over the sale of journal boxes, including the Joliet and Franklin boxes, formerly handled by the Northwestern Malleable Iron Company, Milwaukee, Wis. Officers of the new company are, president, G. A. Woodman, sales manager of the Northwestern Malleable Iron Company; vice-president and secretary, A. M. Talbot, vice-president of the A. H. Talbot Company; treasurer, A. M. Tufts, manager of the Commercial Utilities Company. Mr. Woodman was born in Dunkirk, N. Y., in 1866, and in 1883 entered the employ of the Brooks Locomotive Works as a machinist, later becoming a draftsman. In 1887 he was appointed mechanical engineer of the Milwaukee & Northern, now a part of the Chicago, Milwaukee & St. Paul, which position he held until 1889, when he returned to the employ of the Brooks Locomotive Works as a draftsman. From 1891 to 1895 he was a draftsman for the Illinois Central and in the latter year was appointed chief draftsman of the Lima Locomotive & Machine Company. In 1897 he was appointed assistant master car builder of Swift & Company, Chicago, which position he held until 1898 when he was appointed assistant superintendent of the American Car & Foundry Company, Chicago. In 1900 he became mechanical engineer in charge of production of the Kirby Equipment Company, Chicago, which position he held until 1912 when he became sales manager of the Northwestern Malleable Iron Company, with headquarters in Chicago.

G. A. Woodman

Charles A. Swan has been appointed assistant manager of steel sales at the Timken Roller Bearing Company, with headquarters at Canton, Ohio.

The Bettendorf Company, Bettendorf, Iowa, plans the construction of a three-story office building 76 ft. by 137 ft., to cost approximately $175,000.

The Welding Service & Sales Company, Donovan building, Detroit, Mich., of which T. M. Butler is manager, has been appointed agent in the Detroit territory for the Gibb Welding Machines Company, Bay City, Mich., for its arc, spot and seam welding machines.

A. H. Beale, president of the Lebanon Iron Company, Lebanon, Pa., has resigned to become president of the A. M. Byers Company, Pittsburgh, Pa.

The McGill Manufacturing Company, Valparaiso, Ind., has appointed the J. G. Pomeroy Company, San Francisco, Cal., its Pacific coast representative.

A. Van Hassel, secretary of the Magor Car Corporation, with headquarters at New York, has been elected also vice-president. The company's works are at Passaic, N. J. Mr. Van Hassel was born on November 12, 1889, in Paterson, N. J. He received his education in the grammar and high schools of that city. His first position was with the Rogers Locomotive Works. He subsequently entered the service of the Cook Locomotive Works in Paterson, N. J. Mr. Van Hassel became associated with the Magor Car Corporation in 1909, and served in various capacities until 1921 when he was elected secretary. Mr. Van Hassel is also assistant treasurer and assistant secretary of the National Steel Car Corporation, Hamilton, Ontario.

A. Van Hassel

The John H. McGowan Company, Cincinnati, Ohio, has bought the Twinvolute Pump & Manufacturing Company, Newark, N. J., builders of centrifugal pumps.

The National Malleable & Steel Castings Company, Cleveland, Ohio, has moved its Chicago sales office from 311 Railway Exchange to 501 Railway Exchange.

John Luther Nicholson, president of the Locomotive Firebox Company, with headquarters in Chicago, died on March 23 of pneumonia. Mr. Nicholson, who was born on June 25, 1875, in New York, was first employed at Chicago assisting his father, who was master mechanic on the South Side Elevated Railroad Company at the time of its construction. In October, 1895, he entered the employ of the Chicago & North Western as a locomotive fireman on the Wisconsin division. Later he worked extra in the same position on the Galena division. In July, 1902, he was promoted to engineman and in 1903 was promoted to assistant road foreman of engines on the Wisconsin division. He held this position until April, 1905, when he became associated with the American Locomotive Equipment Company, Chicago, to handle the sale of hollow arches for locomotives, of which he was one of the inventors. Later he entered business for himself to handle the sale of appliances which he invented. In 1918 he invented the thermic syphon and organized the Locomotive Firebox Company, taking charge of its manufacture and sales as president.

J. L. Nicholson

J. J. Flaherty, formerly in charge of welding for the Boston Elevated Railways, has been appointed director of sales of the Page Steel & Wire Company, with headquarters at Bridgeport, Conn.

The Yost Manufacturing Company, Meadville, Pa., has opened an office and warehouse at 25 South Jefferson street, Chicago, with H. S. Huncke in charge.

H. B. Warren, Cincinnati sales representative of the Thomson Electric Welding Company, has been made sales manager of the company, with office at Lynn, Mass.

E. H. Batchelder, Jr., Lytton building, Chicago, has been appointed western railroad representative of the varnish and enamel division of the Beaver Products Company.

The General American Tank Car Corporation and the General American Car Company have moved their general offices from the Harris Trust building to the Illinois Merchants Bank building, Chicago.

W. L. Bryson, formerly district manager of the Beaver Products Company, Kansas City, Mo., has been appointed manager of the St. Louis division of the Celotex Company, with headquarters in St. Louis, Mo.

H. F. Welch, in charge of railroad sales of the Niles-Bement-Pond Company, New York, has been appointed sales manager of the New York district. Mr. Welch will also continue to perform his former duties.

The Union Railway Equipment Company, Chicago, has discontinued its sales arrangement with Hope E. Scott & Co., Ltd., of Montreal, Que., and in future until further notice all Canadian business will be handled direct from the general offices, Chicago.

William Bonn, formerly assistant general sales manager of the auto body plant of the Pullman Company, has been appointed assistant general manager of the W. M. Laylor Company, railway sales representatives of the Zapon Company, with headquarters at Chicago.

W. R. Quinn, former manager of the fuel oil department of the Combustion Engineering Corporation, New York, has been appointed Pacific Coast agent, with headquarters at San Francisco, Cal. Mr. Quinn's territory will include Washington, Oregon and California.

Harry A. Flynn, who has served as general air brake supervisor of the Delaware & Hudson since 1904, has been appointed mechanical representative of the New York Air Brake Company in the New England territory, with headquarters at Boston, Mass. He succeeds N. A. Campbell, deceased.

C. E. Shearer has been appointed advertising manager of the Industrial Works, Bay City, Mich., and A. R. Olsen has been placed in charge of the art department. It was erroneously stated in the February issue of the *Railway Mechanical Engineer* that Mr. Olsen had been appointed advertising manager.

Allan M. Cullum has been appointed to the sales force of the Reading Iron Company, Reading, Pa. His headquarters will be at the general office of the company in Reading. R. I. Fretz has been placed in charge of marketing boiler tubes. Mr. Fretz formerly represented the Bethlehem Steel Company and the Midvale Steel & Ordnance Company for a number of years. He has been a student of metallurgy and metallography and spent some time in the Reading Iron Company's plant with a view to securing a working knowledge of its methods.

The Whiting Corporation, Harvey, Ill., has appointed new sales agents as follows: Snyder Foundry Supply Company, Los Angeles, Cal.; S. G. Elbe, Inc., 211 Tramway building, Denver, Colo.; Edward S. King, 306 Elmhurst building, Kansas City, Mo. Bradford H. Whiting, vice-president and general manager of the company, and president of its subsidiary, the Grindle Fuel Equipment Company, on account of ill health has resigned and severed his connections with these companies. Mr. Whiting has also given up his directorship in both companies.

Harry W. L. Porth, assistant master car builder of Swift & Co., Chicago, and president of the Chicago Car Foremen's Association died on March 2 in Chicago. Mr. Porth was born on January 18, 1889, in Utica, Kans. He entered the employ of Swift & Co. in April, 1912, as an engineer in the mechanical department at Kansas City, Mo. During the next few years he was promoted to assistant master mechanic and was transferred to the car department, Chicago, as a sub-foreman. In December, 1917, he was promoted to assistant master car builder, which position he held until his death.

Trade Publications

Pinch bug riveters.—Bulletin R-202, illustrating and describing Shepard pinch bug riveters, has been issued by the Hanna Engineering Works, Chicago.

Storage tanks.—A 12-page folder descriptive of cast iron storage tanks for all industries where storage and materials transfer are needed, has been issued by the Conveyors Corporation of America, Chicago.

Welding electrodes.—The characteristics and applications of three types of welding electrodes, designated as Types A, B and C, are described in a 16-page illustrated booklet, entitled "G. E. Welding Electrodes," which has been issued by the General Electric Company, Bridgeport, Conn. Brief instructions covering the use of each type are also given.

Machinery and tools.—General catalogue, No. 138, listing a complete line of machinery, tools, cutters, attachments, etc., has been issued by the Brown & Sharpe Manufacturing Company, Providence, R. I. Each piece of equipment is illustrated, and detailed descriptions as well as tabulated specifications and dimensions are given. The catalogue contains over 600 pages and is of a convenient pocket size.

Steel preservative paints.—A 24-page, illustrated booklet has been issued by Toch Brothers, New York City, which describes the various forms of steel preservative paints which this company manufactures. The text matter includes a detailed description of each of the various kinds of paints, the purpose for which it is best fitted, and the recommended manner of applying it. This subject-matter is indexed at the back of the booklet with general headings covering types of construction and character of surface. The illustrations show a variety of structures protected by the paints of this company.

Drinking water appliances.—Sanitary drinking water appliances manufactured particularly for railroad service by the Henry Giessel Company, Chicago, are described in a fully illustrated, 29-page catalogue, recently issued by this company. The catalogue is in loose leaf form so that new bulletins issued by the company can be readily included from time to time and the catalogue thus kept up to date. Sanitary drinking water coolers, filters, cooling apparatus and auxiliary appliance are described in the catalogue. A full page is devoted to the attractive monogrammed name plate which the company provides with all equipment.

Plibrico furnace lining.—The Plibrico Jointless Firebrick Company, Chicago, has issued a 36-page catalogue of standard filing size, 8½ by 11 in., a large section of which is devoted to the proper installation of monolithic furnace linings. This section, step by step, tells how monolithic linings should be installed. Another section gives the reasons for the superiority of this type of furnace lining over other and less modern types. Sections describe the use of this lining for furnace fronts, arches, side walls, and bridge walls in boiler furnaces and for heating furnaces, baking ovens, stills and other industrial furnace and miscellaneous applications. There is an interesting section on lining furnaces under oil-burning boilers.

Dump cars.—Facts covering three basic designs of dump cars: the first, a car of the lifting door type; the second, a car of the lifting door type in combination with an outward folding chute, and the third, a car with an outward folding door, making the door of the car when in a dumped position a continuous slope in conjunction with the floor, are contained in Catalogue D, a neatly arranged booklet of 22 pages which has been published by the Magor Car Corporation, New York. Each of these three basic designs, subdivided into different cubical and weight capacities, depending on the service for which they are required, are illustrated in both loading and dumping positions. Lists of specialties with which the cars are equipped and specifications accompany the illustrations. Inserted between each page of descriptive data are blue print drawings showing details of construction. The cars, which are of the automatic or hand operated type for standard or narrow gage roads, are built for railroad, mining, contractors or industrial service.

Personal Mention

General

Robert Draycott has been appointed traveling fireman of the Central division of the Central of New Jersey.

W. C. Smith has been promoted to assistant to the chief mechanical officer of the Illinois Central, a newly created position.

R. J. Howard has been appointed superintendent of shops of the Pacific Fruit Express at Colton, Cal., succeeding James King.

W. H. Bender, shop superintendent of the Missouri Pacific at St. Louis, Mo., has been appointed mechanical inspector, with the same headquarters.

George G. Lynch, chief draughtsman of the Atlantic Coast Line, has been appointed assistant mechanical engineer, with headquarters at Wilmington, N. C.

L. E. Cartmill, superintendent of shops of the Pacific Fruit Express, with headquarters at Los Angeles, Cal., has been promoted to assistant general superintendent of the car department, with headquarters at San Francisco, Cal.

E. L. Johnson has been appointed assistant engineer of materials and equipment tests of the New York Central, his former positon—that of engineer of service tests—having been abolished and its duties taken over by E. C. Hardy, general inspector.

H. S. Peck, train lighting maintainer of the Chicago, Milwaukee & St. Paul, with headquarters at Milwaukee, Wis., has been promoted to supervisor of locomotive and power plant operation, with headquarters at Chicago, a newly created position. Mr. Peck was born on March 27, 1889, at Roy, Mont., graduating from Montana State College in electrical engineering in 1911. He entered railway service as a draftsman, inspector and designer in the electrification department of the Chicago, Milwaukee & St. Paul, in which position he remained until the fall of 1917, when he entered the United States Army, serving in France on the technical staff of Chief of Engineers of A. E. F. Department of Construction and Forestry, until July, 1919. Mr. Peck re-entered railway service in the office of the general superintendent of motive power of the Chicago, Milwaukee & St. Paul, being appointed train lighting maintainer on January 1, 1924, which position he held until his recent promotion to supervisor of locomotive and power plant operation.

F. H. Adams, whose promotion to mechanical valuation engineer of the Atchison, Topeka & Santa Fe, with headquarters at Topeka, Kans., was reported in the February issue of the *Railway Mechnical Engineer,* was born on April 15, 1868, in Mississippi. He attended the University of Minnesota from 1885 to 1887, entering railway service in September of the latter year as a special apprentice on the St. Paul & Duluth, now a part of the Northern Pacific. He entered the service of the Gulf, Colorado & Santa Fe in February, 1891, in the office of the superintendent of machinery. He was promoted to engineer of shop extensions in November, 1901, and held that position until February, 1914, when he resigned to enter the Bureau of Valuation of the Interstate Commerce Commission. Mr. Adams returned to the Atchison, Topeka & Santa Fe in November, 1921, being assigned to special work in connection with the settlements with the Railroad Administration for under-maintenance of equipment during the period of federal control. He was later promoted to mechanical valuation assistant, which position he held until his recent promotion to mechanical valuation engineer.

Master Mechanics and Road Foremen

G. H. Warning has been appointed master mechanic of the Canadian National, with headquarters at Regina, Sask.

John B. Starbuck has been appointed road foreman of engines of the Sacramento division of the Southern Pacific, with headquarters at Roseville, Cal.

George B. Weller has been appointed assistant road foreman of engines of the Central division of the Central of New Jersey, with headquarters at Jersey City, N. J.

W. F. Laure, general foreman of the Illinois Central, with headquarters at Memphis, Tenn., has been promoted to master mechanic to succeed O. A. Garber, resigned to accept service with another company.

Henry C. Stevens has been appointed master mechanic of the Alamosa division of the Denver & Rio Grande Western, with headquarters at Alamosa, Colo. Mr. Stevens was born at Camden, S. C., on July 2, 1876. He attended the Waycross, Ga., high school and completed a mechanical course in the C-5000 class of the International Correspondence School of Scranton. He entered the Plant System shops as a machinist apprentice at Waycross in November, 1890. He then served as inspector of pumps and elevators from Savannah, Ga., to Jacksonville, Fla., on the Brunswick & Western, and as machine foreman at Waycross. In 1901 he became general foreman of the Atlantic Coast Lines at Montgomery, Ala.; in 1903, mechanical draftsman of the Gillon Machine Company at Waycross; in March, 1905, general foreman of the Montgomery district of the Mobile & Ohio, and in March, 1910, master mechanic of the Denver & Rio Grande at Alamosa. In March, 1918, he was transferred to the Burnham shops at Denver, Colo., serving as shop superintendent throughout the war period and the building of new shops at that point. He returned to the Alamosa division as master mechanic on February 15.

H. C. Stevens

Obituary

F. L. McClennan, foreman of the brass shop, rolling stock department, of the New York Central at West Albany, N. Y., died on February 20. Mr. McClennan entered the employ of the New York Central in March, 1901, as foreman of the brass shop.

John Howard, superintendent of motive power of the New York Central, with headquarters at New York, died suddenly on March 24. Mr. Howard entered the railway service as a machinist apprentice on the Pennsylvania at Renovo, Pa., and from 1883 to 1884 was successively machinist apprentice and locomotive inspector on the New York, West Shore & Buffalo (now a part of the New York Central) at Kingston, N. Y. From 1884 to 1891 he was foreman of the enginehouse of that road at Frankfort, N. Y. In 1891, he become general foreman; and in 1892 master mechanic of the River division of the West Shore at New Durham, N. J. He was promoted to superintendent of motive power and rolling stock of the Pennsylvania division of the New York Central at Corning, N. Y., in 1901 and, in 1902, became superintendent of motive power of the Western division of the same road at Depew, N. Y. From May, 1904, to November, 1904, he was superintendent of motive power and rolling stock of the Boston & Albany at Boston, Mass., and on November 1, 1904, became superintendent of motive power of the New York Central at New York.

Request for change of address should reach the New York office two weeks before the date of the issue with which it is to go into effect. It is difficult and often impossible to supply back numbers to replace those undelivered through failure to send advance notice. In sending us change of address, be sure to send us your old address as well as the new one.

Subscriptions, including the eight daily editions of the Railway Age published in June, in connection with the annual convention of the American Railway Association, Mechanical Division, payable in advance and postage free: United States, Canada and Mexico, $3.00 a year; foreign countries, not including daily editions of the Railway Age, $4.00. Foreign subscription may be paid through our London office, 34 Victoria Street, S. W. 1, in £ s. d. Single copy 35 cents.

The *Railway Mechanical Engineer* is a member of the Associated Business Papers (A. B. P.) and the Audit Bureau of Circulation (A. B. C.).

Railway Mechanical Engineer

Vol. 99 May, 1925 No. 5

Rational car inspection

Unquestionably the interchange inspection and terminal inspection of railway cars is of great importance. The methods of inspection are important, as are also the thoroughness and rapidity with which the work is carried on. Without adequate inspection, the safe movement of all passengers and passenger equipment, freight and freight equipment handled in train service, would be impossible. Therefore the business of inspecting cars is second to none in importance on the railroads and should attract to this service men of intelligence, keen perception and reliability, who have a full understanding of their duties and responsibilities.

The business of inspecting cars calls for the display of much judgment and good, sound common sense. How many times are cars delayed and material wasted because of too technical inspection and too much emphasis on the letter rather than the spirit of the law? Too technical inspection as opposed to rational car inspection is quite likely to be the rule after a wreck on the line has caused the inspection forces to be called to account, although the wreck is far more often caused by failure to observe defective parts rather than laxness in maintaining the rules. The demands for economical operation are fully as pressing in railroading as in any other line of business and therefore rational or reasonable inspection should at all times be the ideal toward which car inspectors strive.

A waste in gas cutting

Considerable credit for the development of good welding and cutting practice in this country must be given to the careful and conscientious experimental work which has been carried on in the railroad shops of this country. Practically every railroad has made it its business to try out all the various processes on practically every kind of metal and on account of the necessity for taking certain safety precautions, a large part of this experimental work has resulted in the standardization of methods and proper regulations for all the processes. There has been, however, little done towards the improvement of one phase of this work and that is the use of the torch for cutting scrap material. Undoubtedly, the largest proportion of this work is performed in cutting up scrap metal in the car repair yard and at the scrap dock, and for some reason there seems to be a tendency to give the least amount of thought and attention to the finer details of operation in this work. The cutter who is engaged in it necessarily operates under a number of disadvantages which prevent him from making the speed and maintaining the low gas cost which is possible under conditions where output is a more important factor. Perhaps the principal reason for neglecting this study of cutting scrap material is because it is scrap. There are instances where a considerable saving has been accomplished by devoting a reasonable amount of study to this particular phase of shop work. If your gas cutting costs are too high, perhaps you will find the wasted gas and wasted time in the scrap pile.

Safety is not enough

The periods at which the various parts of the air brake equipment require attention in order to keep them functioning properly have been very well established. Practically every railroad has instruction pamphlets, circular letters, etc., in force outlining the attention that should be given to different parts and stating the periods at which it should be given. Very little trouble is experienced where the instructions are followed closely, which indicates that this is the policy that should be followed in order to attain the desired efficiency. However, instances have occurred where the instructions were found to be at fault relative to the time assigned for periodic inspections.

It is well to keep in mind that the limits established by the Interstate Commerce Commission are limits beyond which the device is not permitted to remain in service. It is evident that there may be cases where the device will not be in good working condition for a considerable period of time before it reaches the condemning limits. For example, the Interstate Commerce Commission requirements for the capacity of an 8½-in. cross compound air compressor are that the pump must maintain 60 lb. main reservoir pressure, the air escaping from the main reservoir through an orifice 9/32-in. in diameter, and the speed of the pump not to exceed 100 strokes per minute at an altitude not to exceed 1,000 ft. This test, which is required every three months, merely determines the efficiency of the air end of the pump. The number of strokes, however, can be increased by leakage past packing rings, air valves, piston rod packing, and to some extent by carbonized ports and passages. An air compressor, other than the cross-compound, operating at its best is not economical in its use of steam as no means has been provided for utilizing the expansive force, and anything that causes an increase in the number of strokes necessary to maintain pressure is wasting fuel, even with the cross-compound air compressor.

Another example of a device that can cause considerable waste and a possible air brake failure, is the feed valve. An entire air brake equipment may be seriously affected by a feed valve which is not functioning properly. It gets out of order easier than other parts and considerably more depends upon its successful operation than, for example, a single brake cylinder.

There are too many air brake inspectors and repair men inclined to let repairs to their equipment go to the limits prescribed by law as being in a safe and suitable condition

for service. The majority of delays due to air brake defects can usually be traced directly or indirectly to the failure on the part of someone to do the thing which should have been done at the proper time. From the standpoint of economy it is essential that each part function properly in its relation to the other parts of the air brake equipment. The most successful way to prevent waste through the operation of air brake equipment is to see that the instructions require that attention be given to the various parts at periods estimated to secure efficient operation and not merely to comply with the law.

The Foreman's Job

Last fall the *Railway Mechanical Engineer* announced a competition for the best articles dealing with the opportunities and responsibilities of the foreman. The contest closed on December 1, 1924. The decision of the judges has been delayed for two reasons. In the first place the competition proved to be one of the most successful that we have ever held, judged on the basis of the number of manuscripts that were received. In addition to this, however, the grade of the material was high and some difficulty was found in classifying it and coming to a final decision as to the two prize winners. The articles as they were submitted to the judges had the names of the competitors and all identification marks removed and were designated by number. In checking up we find that the first prize of $50 goes to "Bill Brown." This is a nom de plume, the writer preferring, for various reasons, to keep his identity secret. We can say, however, that he is a superintendent of a large and one of the most successfully operated railroad shop plants in the United States. The second prize of $35 goes to John H. Linn, assistant supervisor of apprentices, Atchison, Topeka & Santa Fe, Topeka, Kans. No third prize was offered, but at the suggestion of the judges we are adding a third prize of $25 for the contribution submitted by J. W. Murphy, the general foreman of the Boston & Albany at West Springfield, Mass. Several of the other articles crowded the prize winners pretty hard and these will be published during the coming months, particularly since they present more or less widely varying viewpoints. The first prize article will be published in our June number and will be accompanied by the results of a study which we have been making as to the practices of the various railroads in coaching and training the foremen to develop their leadership ability. A study of the articles which were received in the competition indicates that a very widespread and deep-seated interest is being shown in this question.

A maintenance department for motor cars

The utilization of the rail motor car for handling traffic on lines where business is light has already passed the experimental stage on a number of railroads. The Chicago Great Western has been among the leaders in adopting the motor car for this type of service and the mechanical department of this road has made special efforts towards solving the problem of maintenance on this particular type of equipment. The reader can gain considerable information relative to motor car maintenance from the abstract of a paper published on another page of this issue, by E. J. Brennan, superintendent of motive power, Chicago Great Western, Oelwein, Iowa, which was read before the Minneapolis section of the Society of Automotive Engineers. The Chicago Great Western has found it necessary to develop a gas engine department for the care of its motor cars and this department is in a great degree responsible for their successful performance. The gas car organization includes a motor car expert who is on the immediate staff of the superintendent of motive power and his jurisdiction extends over the entire system. It is his business to see that the cars are properly maintained and that the enginemen who want to qualify as motor car operators are properly instructed. The main shop at Oelwein has a gas engine repair organization for performing heavy and medium repairs, consisting of a foreman and several mechanics, helpers and apprentices who are engaged in gas engine work entirely. Light repairs on cars laying over at the engine terminal are performed by a specially trained gas engine mechanic. The Chicago Great Western is now considering the building of a separate repair shop somewhat removed from the main locomotive repair shops, owing to the fire hazard existing in motor car maintenance.

It is well to bear in mind that as new equipment of this type is purchased it must be maintained. The principal reason for buying motor equipment is to reduce operating expense and it is the job of the mechanical department to see that the expense of maintenance is kept at a minimum. This can be done if the responsible mechanical department officers make it their business to see that proper steps are taken towards placing the work of maintenance on the right basis at the beginning so that it can be developed as the number of motor cars increase. It is harder to reorganize a system which has been allowed to develop in a haphazard manner than to see that the work is properly organized at the start.

Attend the Fuel Association convention

The first of the important railroad mechanical meetings with which the convention season will open this year is that of the International Railway Fuel Association, to be held in Chicago, May 26-29. The program for this convention, which is published elsewhere in this issue, marks a unique undertaking in respect to the scope of topics to be considered and in an arrangement of subjects that serves to emphasize the relation of operating, mechanical and purchasing departments to fuel conservation. Of these departments, the mechanical is most closely identified with fuel use and can probably make the greatest contribution toward fuel conservation. The magnitude of railway fuel expenditures and opportunities for economy in fuel use are so large on all railroads that every mechanical officer should take an interest in the activities of an association devoted to railway fuel conservation.

Many mechanical officers other than those directly affiliated with fuel organizations will benefit by attending this convention. In this class there is no one man, other than the chief mechanical officer, who can individually control fuel use to a greater extent than the mechanical engineer through attention to details in design, and insistence upon standards that are essential to economy. If tests are conducted under the jurisdiction of the mechanical engineer this affords a further opportunity for promoting fuel efficiency by analytical study and judicious selection of efficient equipment. It will be noted that the convention program referred to includes a number of individual papers and reports by mechanical and test engineers on subjects relating to equipment that affects fuel use.

The first report on Diesel locomotives to be presented before a technical association in this country will be included in the proceedings of the Fuel Association together with a discussion of this development from an operating and fuel standpoint.

Incidentally, it will be observed that the practice in

regard to fully scheduling subjects and discussions followed by some of the leading technical societies will be adopted for the first time by a railway association and it is hoped that this innovation will prove successful as there is no doubt but that the proceedings at a majority of conventions could be made to cover a wider field more effectively by strict adherence to a systematic division of time between the topics to be considered.

Other classes of mechanical department employees, besides those included in the fuel organization, who would benefit particularly by attending this convention, are the roundhouse foremen, road foremen and master mechanics. It is understood that one railroad will make an especial effort to have as many roundhouse foremen as possible attend this convention knowing that these men are in a position to effect large fuel savings by the attention given to maintaining motive power and the manner in which this equipment is handled at the terminals. The International Railway Fuel Association was the first to inaugurate a committee on locomotive feed water heaters and subsequent reports of this committee have shown to what extent the efficiency of this device is influenced by the maintenance attention it receives at terminals. This is one of the subjects to be considered at the approaching convention and in addition to this, the committee will have information of interest to roundhouse foremen on the fuel cost of firing up locomotives at terminals and methods employed.

To the man in the fuel department who is identified with a mechanical organization, the work of this Association is indispensable and the program for this year's convention contains an unusual number of items of vital educational value. To the man in the operating department, the paper "How Can Railroad Management Affect Fuel Economy?" by A. R. Ayers, assistant general manager of the Nickel Plate, will perhaps be of most interest. Purchasing and stores officers responsible for placing orders for railway fuel will doubtless find much food for constructive thought in the paper by H. C. Pearce, director of purchases and stores of the Chesapeake & Ohio, "How Can Fuel Purchases Effect Economy?" The way in which mechanical officers can influence fuel economy will be discussed by John Purcell, assistant to the vice-president of the Atchison, Topeka & Santa Fe.

Turn to the International Railway Fuel Association convention program presented elsewhere in this issue and study it carefully. You will probably decide that in the interests of your road and your own mental improvement, you cannot afford *not* to attend this carefully planned, constructive and instructive convention. The opportunity to study at first hand the many fuel saving devices and equipment to be shown at the accompanying exhibition will alone be worth the cost of the trip to Chicago.

New Books

Technical Mechanics, Statics, Kinematics, and Kinetics. *By Edward R. Maurer, Professor of Mechanics, and Raymond J. Roark, Assistant Professor of Mechanics, University of Wisconsin. 364 Pages, 6 in. by 9¼ in., with Illustrations and Diagrams. Price $3.50 Net. Published by John Wiley & Sons, Inc., New York.*

Written primarily as a text book for engineering students, the authors have succeeded in handling what is generally conceded to be a subject requiring close application on the part of the reader in an interesting manner. Considerable pains have been taken in distinguishing the difference between theoretical and applied mechanics. The former is divided into statics, which treats of the relations between forces that act on bodies at rest; kinematics, which treats of motion, or the manner in which things move without regard to the cause of their motion; and kinetics, which treats of the effect of forces in producing or modifying motion. The explanations of the various factors entering into the body of exact laws and principles, comprising theoretical mechanics, that have been mathematically deduced from certain fundamental facts are unusually clear and are well illustrated with numerous diagrams, based largely on practical applications. The utilization of the various laws and principles of theoretical mechanics in the solving of practical problems in applied mechanics, is explained by problem or illustration in each case. The problems and illustrations have evidently been selected from such as should already be known to the student through past experience, though probably in a more general and qualitative, rather than in a precise and formal way.

The book is divided into 14 chapters, with two appendices and a section devoted to problems. The first seven chapters are devoted to the general subject of statics, which discusses the subjects of forces and force systems, composition and reduction of forces, forces in equilibrium, simple structures, friction, center of gravity; centroids, and suspended cables. The subject of kinematics is divided into two chapters on the motion of a point and the motion of a rigid body. The last chapter in the section includes a discussion of relative motion. Chapters 10 to 14 inclusive are placed under the general head of kinetics, and are divided under the following sub-heads, i.e.; fundamental facts; kinetics of a particle, kinetics of a body, work, power, energy, momentum and impulse, and the dimensional motion of a rigid body. Appendix A is a discussion of the theory of dimension of units and Appendix B is on the moment of inertia of wheels.

What Our Readers Think

Further comment on floating bushings

Peru, Ind.

To the Editor:

In your April issue appeared a letter from S. J. Stark, general roundhouse foreman, International-Great Northern, San Antonio, Tex., regarding the advantages of the floating bushing. The Federal inspection of locomotives at the present time is quite exacting and is becoming more so each year, and there are times when it is a struggle to get power when it is badly needed. The brasses in solid rods are held in position by a press fit and keeper bolts. This has been the practice for about 40 years, about the length of time that solid rods became universal in the United States.

With the modern Mikado type locomotive, it takes about 24 man-hours to apply a set of rod bushings. The brass alone, not counting the labor for machine work, costs about $150. If the keeper bolts are lost, the bushing will move in the rod and this usually results in a damaged pin or a cut bushing, because the lubrication is cut off from the pin. If the rod moves as much as ¼ in. on the brass, it constitutes a Federal defect and I might mention that no keeper bolt ever held a bushing in place if the bushing was loose in the rod.

We have a bearing on the Wabash that can be applied to a set of rods on a Mikado type locomotive in two hours without removing the rods from the pins. The cost of the

brass in this bearing does not exceed $50, and it is impossible to get a Federal defect from side play. The lubrication is positive at all times as provisions have been made for a reserve supply of grease in the rod. Recently a bearing was changed on one of our Pacific type locomotives in seven minutes. I know that many old shopmen will say that this is impossible, but it was done, nevertheless. This type of floating bushing has been applied to a number of Wabash locomotives and they are giving excellent results.
J. E. Allen.

The advantages of floating bushings

Brownwood, Tex.

To the Editor:

I read the letter from S. J. Stark in your April issue asking what advantages have floating bushings. I am of the opinion that the floating bushing was designed to reduce the cost of labor, reinforce the rods, eliminate the old strap and to reduce engine failures. It is claimed that 75 per cent of the engine failures are due to rod defects. Taking this into account, we also find that there is another item to consider and that is the fact that main crank pins will wear out of round as the bushing becomes worn. It is evident that all enginehouses ought to be equipped with devices for turning crank pins.

If we figure the extra cost, I don't think a very large percentage has been gained. I do not wish to condemn the floating bushing idea, but I merely am stating the facts resulting from my experience along this line of work.

I would also like to suggest to the mechanical engineers that some device should be designed to overcome this defect on pins, such as using a sliding flanged brass, split in half with heavy wedge blocks. It seems to me that such an arrangement is worth consideration.
B. G. Miller.

More mechanical supervision

Chicago.

To the Editor:

The mechanical department on our road has to a considerable extent organized along the lines suggested in the editorial, "More specialized men needed," published in the February *Railway Mechanical Engineer*, page 74. The executives in charge of many railroads, who have had ample time to analyze carefully maintenance of equipment problems, will recognize the value of a thoroughly specialized organization composed of men particularly selected on account of their experience, training and ability to handle a definite section of the organization which keeps railroad equipment in condition to give efficient service.

Officers in charge of railroad mechanical departments, so far as I have been able to learn, are seldom overpaid and in many instances their salaries are much lower than those accorded men holding equal or less responsible positions in other industries. The one hopeful feature for the mechanical officer, I would say, is the fact that railroad executives are of late years recognizing to a greater extent than ever before the possibilities for better and more economical service. They are providing more adequate facilities and equipment, even though progress along this line appears to be slow. Some intangible thing about railroad work is extremely fascinating, and this undoubtedly answers the question why railroad companies are able to hold competent men as they do when attractive offers come from other industries.

The difficulty in retaining the right caliber of men will doubtless force a change in the general aspect of the situation as experienced in the past, and it may be that the modification in viewpoint mentioned will carry with it a demand for a different type of mechanical officer and remuneration commensurate with the ability to obtain greater real results.
Superintendent of Motive Power.

Bronzing driving boxes

A question

Topeka, Kansas.

To the Editor:

In this shop we occasionally have difficulty in getting the brass liners on the shoe and wedge faces of driving boxes to lay down tight against the box. They are cast on, the box receiving two crosswise dovetail slots on the planer before it is sent to the brass foundry. In the foundry the box is not heated nor tinned but the brass is poured on the box cold. I think tinning should be considered only as a last resort as it would be quite expensive to tin all the boxes before casting on the liners. We find the brass lays down a little better on a new box than it does on an old, greasy one. Possibly the experience of some of your readers would be of assistance to me in the solution of this problem.
A Foreman.

The answer

Portsmouth, Ohio.

To the Editor:

In reply to an inquiry from one of your readers relating to bronzing the shoe and wedge faces of the driving boxes, if he will dovetail the driving boxes as described in an article on driving box work by the writer, which appeared in the September, 1924, *Railway Mechanical Engineer*, instead of crossing the dovetail grooves he will not only get better results but will be able to do the job much more quickly. Less than two per cent of our brass liners work loose on driving boxes.

In doing this work, the old bronze is stripped off the driving boxes and the grooves and anchor holes are cleaned of all pieces of the old bronze. The boxes are then sent to the bronze shop, where they are heated with a special torch using kerosene or crude oil, heating both sides of the boxes at one operation. This burner or heater is made of one 2-in. pipe drilled with 1/32-in. holes 4 in. apart, much the same as a tire heater would be made except that it is made to fit the boxes. It is not necessary to get the boxes very hot. After they are heated, the bronzing jig shown in the above mentioned article is placed on the box and the bronze poured on one side and then the other side. The jig is then removed and the box allowed to cool gradually.

We find that it is not good practice to put this bronze on too thin. Not less than ½ in. of bronze should be applied to a box, ⅛ in. of this for finishing, leaving about ⅜ in. of bronze after the boxes are machined. Several anchor holes should be drilled in each side of the box in addition to the dovetail grooves. You will note that the sketch referred to shows two dovetail grooves tapering together at the top; that is, the grooves are much closer at the top of the boxes than at the bottom. This also has a tendency to keep the liners tight should they show any signs of getting loose.

If these instructions are followed, I am sure there will be an improvement in the application of the bronze liners to the shoe and wedge faces of driving boxes.
J. H. Hahn,
Machine shop foreman, Norfolk & Western.

Long locomotive runs on the C. B. & Q.

Greatest economies are made in fuel and enginehouse expense—Savings exceed nine thousand dollars per month

PASSENGER locomotives of the Chicago, Burlington & Quincy were run through from Chicago to Burlington, Iowa, as early as 1911. However, the first regular long engine run on this road was put into effect in freight service between Alliance and Ravenna, Neb., in December, 1920; a passenger run between Wymore and McCook, Neb., was inaugurated in March, 1922; and in May, 1923, the first Burlington locomotive hauled train No. 2 from Denver, Colo., past three intermediate terminals to Lincoln, Neb., a distance of 485 miles and one of the longer coal-burning locomotive runs now regularly made.

In the past two years long engine runs have been extended quite generally over the Burlington System, giving the road an extensive experience which, under varying conditions, has demonstrated the value of this method of securing greater and more economical service from its motive power. On the system as a whole, the monthly and yearly savings and the number of locomotives released for other service are as follows:

System savings, freight and passenger service, due to long runs

	Monthly saving	Yearly saving	Engine released for other service
Lines East	$5,889	$70,668	17
Lines West	3,537	42,444	13
Total	**$9,426**	**$113,112**	**30**

These savings have been made possible by the co-operation of all departments, and also to some extent, from a mechanical point of view, by the substitution of Hulson grates for the common finger grates formerly used. With certain of the bituminous mine-run coals burned on the Burlington, 200 miles has been about the practical limit which a locomotive equipped with finger grates could run, owing to the accumulation of excessive quantities of clinker and ash. Tests have shown that with the new grates and the exercise of reasonable care on the part of firemen, these conditions are prevented and fires can be kept well beyond the mileage limit established by other considerations.

Experience on the Burlington indicates that the extension of locomotive runs over two or more divisions has practically no bearing on the cost of repairs per mile, but that real economies are to be found in the more intensive use of locomotives, the saving of enginehouse expense at intermediate terminals and in fuel economy. Moreover, the release of certain engines has permitted a reassignment of motive power to runs where it can give a more efficient performance. For example, quite a number of engines designed primarily for freight service were used on passenger trains until the inauguration of the long runs enabled them to be released.

Principal dimensions of Burlington engines used in long runs

	0-1-A	S-1	S-2	S-3	B-1
Wheel arrangement	2-8-2	4-6-2	4-6-2	4-6-2	4-8-2
Tractive force	52,300 lb.	37,200 lb.	37,200 lb.	42,200 lb.	52,750 lb.
Grate area	58.8 sq. ft.	54.2 sq. ft.	54.2 sq. ft.	58.7 sq. ft.	78.0 sq. ft.
Total square feet heating surface	4,145 sq. ft.	3,699 sq. ft.	3,680 sq. ft.	4,115 sq. ft.	5,629.7 sq. ft.
Weight on drivers	214,550 lb.	150,000 lb.	153,100 lb.	171,300 lb.	235,500 lb.
Weight of engine	272,300 lb.	228,000 lb.	236,100 lb.	269,200 lb.	350,000 lb.
Total weight engine and tender	467,300 lb.	376,200 lb.	396,400 lb.	432,740 lb.	555,450 lb.
Cylinders	27 in. by 30 in.	22 in. by 28 in. and 25 in. by 28 in.	22 in. by 28 in. and 25 in. by 28 in.	27 in. by 28 in.	27 in. by 30 in.

All of the long engine runs, both passenger and freight, now being made on the Burlington are shown in Tables I and III, the savings being given in Tables II and IV. The locations of the various terminals are indicated in the map which also shows how generally the long runs are distributed over the entire Burlington system.

There are six trains (Nos. 47, 48, 49, 50, 51 and 52) between Chicago and St. Paul, Minn., making a total of 2,586 miles a day. Formerly these trains were handled by nine locomotives which number has now been reduced to seven. This has saved two locomotives and increased the average miles per day for these locomotives from 276 to 369, or 93 miles.

Between Burlington, Iowa, and Lincoln, Neb., there are six trains (Nos. 2, 3, 5, 6, 9 and 12) making a daily mileage of 2,070. Formerly handled with thirteen locomotives, these trains are now handled with nine locomotives, releasing four for other service. The average daily mileage per locomotive has increased 71.

On the Nebraska district 10 trains (Nos. 3, 5, 9, 15, 17, 2, 6, 14 and 16) make a daily mileage of 4,189. Prior to extended runs, 25 locomotives were used in this service, making the average daily mileage per locomotive 167. Under the new system 18 locomotives are being used, increasing the average daily mileage per locomotive to 233, or an increase of 66. These are but a few selected long runs. On the road as a whole the inauguration of long engine runs has increased the average daily mileage of the passenger locomotives involved, by 72 miles, as shown in Table V, resulting in the release of 23 locomotives for other service. The total daily train mileage made is 14,607.

Reference to Tables I and III will indicate the preponderance of passenger over freight locomotive runs. Long runs are being inaugurated in freight service, however, as fast as practicable.

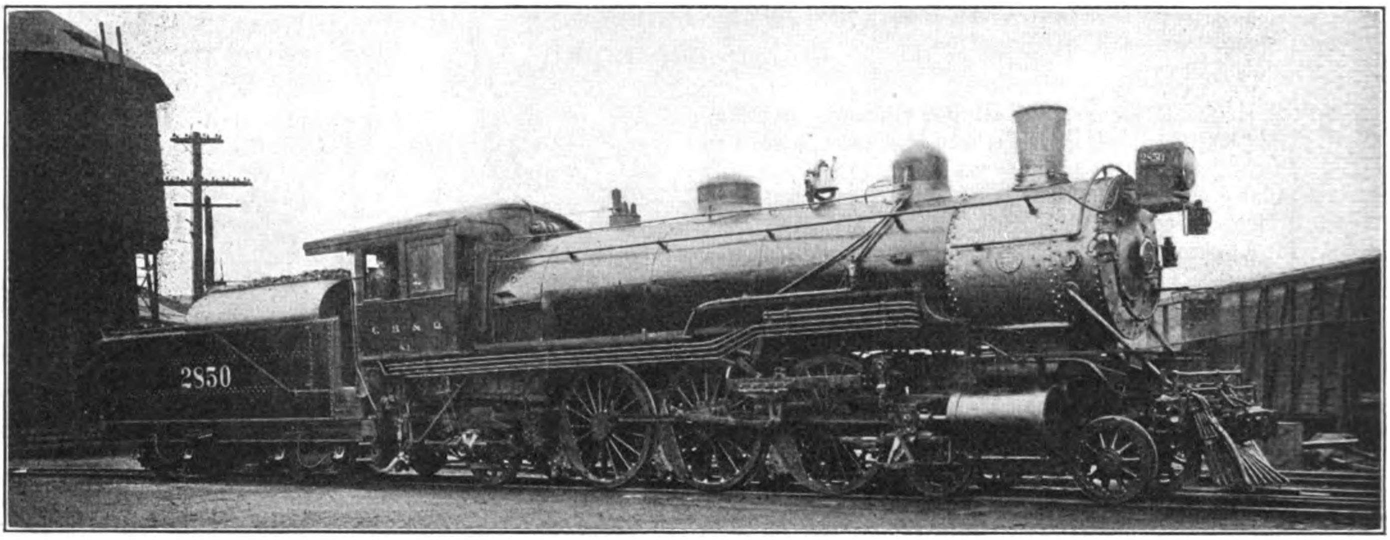
In connection with the Lincoln-Denver runs it will be noted that eastbound there is no engine change but, owing to adverse grades westbound and the consequent heavy working of the locomotives, considerable more attention is required at McCook, Neb., than could be given without undue delay to the trains. As a result, train Nos. 3 and 9 change locomotives at McCook.

More or less the same conditions exist with regard to the Denver, Colo., to Billings, Mont., runs. All locomotives are changed at Casper, Wyo. Northbound they also change at Greybull, but southbound they run through from Billings to Casper.

Formerly the Colorado & Southern used one engine between Denver and Cheyenne on trains 29 and 30—one engine between Cheyenne and Casper on the same trains

and the Chicago, Burlington & Quincy furnished one engine between Casper and Cheyenne, making a total of three engines between Denver and Casper. The engine runs are now between Casper and Denver. One C. B. & Q. engine is being used instead of two Colorado & Southern service, being used to the best advantage to fit the tonnage east and west of Bonneville.

In the freight pool between Alliance and Ravenna, Neb., twenty 0-1-A locomotives were formerly used. Since running through the terminal at Seneca without change,



Engine 2850 equipped with Hulson grates made 1,492 miles in 121 hours with a single fire

engines to equalize the mileage, since 240 of the 339 miles are on the Colorado & Southern.

Freight engines are run through from Casper and Greybull as business requires. A mixed class of power is in only eighteen locomotives are required, thus saving two 0-1-A locomotives.

From a consideration of Tables II and IV it will be evident that on both the east and west lines of the Burling-

Table I—Long engine runs on the C. B. & Q. (Lines east)

ton the savings in enginehouse expense at intermediate terminals has exceeded the fuel savings. To a certain extent increased attention at final terminals, more careful inspection at stations en route, the disposition of ashes when ashpans are cleaned away from regular terminals and other conditions necessitate additional expense. At many intermediate terminals, however, the operations of inspecting and caring for locomotives have been greatly reduced in magnitude so that a net saving for the system is obtained as shown in the tables. The work saved at intermediate terminals consists of inspection, cleaning, knocking and rebuilding fires, washing boilers and normal repair work by enginehouse maintenance forces.

Enginehouse and fuel savings

The fuel savings shown in the tables are conservative, being based quite largely on the number of fires saved and not taking into account the standby losses occasioned when locomotives have their fires knocked at intermediate terminals and are later held under steam waiting for call. Every time a locomotive goes to a terminal there is more or less unavoidable waste of coal in keeping up steam pressure and direct loss to the ash pit. Before leaving, the fireman almost always throws on a few shovelfuls of coal to make sure that there will be steam enough to move the locomotive over the ash pit and, in heading, the hostler usually throws on a little more fuel for the same reason. All of this coal, together with other unburned coal in the firebox, goes into the ash pit when the fire is knocked. This loss is in direct proportion to the frequency with which the locomotives have to pass over the ash pit for cleaning.

More coal is saved in winter than in the summer months owing to increased radiation losses and the necessity of

keeping locomotives, not in the enginehouses, fired up to prevent freezing.

Maintenance standards kept high—Lubrication

A high standard of maintenance and consequently high mileage per engine failure is responsible in no small measure for the success of the Burlington in inaugurating long engine runs. The present excellent condition of Burlington locomotives engaged in running over two or more divisions has been brought about by tightening up in the work of inspection, and making minor repairs promptly before defects have time to develop and possibly cause failures. Another contributing factor is the general improvement program carried out at the various shops on the system whereby locomotive parts such as frames which have shown themselves to be weak and a frequent source of failure have been strengthened by putting in heavier sections. Old type cylinders subject to breakage between the valve chambers and frames have been replaced by improved modern designs.

The question of proper lubrication is important to the success of long engine runs and the way in which this is handled on the Burlington may be illustrated by the practice on locomotives running between Chicago and St. Paul, Minn. Three-pint lubricators are used on most of the locomotives in question and when they leave the Chicago terminal the lubricator is full and the engineman has 4½ pints in the tallow pot in addition. At Savanna, Ill., a service man meets the locomotive at the station and fills the lubricator, also the side and main rod grease cups. The same operation is repeated at Grand Crossing, Wis. Six pints of black or engine oil is provided. On the run from Chicago to Creston, Iowa, the lubricators are refilled at Burlington, Iowa. On this run the engineman starts out with five pints of valve oil in addition to the three pints in the lubricator. He is furnished with eight pints of black or engine oil.

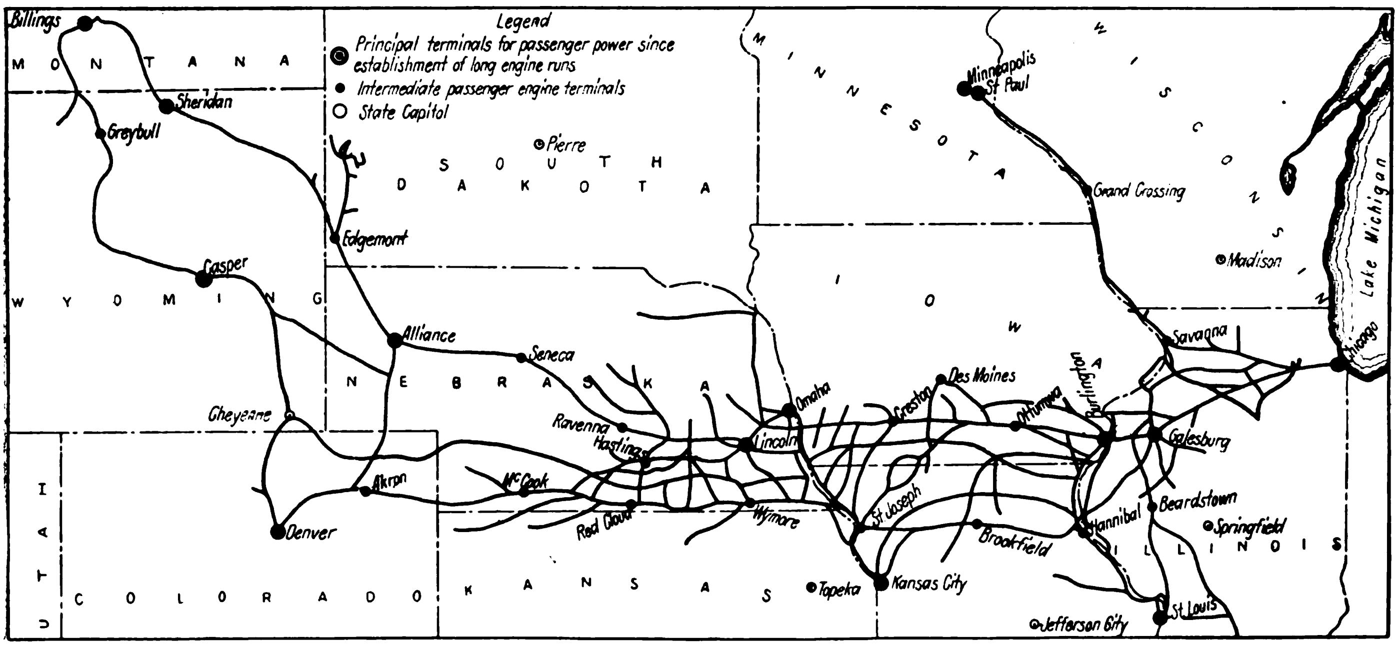
Hulson grates aid long runs; now standard on system

Approximately 40 per cent of the locomotives used in long runs on the Burlington are equipped with Hulson grates which are now the system standard and which are being applied to the balance of the power as rapidly as practicable. Both trial and service tests of these grates showed that they aid materially in enabling coal-burning locomotives to run past intermediate terminals where the locomotives formerly stopped to receive enginehouse attention, including new fires. On account of the rocking feature of these grates experience showed that the fires were not broken up in shaking, and in fact it was possible to remove just the right amount of ash from the bottom of the grates by a light shaking, thus keeping the fires at the proper thickness. This feature, in conjunction with the 55 per cent air opening, practically prevented clinker



Map of the Burlington System showing the principal terminals handling passenger power since long runs have been established

formation with any of the coals burned. The grates proved popular with the crews owing to the ease of shaking which also encouraged firemen to shake their grates frequently and to keep the fires in a good clean condition.

The possibilities in the way of long fire life were indicated by two tests conducted in the latter part of 1923, in one of which Engine 2850 made 1,492 miles before the fire was knocked, the life of this fire being 121 hours. In the other case Engine 2855 made 2,645 miles with a single fire, the life of which was 183 hours. The following is a detailed report of the performance of these two engines during the periods referred to:

Life of fire on engine 2850—Equipped with Hulson grates

Engine out of shops, West Burlington, Iowa	October 17
Fired up at Burlington enginehouse, at 10 a. m.	October 18
Trial run to New London and return (total 50 miles)	October 19
(Fire not cleaned)	
Called for No. 4 at 11 p. m.	October 19
Arrived at Chicago at 6:37 a. m.	October 20
(Ash pan cleaned; fire not cleaned)

(Ash pan cleaned; fire not cleaned)	
Called for No. 4 at 2:40 p. m.	November 24
Arrived at Burlington at 9:30 p. m.	November 24
(Ash pan cleaned; fire not cleaned)	
Called for No. 7 at 6:55 a. m.	November 25
Arrived at Creston at 11:30 a. m.	November 25
(Ash pan cleaned; fire not cleaned)	
Called for No. 4 at 2:40 p. m.	November 25
Arrived at Burlington at 9:30 p. m.	November 25
(Ash pan cleaned; fire not cleaned)	
Called for No. 18, Burlington to Chicago, at 9:10 a. m.	November 26
Arrived at Chicago at 2:40 p. m.	November 26
Called for No. 15, Chicago to Creston, at 9 p. m.	November 26
Arrived at Creston at 5:40 a. m.	November 27
(Ash pan cleaned; fire not cleaned)	
Called for No. 4 at 2:40 p. m.	November 27
Arrived at Burlington at 9:30 p. m.	November 27
(Ash pan cleaned; fire not cleaned)	
Called for No. 12 at 3:05 a. m.	November 28
Arrived at Chicago at 9 a. m.	November 28
Engine held for washout	November 28
Fire was knocked in 10 min.	November 28
Total running time	80 hr. and 30 min.
Total enginehouse time	102 hr., 30 min.
Total life of fire	183 hr., 45 min.
Total mileage	2,645

In the test of Engine 2855, it performed a variety of service, handling passenger, mail and freight trains between Chicago, Burlington and Creston, Iowa. The fire was finally knocked after 2,645 miles to permit a thorough boiler washout. The life of the fire was 183 hr., 45 min., and it was the consensus of opinion that it could have continued indefinitely, burning the average run of coal on these divisions. There was a saving of the knocking and building of 12 fires. Successful test runs of a similar character were made on the Brookfield division where the water is bad and locomotives must be held for a washout every 400 miles.

Table V.—Increase in daily mileage of passenger locomotives

Division	Train numbers	Daily train miles	No. of engines now used	No. of engines formerly used
Alliance-Sheridan	41-42-43-44	1,332	6	8
Denver-Billings	29-30	1,344	5	7
St. Louis-Galesburg	47-48-51-52	832	4	7
Nebraska District	(3-5-9-2-6-22) (15-17-14-16)	4,189	18	25
Galesburg-Kansas City	55-56	650	2	3
Hannibal-St. Joseph	14-15-16-17	824	3	4
Omaha-Kansas City	20-21-22-23	780	4	5
Chicago-St. Paul	47-48-49-50-51-52	2,586	7	9
Lincoln-Burlington	2-3-5-6-9-12	2,070	9	13
		14,607	58	81

Former average daily locomotive mileage	180
Present average daily locomotive mileage	252
Miles per day increase	72
Percentage increase	40
Locomotives released to other service	23

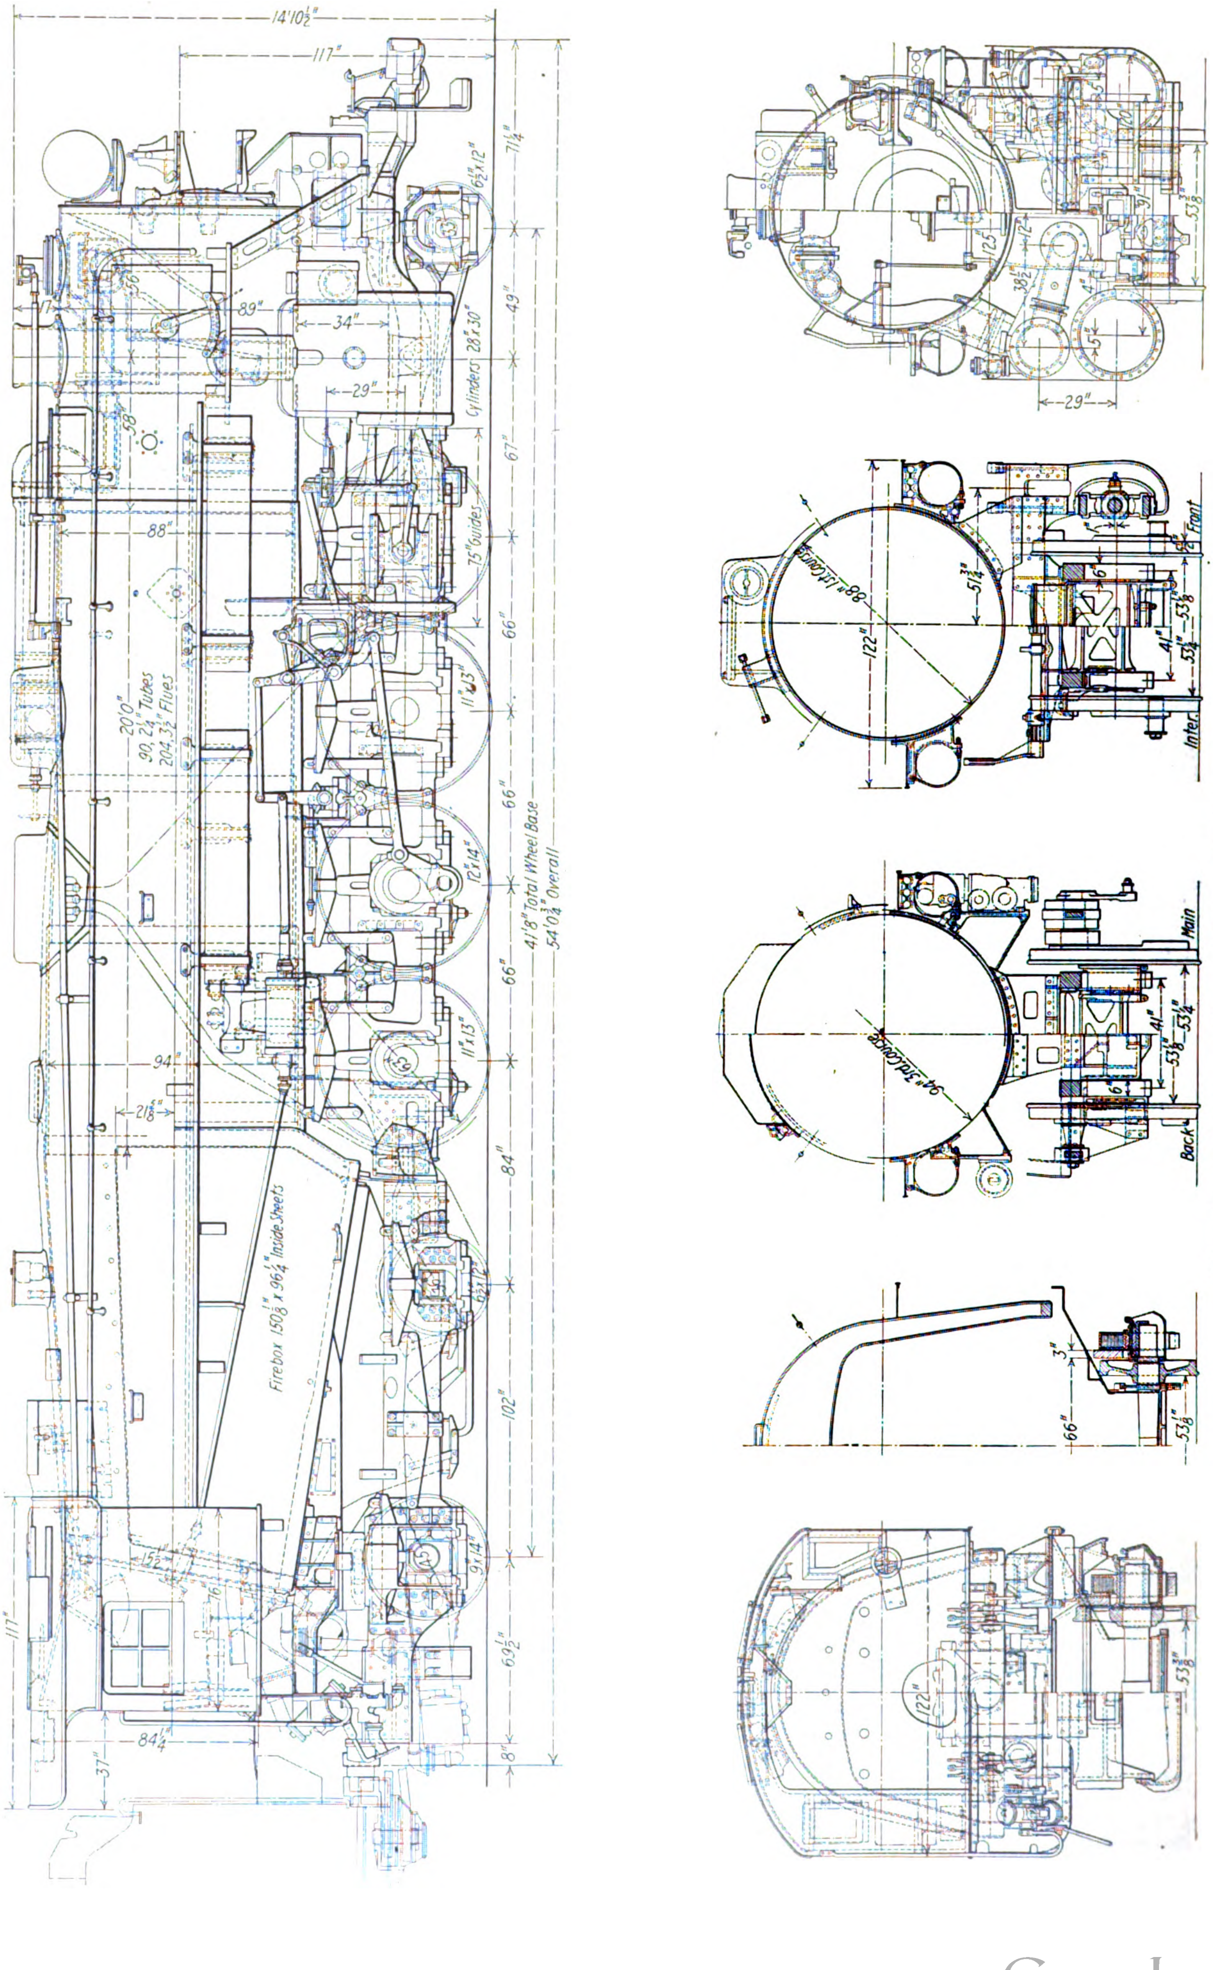
From an examination of this record it will be evident that engine 2850 made seven trips in regular passenger service between Chicago and Burlington, Iowa, with a single fire, and then the fire was knocked because the locomotive was scheduled to take No. 49 into a bad water district making it necessary to wash out the boiler. In connection with the ratio of running to enginehouse time, it is interesting to note that Engine 2850 was in service 47.5 per cent of the time, which is considerably better than the national average of 33⅓ per cent.

No firing tool was used on Engine 2850 during the runs, the fire being kept clean by shaking the grates lightly. On arrival at a terminal the fire was shaken and enough coal added to keep it in shape while in the enginehouse. There was no formation of clinkers and the thickness of the fire at the end of the run is indicated by the fact that only four minutes were required on the cinder pit.

The grates were shaken four or five times on each trip and at no time were they difficult to shake.

The coal varied from good to dirty mine-run, from Southern Illinois. This test indicate the better combustion obtained with the 55 per cent air opening, and that the grates can be shaken lightly under a thin fire without disturbing the fire bed. The fine ash, being sifted from underneath the fire as it formed, resulted in a clean fire at practically all times.

The Legislature of Missouri has passed a bill providing that water glasses must be so placed on locomotives that both the engineman and fireman will be able to see the water level from their seats.



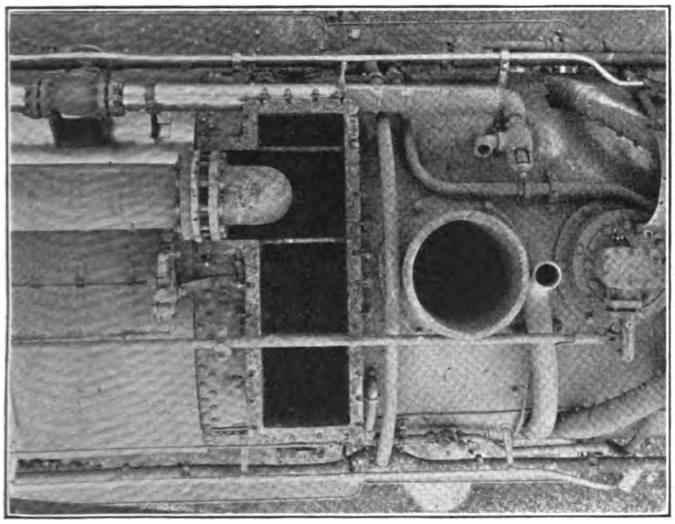
Elevation and cross sections of Lima 2-8-4 type locomotive

High power 2-8-4 type locomotive

Has 100 sq. ft. of grate, 4-wheel trailer truck and 60 per cent maximum cut-off—Tractive force with booster, 82,600 lb.

THE Lima Locomotive Works, Inc., late in January, completed a 2-8-4 type freight locomotive with 100 sq. ft. of grate area. This locomotive, which is owned by the builder, was placed in service on the Boston & Albany in February. It weighs 385,000 lb., of which 248,200 lb. is on the drivers and 101,300 lb. on the four-wheel articulated trailing truck. It carries 240 lb. boiler pressure and, with a maximum cut-off of 60 per cent, develops a tractive force of 69,400 lb. Including the booster, which drives on the rear pair of trailing wheels, the total tractive force is 82,600 lb.

The principal objectives in the design of this locomotive were the development of high horsepower capacity and improved economy in the use of fuel. It may be considered a logical step forward in carrying out the principles on which this builder has been working since the inception of the design of Locomotive 8000 which was built for the Michigan Central in 1922, and of which design over 300 have since been built for various parts of the New York Central System. A comparison of the more important dimensions and proportions of the two locomotives will serve to indicate the methods by which it is expected to obtain the increased horsepower and higher fuel economy. Such a comparison will be found in the table.

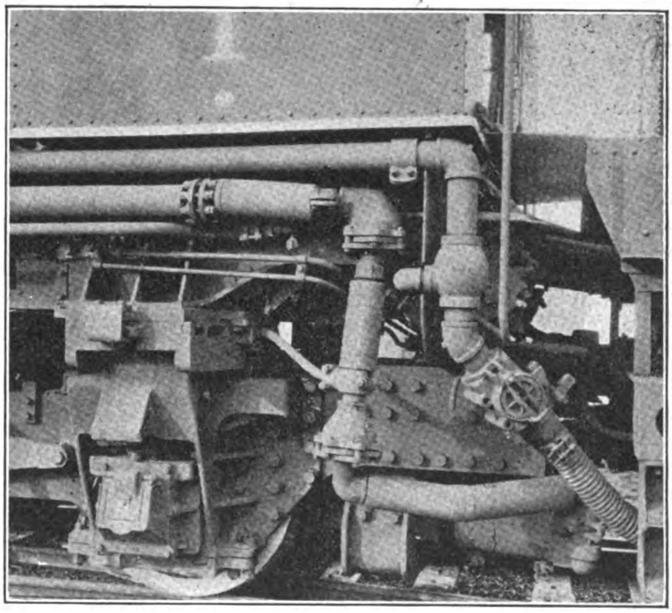


Looking down on the top of the smoke box—The superheated steam line of the turret is shown at the top of the picture

It will be seen that the cylinders are the same size on both locomotives. This suggests that an increase in tractive force was not the primary objective, although some increase has been possible because of the smoother torque curve and the resulting lower factor of adhesion which the employment of limited cut-off made possible. The outstanding difference in proportions is in the size of the grate, the new 2-8-4 locomotive having approximately 50 per cent more grate area than did the earlier Mikado. It will also be noted that the boiler is somewhat larger in other respects. The total evaporative heating surface has been increased about 12 per cent and there is an 18 per cent increase in the amount of superheating surface, resulting in an increase of combined evaporative and superheating surface of about 13½ per cent. While these figures indicate a considerable increase in capacity for heat absorption, the greatest increase in boiler capacity will undoubtedly result from the ability to release at the grate a large aggregate amount of heat at exceptionally low rates of combustion. This favors both high boiler capacity and high fuel economy.

Comparison of Locomotive A-1 and Locomotive 8000

	A-1	8000
Type	2-8-4	2-8-2
Cylinders, diameter and stroke	28 by 30	28 by 30
Cut-off in full gear	60 per cent	Full stroke
Boiler pressure	240 lb.	210 lb.
Weights in working order:		
On drivers	248,200 lb.	248,000 lb.
On front truck	35,500 lb.	29,000 lb.
On trailing truck	101,300 lb.	58,000 lb
Total engine	385,000 lb.	335,000 lb
Diameter drivers	63 in.	63 in.
Heating surfaces:		
Firebox, incl. arch tubes	337 sq. ft.	291 sq. ft.
Tubes and flues	4,773 sq. ft.	4,287 sq ft.
Total evaporative	5,110 sq. ft.	4,578 sq. ft.
Superhating	2,111 sq. ft.	1,780 sq. ft.
Comb. evaporative and superheating	7,221 sq. ft.	6,358 sq. ft.
Grate area	100 sq. ft.	66.4 sq. ft.
Net gas area through tubes and flues	1,536 sq. in.	1,348 sq. in.
Rated tractive force:		
Engine	69,400 lb.	66,700 lb.
Engine and booster	82,600 lb.	77,700 lb.
Factor of adhesion	3.58	3.72



Furnace expansion and trailer lateral motion bearings

The other principal factor in this design for the improvement of fuel economy is the employment of the limited maximum cut-off which is accompanied by an increase in boiler pressure primarily to offset the reduction in the ratio of mean effective pressure to initial pressure resulting from the limited cut-off. While the

value of the limited cut-off as an economy factor is more apparent within the speed range at which full-stroke cut-off locomotives are ordinarily operated, it has also been found that a significant reduction in water rate occurs throughout the entire speed range. For freight service, a very considerable percentage of the locomotive mileage is made in the speed range within which full-stroke locomotives operate at more than 60 per cent cut-off.

There is some tendency toward improved thermal efficiency because of the higher boiler pressure. Its principal effect, however, is to increase the tractive force over that of the full-stroke cut-off locomotive at speeds where less than 60 per cent cut-off is required. This means correspondingly increased horsepower at these speeds.

Aside from the proportions of the new locomotive, its construction embodies four important innovations in detail design.* These are the cast steel cylinders which have made possible a saving of 4,000 lb. in weight; the articulated four-wheel trailing truck which does not require rear frame extensions and has made possible a marked improvement in ash pan design; the articulated main rod which delivers its load on two outside crank pins instead of on one, and the simple port arrangement by which an unbalanced cut-off has been obtained in the two ends of the cylinders at starting, with a resulting increase in the smoothness of the starting torque curve.

Cast steel cylinders

This is not the first application of cast steel cylinders. It will be remembered that Locomotive 50,000 built in 1911 by the American Locomotive Company was equipped with cylinders of this material. The cylinders on Locomotive 50,000 called for the use of outside steam pipe connections, but the exhaust passages from the valve chamber were cored inside the body of the casting. In the case of the cylinders on the new locomotive, there are no steam passage connections from the valve chamber to the saddle proper. The only steam passages in the saddle are from the front and back faces of each half saddle inward and upward to the exhaust standpipe base. The cores for these passages are supported in the mold at each end, making the floating of the core very unlikely, and the walls of the passages are accessible should it be necessary to close a blow-hole by welding.

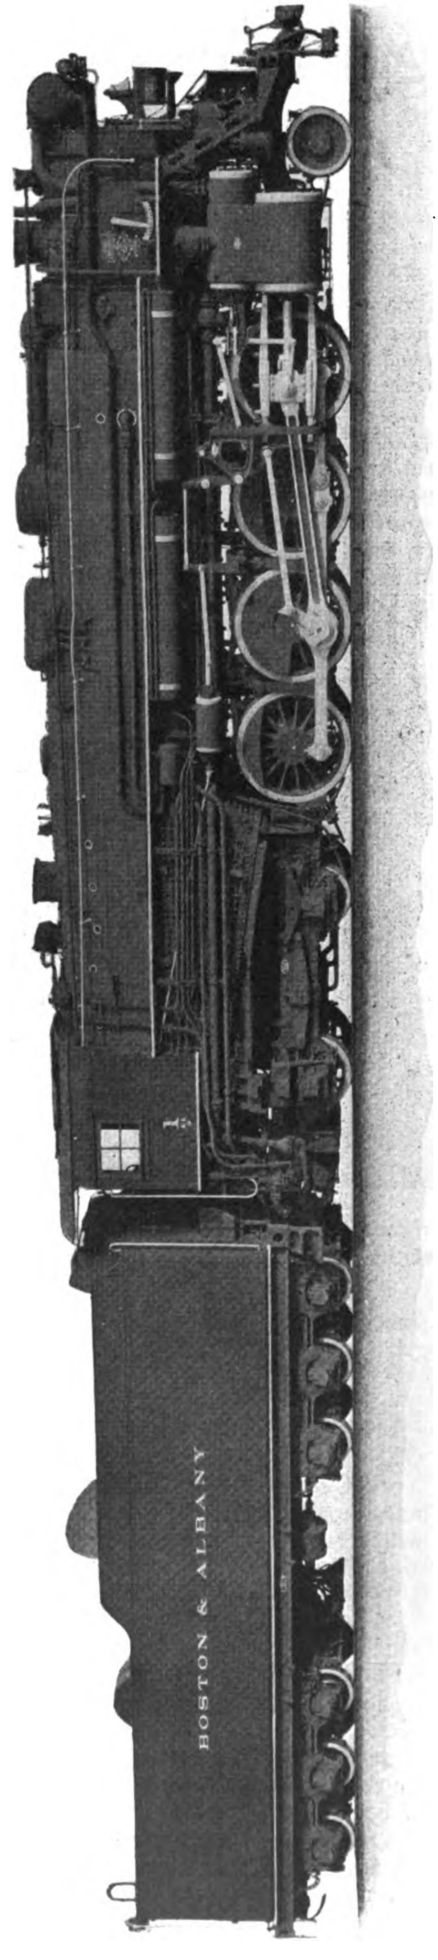
The photographs show clearly how connection is made from the valve chambers to the saddle exhaust passage by means of cast pipes which are bolted to openings in the valve chamber extension heads at one end and against the face of the saddle casting at the other. This construction leaves the designer free to distribute his metal in the connections between the saddle and the cylinder and valve chamber with one objective in mind—the strength and quality of the casting.

Before the design of the new locomotive was laid down, a cylinder and half-saddle of this design was cast, machined and pressure tested. As a result of the experience obtained from this casting, the cylinders for the new locomotive were cast with only minor changes in the pattern.

The four-wheel trailer truck

The articulated four-wheel trailing truck is a unique development in the design of the frame and the equalizer systems. This truck in effect forms a part of the main frame system, leaving no need for a rear frame extension back of the main frames. The main frames terminate just back of the rear pair of drivers. Between them is bolted a hinge casting of the Mallet type; a corresponding

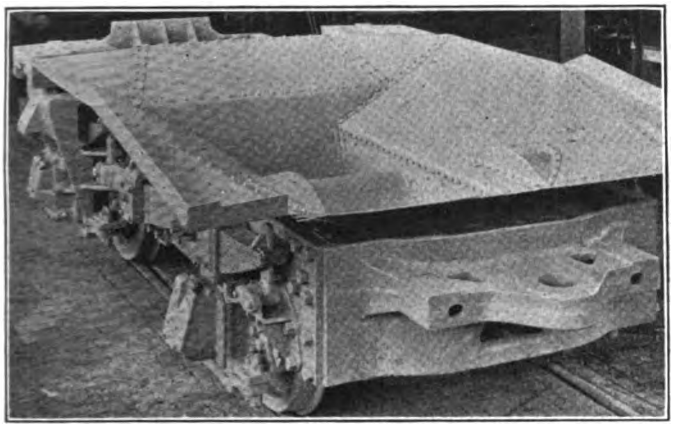
* These details and other features and combinations embodied in this locomotive are covered by patents or patents pending.



A departure from customary locomotive proportions—A grate area of 100 sq. ft. reduces the rate and improves the efficiency of combustion; a maximum cut-off of 60 per cent improves steam economy and increases horsepower output at medium and high speeds

hinge casting forms the front member of the trailer truck. The buffing and pulling stresses are thus transmitted directly through the trailing truck frames and the drawbar pocket forms a part of the rear trailer frame casting. These frames have a section of 3 in. by 17 in. where the rear frame casting is bolted between them and are 3 in. by 21 in. in section between the axles.

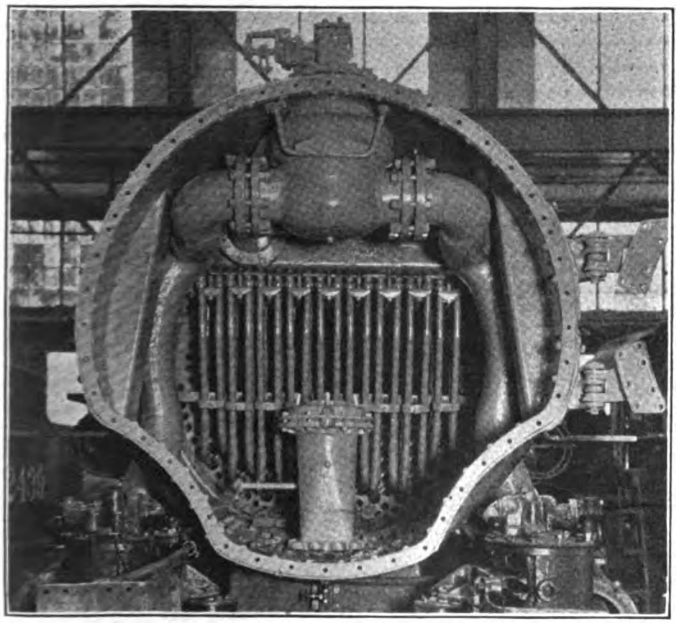
The vertical load is transmitted to the trailer truck at



The front end of the trailer truck, showing the ash pan in place

two points on each side: at the front corners of the trailer hinge casting, on the top surface of which rest extensions of the main frames, and at the rear corners of the firebox, each of which is supported on a combined expansion and self-centering lateral motion bearing. It will thus be seen that while the trailer truck is free to swing laterally about its hinge joint, its vertical alinement remains unchanged with respect to the main frames, of which, in effect, it forms a part.

The two journal boxes on each side of the trailer are

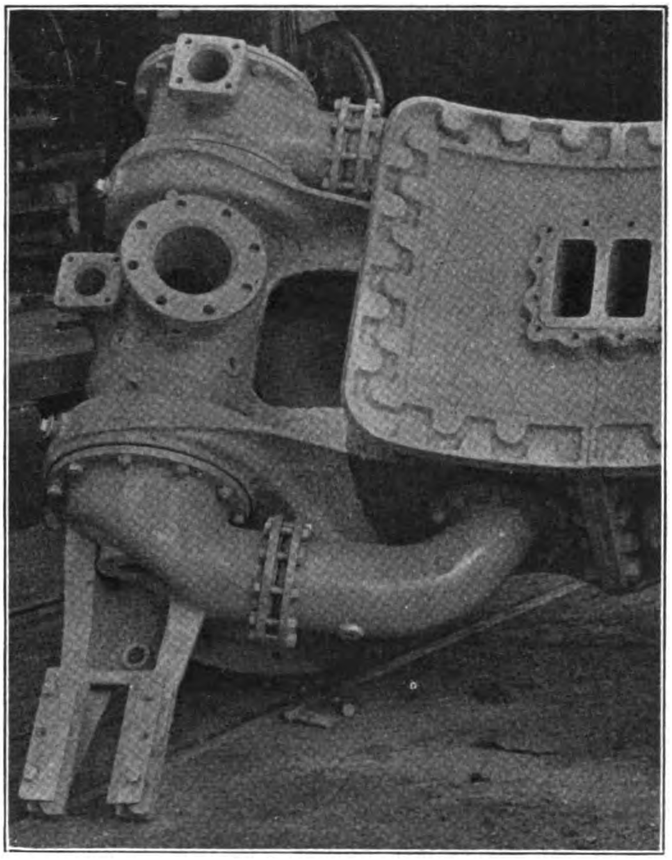


Interior of the front end during construction

equalized together, each side thus forming one point of the three-point spring suspension. The entire driving wheel base on each side of the locomotive is equalized together and the two sides are cross-equalized with the leading truck, so that the leading truck and the entire driving wheel base form the third point of the spring suspension.

One of the influences of this truck on the design of the locomotive, which, although incidental, is none the less important will be seen in the ash pan. The elimination of the rear frame extensions has removed one of the worst restrictions on securing a satisfactory slope of the ash pan side sheets and the space between the trailer axles has permitted the building of hoppers of unusually large capacity. Although the grate is unusually large, the ash pan provides but little less than one cubic foot of capacity per square foot of grate.

The ash pan, instead of being attached directly to the mud ring, is built into the trailer truck and when the trailer truck is removed from the locomotive the ash pan is removed with it. The width of the flare required to keep the ash pan under the firebox when the trailer is displaced laterally on curves also provides an unrestricted



The cast steel cylinder, showing the outside exhaust pipe connections

air opening all around between the ash pan and the mud ring.

In the absence of rear frame extensions from which the cab and a number of items of auxiliary equipment are supported, heavy cast steel cab brackets are attached to the back corners of the mud ring. Heavy lugs are cast below the back and sides of the mud ring at the corners to support these brackets, which also form the top members of the combined furnace bearers and trailer truck lateral motion bearings.

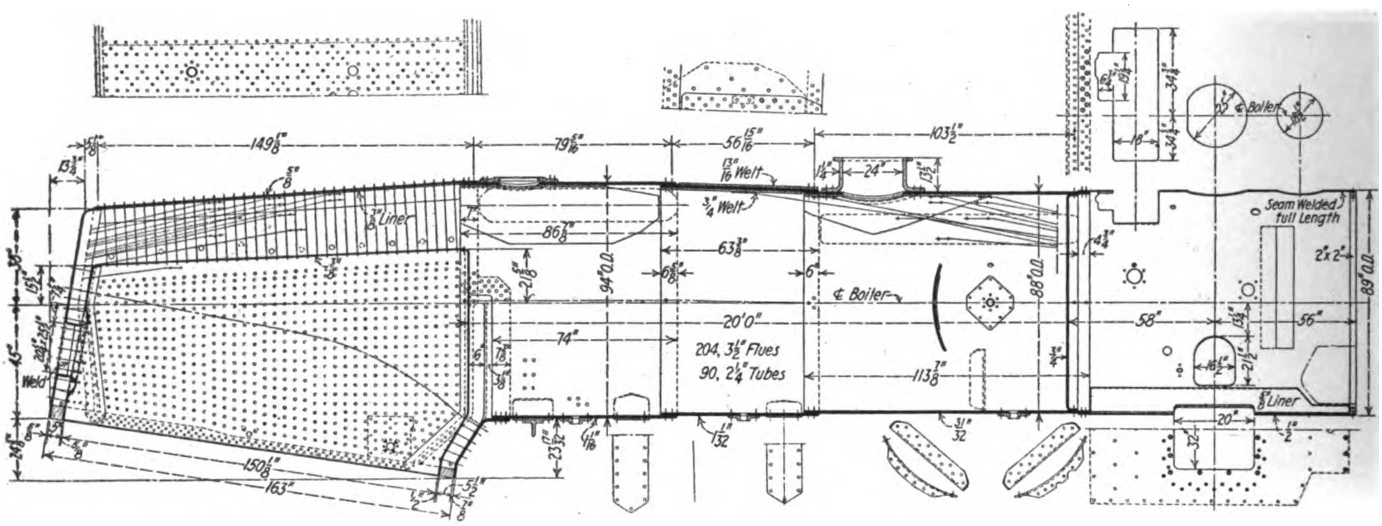
As has already been indicated, the booster drives on the rear trailer axle. This axle has 9-in. by 12-in. journals and 45-in. wheels. The front trailer axle is of standard M.C.B. type, with 6-in. by 12-in. journals and 36-in. wheels. The booster frame and cylinders are located back of the rear trailer axle and are suspended from the trailer frames by a cast steel yoke. The arrangement is shown in one of the photographs included in this article.

One of the greatest problems in connection with the use of the limited cut-off is to provide for the increase in the main crank pin and driving box loads which results from the high initial piston load. The solution of this problem has been attacked in an original manner in the new 2-8-4 type locomotive.

The driving rods

The main rod is built in two parts, one of which drives directly on the main crank pin, while the other carries back part of the load to the rear crank pin, thus relieving the main crank pin of one-quarter of the full driving load. This rod arrangement is shown in one of the photographs.

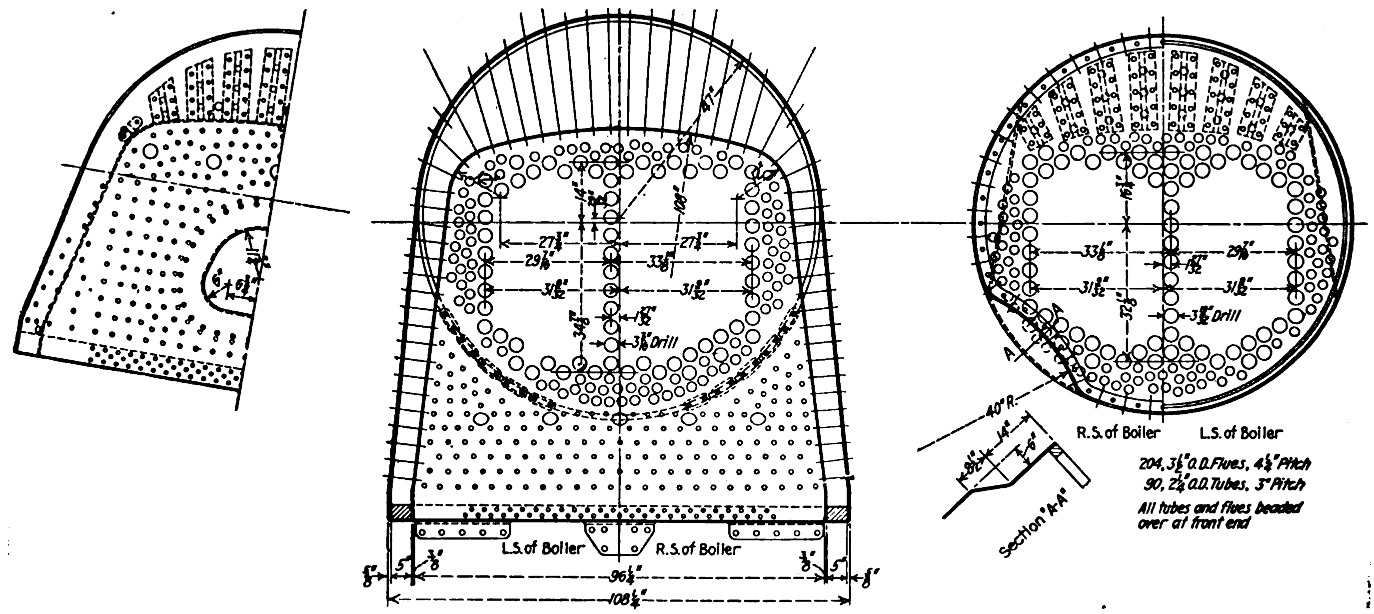
The back end of the main rod proper is forked to receive the parallel section of the main rod. With the two parts of the rod thus assembled, a heavy steel bushing is pressed into the forked end of the main rod proper, holding in place and providing a bearing for the parallel section of the rod. This bushing transmits directly from one section of the rod to the other, the portion of the load which is carried back to the rear wheel. Inside of the steel bushing is a floating bronze bushing which serves as a crank pin bearing. The usual side rod arrangement distributes the driving load forward from the main crank pin to the second and first crank pins. This arrangement, by relieving the main pin and reducing the size of the middle connection bearing made possible the same spread of cylinders, with 240 lb. boiler pressure as was formerly used with 200 lb. boiler pressure.



Longitudinal section of the boiler

By the use of the floating bushing on the main pin, which may be pulled and replaced without removing the rod from the pin, it is expected that no difficulty will be encountered in enginehouse maintenance because of the weight and size of this main rod and that, indeed, the amount of work may actually be reduced.

Here again, as in the case of the cast steel cylinders, this rod arrangement was subjected to a service test of considerable duration on a 4-8-2 type locomotive before the design of the new locomotive was laid down. The experience thus obtained indicates that it is practicable.

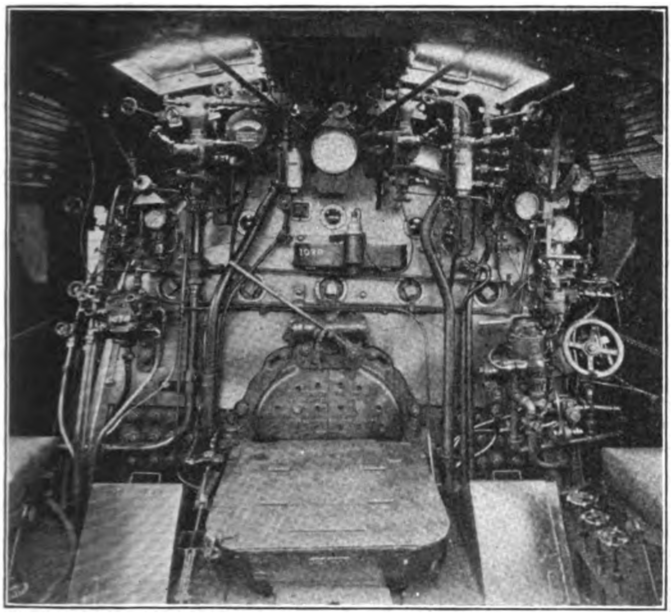


Sections through the firebox and smoke box

Unbalanced cut-off at starting

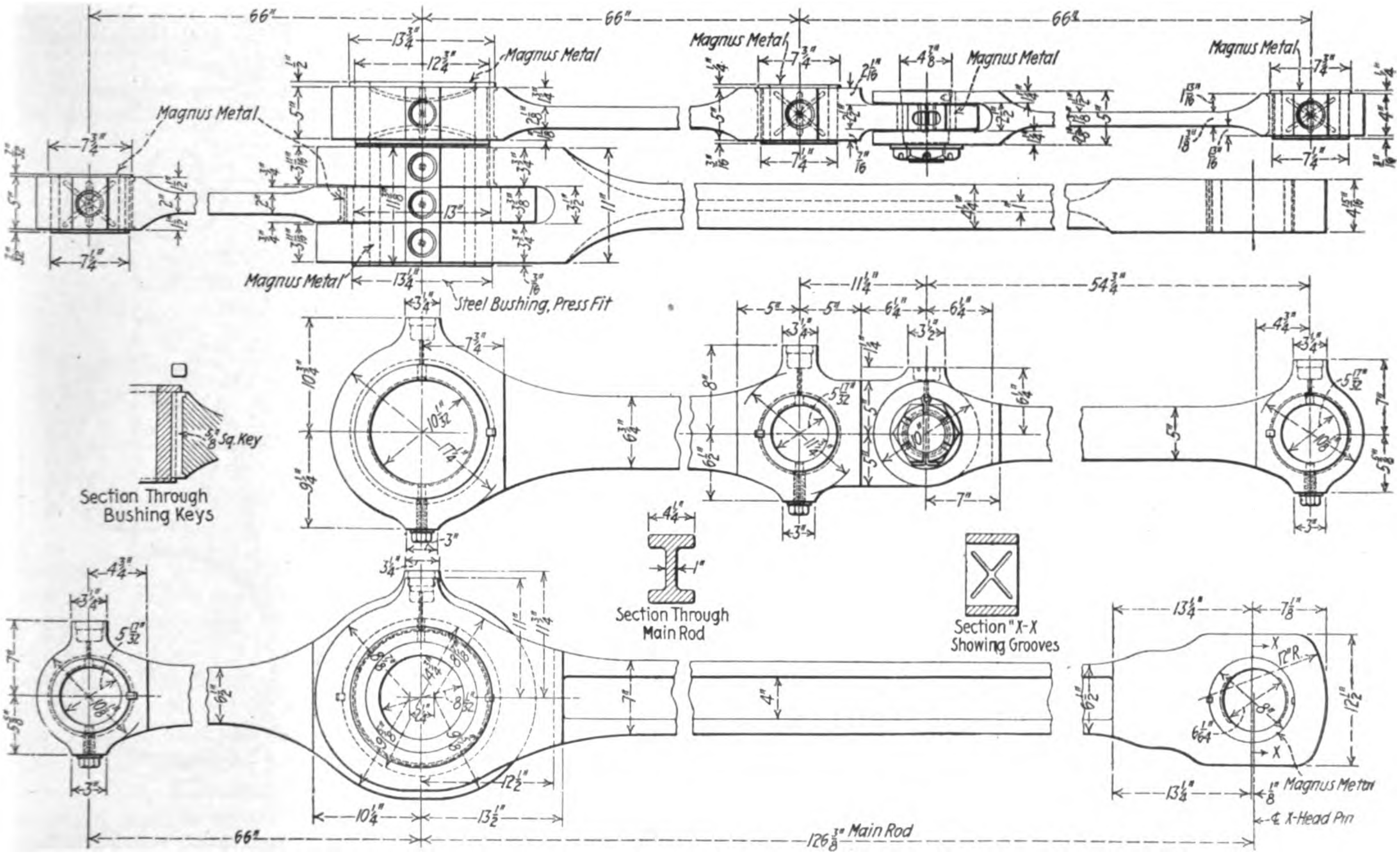
In addition to the auxiliary starting port which is regularly incorporated in the valve chamber bushings of

limited maximum cut-off locomotives, the cut-off at the front end of the cylinder is increased slightly over that at the rear end at starting and very slow speeds, by lengthening two of the ports in the front valve chamber



The interior of the cab

bushing. The ports are 2-3/16 in. wide and in the front bushing two of the top ports are increased 7/16 in. in width toward the center of the valve piston chamber.



Details of the articulated main rod and the side rods (patented)

This simple expedient effectively increases the period of steam admission at slow speeds, but as the speed increases the amount of steam admitted through the extension of the two ports gradually decreases until it becomes negligible in its effect on the cylinder events. For a nominal 60 per cent cut-off, the ports and valves are proportioned to give an actual cut-off of about 60 per cent in the rear end of the cylinder and 63 per cent in the front end.

Boiler equipment

Aside from the size of the firebox, the boiler does not differ materially from the usual type of design. It is slightly larger in diameter and contains a somewhat different tube sheet layout with more heating surface than that of Locomotive 8000. The points of most interest are shown in the photographs. It will be seen that steam is taken from the dome through an outside dry pipe to the Type E superheater header at the rear of the smokebox.

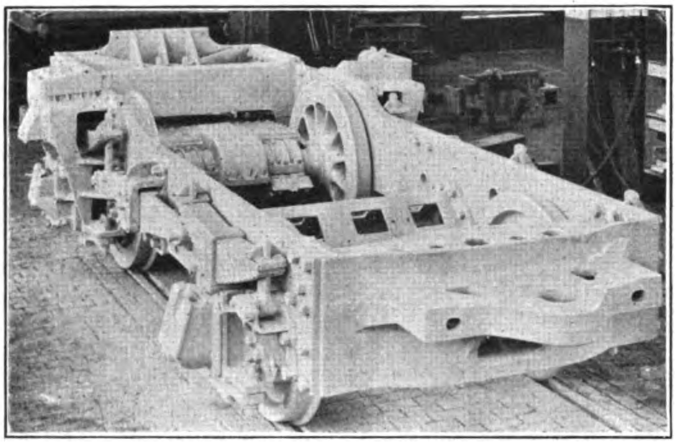
The throttle is located in the smokebox just ahead of the smoke stack. The single steam connection from the superheater header to the throttle is cast integral with the throttle casing. Branch pipe connections are provided on either side of the throttle casing from which the branch pipes lead down inside the front end, passing outside at points just above the cylinders.

Above the superheater header, an opening in the top of the smokebox permits access to the superheater unit bolts which are placed with the nuts at the top. Unit joints may thus be tightened without the necessity of entering the front end.

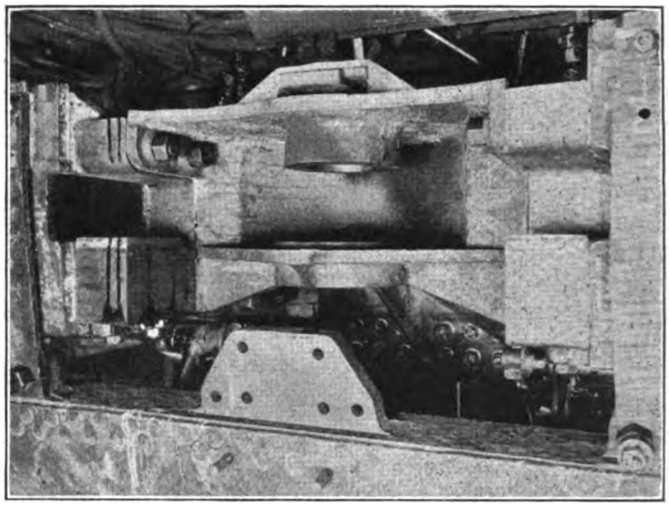
There are two turrets from which steam is distributed to the auxiliaries, both located over the top of the boiler just in front of the cab. One of these furnishes saturated steam to the injectors and lubricators. The other draws superheated steam from the throttle pipe connection to the superheater header for use in the air pumps, the feed water pump, the blower, grate shakers, stoker and headlight generator. The whistle, which also uses super-

heated steam, has its connection welded directly on the steam pipe which feeds the turret. Steam for the booster is taken from the left branch pipe and its exhaust is carried up outside of the smokebox, opening to the atmosphere just in front of the smokebox.

It will be seen from the photographs that two channels of rectangular section are let into the sides of the smokebox. These are provided to take the exhaust steam pipes leading to the feed water heater, which is mounted on brackets in front of the front end, without projecting outside the surface of the smokebox shell. Recesses are also formed in the lower quarters of the front end door ring and in the sheets immediately back of it, to clear the tops of the air compressors, one of which is mounted on a bracket on each side of the front deck casting.



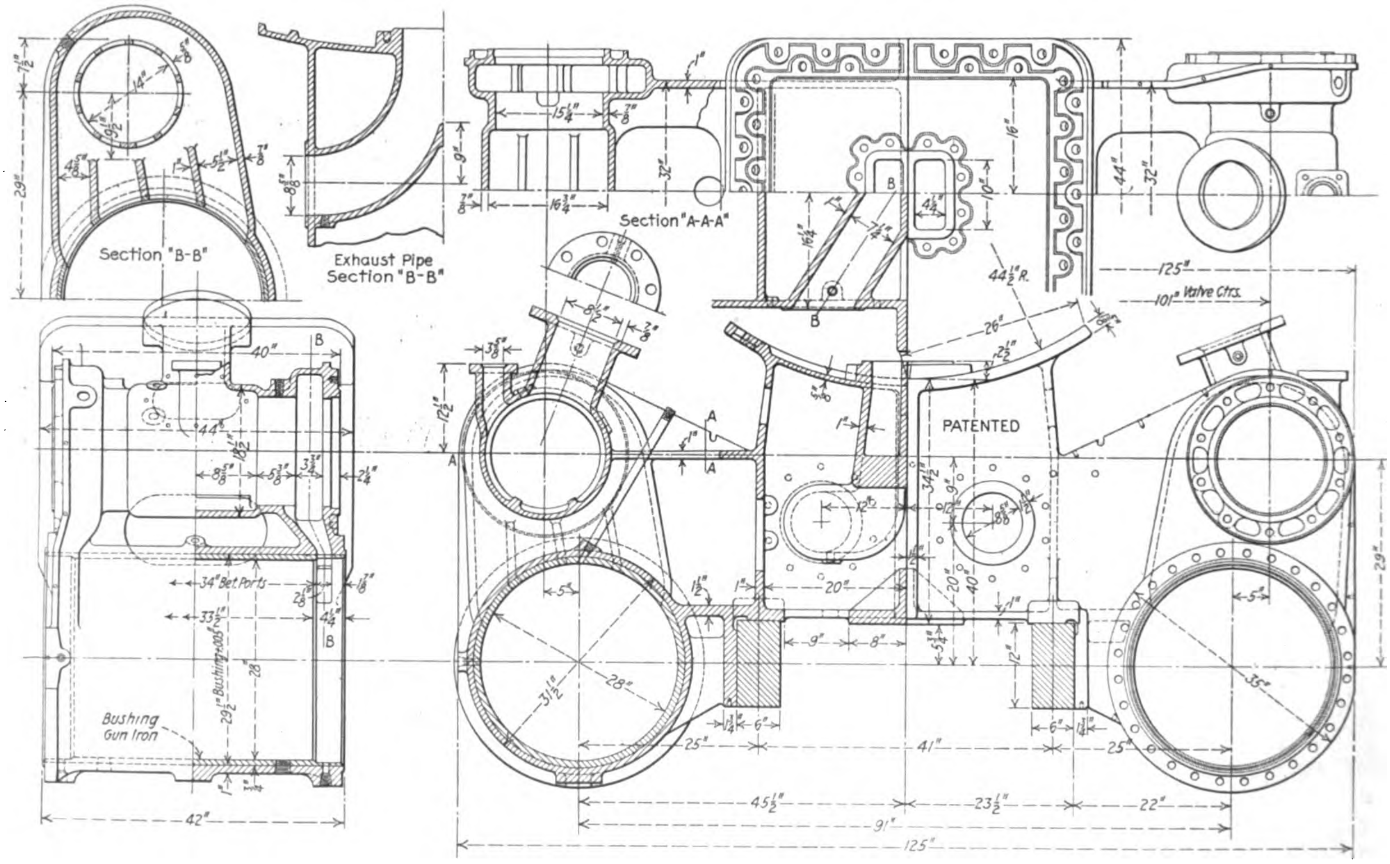
The trailer truck before the ash pan was applied—The side frames are 3 in. by 17 in. in section at the rear deck casting and 3 in. by 21 in. in section between the axles—The journal box pedestals are closed with binders



Looking into the trailer hinge casting at the rear ends of the main frames

Cab arrangement

In arranging the control valves and equipment located in the cab, considerable attention has been given to providing for the convenience and comfort of the engine crew. As far as possible all gages have been brought together in one location where the engineman can see them at a glance. A pneumatic whistle valve has been placed on the side of the cab where the engineman does not have to reach to operate it. The various valve handles have been grouped and labeled, with those most frequently



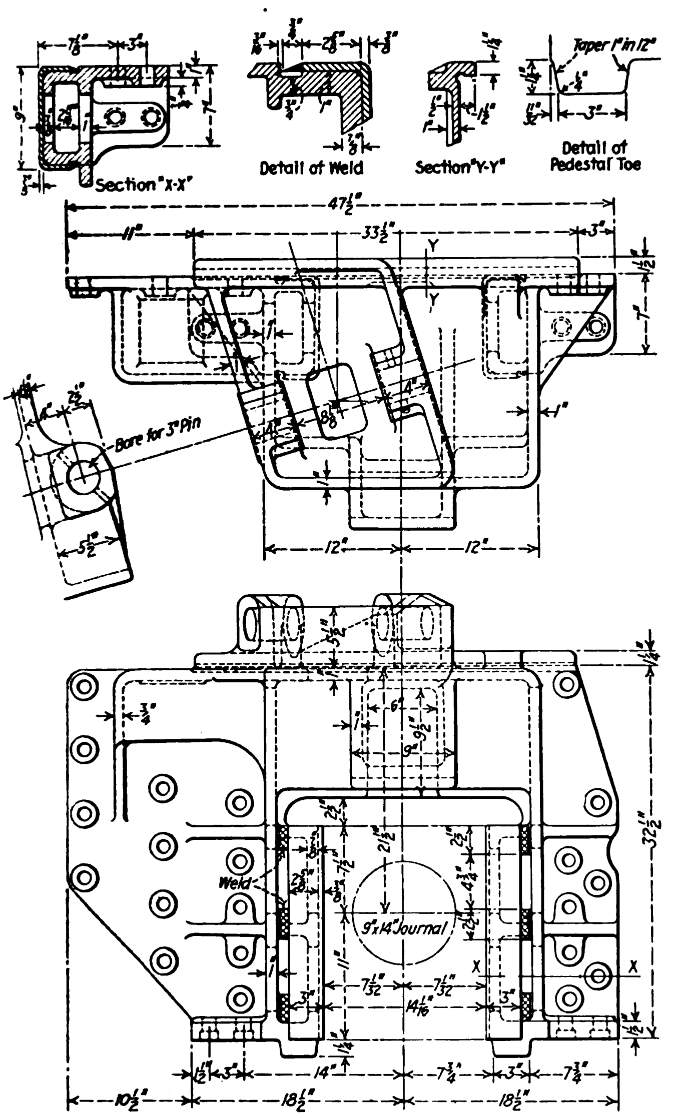
The design of the cast steel cylinders (patented)

operated placed where they are most readily accessible.

Folding spring cushioned seats, the frames of which are supported on coil springs, are provided on both sides of the cab. Back of the fireman's seat is a locker for clothing.

Tractive force fixed by trial

In designing the locomotive considerable latitude was provided for the selection of the final working boiler pressure and maximum cut-off. This was done in order that the maximum cut-off might finally be determined as the result of trials in actual road service. To this end the



Combined rear trailer journal box and lateral motion bearing—the roller which revolves on a 3 in. pin, is geared to the self centering top bearing plate (patented)

locomotive was equipped with a variable exhaust nozzle, the design employed by the Paris, Lyons & Mediterranean having been selected as meeting the requirements of a thoroughly tested and practical device. This nozzle is not intended for manual control by the engineman, but its operating arm is secured to a graduated quadrant on the outside of the front end which permitted adjustments in exhaust nozzle area to be made as frequently as might be desired during the adjustment process without the necessity of entering the front end.

In developing the design of this locomotive, the builders set up the following requirements: That it must be able to handle the same train in drag freight service with 20 per cent less coal than is burned by the Locomotive 8000 design; that, in high speed freight service, it must pull the same train at the same speed as Locomotive 8000 with 12 per cent less coal, or deliver 10 per cent more drawbar pull for the same amount of coal. Experience with the locomotive so far indicates that it will fully meet and probably exceed these requirements. The locomotive is now undergoing tests in service, from which more complete data will later be available.

The principal dimensions and data are shown in the following table:

Type of locomotive	2-8-4
Service	Freight
Cylinders, diameter and stroke	28 in. by 30 in.
Valves, piston type, size	14 in.
Maximum travel	8¾ in.
Outside lap	2 1/16 in.
Exhaust clearance	1/16 in.
Lead in full gear	¼ in.
Cut-off in full gear, per cent	60
Weights in working order:	
On drivers	248,200 lb.
On front truck	35,500 lb.
On trailing truck	101,300 lb.
Total engine	385,000 lb.
Tender	275,000 lb.
Wheel bases:	
Driving	16 ft. 6 in.
Rigid	16 ft. 6 in.
Total engine	41 ft. 8 in.
Total engine and tender	82 ft. 6 in.
Wheels, diameter outside tires:	
Driving	63 in.
Front truck	33 in.
Trailing truck	36 in. and 45 in.
Journals, diameter and length:	
Driving, main	12 in. by 14 in.
Driving, others	11 in. by 13 in.
Front truck	6½ in. by 12 in.
Trailing truck	6½ in. by 12 in. and 9 in. by 14 in.
Boiler:	
Type	Straight top
Steam pressure	240 lb.
Fuel, kind	Bituminous
Diameter, first ring, outside	88 in.
Firebox, length and width	150⅛ in. by 96¼ in.
Height mud ring to crown sheet, back	60½ in.
Height mud ring to crown sheet, front	91¼ in.
Arch tubes, number and diameter	5, 3½ in.
Combustion chamber, length	None
Tubes, number and diameter	90, 2¼ in.
Flues, number and diameter	204, 3½ in.
Length over tube sheets	20 ft.
Tube spacing	¾ in.
Flue spacing	¾ in.
Net gas area through tubes and flues	1,536 sq. in.
Grate area	100 sq. ft.
Heating surfaces:	
Firebox, incl. arch tubes	337 sq. ft.
Tubes	1,055 sq. ft.
Flues	3,718 sq. ft.
Total evaporative	5,110 sq. ft.
Superheating	2,111 sq. ft.
Comb. evaporative and superheating	7,221 sq. ft.
Tender:	
Style	Rectangular
Water capacity	15,000 gal.
Fuel capacity	18 tons
Weight proportions:	
Weight on drivers ÷ total weight engine, per cent	64.2
Weight on drivers ÷ tractive force	3.58
Total weight engine ÷ comb. heat. surface	53.3
Boiler proportions:	
Tractive force ÷ comb. heat. surface	9.61
Tractive force × dia. drivers ÷ comb. heat. surface	605
Firebox heat. surface ÷ grate area	3.37
Firebox heat. surface, per cent of evap. heat. surface	6.60
Superheat. surface, per cent of evap. heat. surface	41.4
Tube length ÷ inside diameter	74.5
Comb. heat. surface ÷ grate area	72.2

THE METHODS OF TESTING BRITISH LOCOMOTIVE TIRES do not vary greatly from the methods used in this country. The British tires must not be too brittle or too soft and must have a tensile breaking stress of from 100,000 to 110,000 lb. per sq. in. and finally the steel from which they are made must pass a chemical test as to its content of sulphur and phosphorus. The tires are given a drop test which is not common practice in this country. One tire out of a lot of 50 is placed in an upright position in the base of the testing machine. A ton weight is raised and dropped on the edge of the tire from varying heights. For a tire weighing 950 lb., the weight is first dropped on the rim from a height of 5 ft., then from 10 ft. and finally the fifth blow is received from a height of 25 ft. The tire should not break or be unduly bent. If the diameter of a 950-lb. tire, measured from the point on which the blows fell, is reduced approximately 4 in., it is considered a good tire and the lot is passed as fit for service.

Railway motor car service on the C. G. W.*

By E. J. Brennan

Superintendent of motive power, Chicago Great Western, Oelwein, Iowa

In the past year quite a few additional cars of the self-propelled type have been built for various railroads, and the Chicago Great Western has installed in the interim, one gas-electric car, two mechanical gear-driven, two-car trains and one steam car. The following data relate to these cars:

Gas-electric car M-300

Length of body	57 ft. 4 in.
Width	9 ft. 8⅝ in.
Weight	76,400 lb.
Baggage compartment	156 sq. ft.
Seating capacity	50
Type of body construction	steel
Standard A. R. A. journal bearings	4¼ in. by 8 in.

Two Sykes trains Nos. M-207, MT-208, M-209 and MT-210

Total length of motor car	46 ft. 10 in.
Total length of trailer	52 ft.
Width	8 ft. 6 in.
Weight of motor car	50,000 lb.
Weight of trailer	36,400 lb.
Baggage compartment	120 sq. ft.
Trucks equipped with Hyatt roller bearings.	
Seating capacity, motor car	30
Seating capacity, trailer	52
Type body construction	steel

The steam car has been developed by installing in the forward end of a McKeen car a tubular boiler, automotive type, working at a pressure of 500 lb. actuated by an oil-fired furnace. The engine in this unit is a six-cylinder compound having three low pressure cylinders, 7-in. bore by 7-in. stroke, and three high pressure cylinders having a 5-in. bore and a 7-in. stroke. This steam car has been handling a 35-ton combination mail and baggage car 55 ft. long making a total light weight of the train, 90 tons, or an average loaded weight of approximately 100 tons. This car has been in service between Oelwein, Iowa, and Ft. Dodge, a distance of approximately 260 miles a round trip each day, making 44 stops averaging 1¾ min. each on a schedule of 24.2 miles per hour.

The above reference to the steam car is preliminary to a final report which will be made by the builders after certain changes now being made to the engine and boiler have been completed and further data compiled at which time an official announcement will be made.

In the various units of equipment recently built, U. S. standards and steam railway practices have been followed in the general construction except the weights, which, generally speaking, are consistent with that type of equipment. In other words, the body design while it is of far lighter construction than standard railway coaches, combination cars, etc., is somewhat heavier than some of the more recently built rail motor cars.

Gas-electric car pulls heavy trailer

Our gas-electric car, although designed to haul a 35-ton coach or trailer, at this time is doing very much more. The car is and has been operating between Osage, Iowa, and Hayfield, Minn., in local main line passenger service, pulling a combination mail and express car weighing 54½ tons, a distance of 70 miles each day, or betwen McIntire and Hayfield, on a schedule of 26 miles an hour. The entire daily run for the car is only 104 miles, 70 of which, as stated, is traveled handling the 54½-ton combination car.

A few minor defects have developed on this unit but they have been very quickly corrected.

The control of the gas-electric car (described on page 371 of the August 30, 1924, *Railway Age*) is very dependable in that it is operated by a control similar to that of a steam locomotive. The first notch on the throttle operates an air starting system which allows the operator to stop the entire power plant by simply closing the throttle and to start the power plant and the car by opening the throttle when he is ready to proceed. This results in a noticeable economy in fuel consumption and maintenance, as gasoline engines develop carbon very rapidly when idling. This system of operation fits in well on steam railroads due to using locomotive enginemen for operators. This car is heated throughout by an Arcola hot water heater to which the builders have attached the water circulating system of the engine so that when the car is obliged to lay over during severe weather it is not necessary to drain it and the possibility of the radiator, piping, engine and other appurtenances freezing is eliminated.

The next two trains for the Chicago Great Western were purchased from the Sykes Company, St. Louis, and are similar to the preceding units except that they are considerably better owing to the inclusion of certain refinements incorporated as a result of our past experience. This refers to better construction of the body which did not materially increase the weight and an increase of at least 50 per cent in the strength of all driving parts. The trains referred to have been built somewhat longer than our previous units to provide more passenger seating capacity as well as additional baggage carrying facilities. A few changes have been made in the spark control of the engine which caused some trouble on account of not being fitted up substantially enough for the service in that a pressed fit was used which we were later obliged to weld solid in order to get it to hold. A roller bearing is used in the trucks of these cars which gave us trouble in the beginning owing to the inner sleeve of the bearing not being applied tight enough. Due to this the sleeves would work off the axle, come in contact with the outer bearing cap and generate sufficient heat to burn up the packing and lubrication, causing a complete failure. This can be overcome by adhering more closely to the mounting pressures recommended by the A. R. A. and used universally in American steam railroad shops. A better system of electric generation and storage by means of an axle lighting device and storage battery has been arranged for.

Sykes trains make 260 miles a day

One of the two Sykes trains referred to is running between Ft. Dodge, Ia., and Council Bluffs, a distance of 268 miles a day, every day. The motor car of the other train is operating between Oelwein and Ft. Dodge, a distance of approximately 260 miles a day, every day, and

*From a paper read on March 26, before the Minneapolis Section of the Society of Automotive Engineers.

is handling a mail and express car that weighs 35 tons light with an average of 10 tons of baggage and express, or equivalent to a 45-ton trailer, and is handling it very successfully.

On some of the units of equipment previously purchased, the cars were equipped with traction brakes which could not be operated in connection with standard steam railway automatic air brakes. These have been changed over, however, and we strongly urge from our experience that future units of motorized equipment be supplied with brakes that will operate in conjunction with the standard coaches, the foundation brake gear on some of the motor cars has been constructed too light, and not enough attention has been given to it generally with respect to clearances as the various parts wear. Instances have been known where, with the slightest amount of lost motion, the brake levers would strike some part of the truck frame before the average brake cylinder piston travel was experienced.

A small gas locomotive

The Chicago Great Western also has on order at this time, but its construction has not been completed as yet, a 25-ton six-wheel gasoline switching locomotive that it is proposed to operate on a branch line running from Cedar Falls Junction to Cedar Falls, Iowa. This locomotive is being built by the Baldwin Locomotive Works and is designed to pull about five loads and one coach at a maximum speed of 18 miles per hour.

These various units of equipment are indicative of the trend in design of motorized equipment on steam railroads. Three years ago we were talking single cars with a baggage space of approximately 50 sq. ft., seating capacity from 36 to 40 passengers, light weight approximately 15 tons, designed to run 40 miles an hour on level track. In this short period of time we have realized the 100-ton motorized train, traveling at 50 miles an hour.

It would be opportune to say at this time also that we are getting very fair service out of our older units of motorized equipment including the first Sykes train, the Service car and the McKeen cars.

Gasoline motor car data

Motor Car	Trailer	Period covered	Miles run	Cost per mile run, cents: Operation	Maint.	Total	Miles run per: Gal. gas.	Pt. oil
M-200	MT-201	Oct. 1922 to Jan. 1925.	59,304	22.92	11.30	34.22	4.01	13.62
M-205	MT-206	Aug. 1923 to Jan. 1925.	65,870	21.16	7.33	28.45	2.62	11.36

*1.23 gal. of fuel oil per mile.

A special maintenance department

The results given above in miles run and costs both for maintenance and operation, also the performance with respect to oil and gas consumption, suggests another very important thought and that is that the Chicago Great Western found it necessary to develop a gas engine department for the care of these cars and this department we know is to a great degree responsible for the successful performance of our motor cars. We have in our gas car organization a motor car expert who is on my immediate staff and whose jurisdiction extends over the entire system in seeing that the cars are maintained and assisting and instructing enginemen who wish to qualify as motor car operators. At our main shops at Oelwein we have a gas engine repair organization consisting of a foreman and several mechanics, helpers and apprentices who are engaged on gas engine work entirely. This refers to heavy and medium repairs particularly. For the light repairs on cars laying over at the engine terminal or roundhouse a specially trained gas engine mechanic is employed to see that the cars and their equipment are properly cared for and repaired.

The Chicago Great Western is now considering the building of a separate repair shop close to but somewhat removed from the main plant owing to the fire hazards existing. The building that we have in mind will be erected consistent with the type and the number of units of equipment that we now have. It will be equipped with special machinery for repairs to our motor cars.

In conclusion, in the construction of motor cars it is always well to bear in mind accessibility in order to facilitate repairs. This refers not only to the truck and body construction but to the engine as well.

Steam for enginehouse heating systems and blower lines*

By H. W. Williams

Superintendent of motive power, Chicago, Milwaukee & St. Paul, Tacoma, Wash.

Low pressure steam is more efficient for heating purposes than is high pressure steam, for the simple reason that the heat content of one pound of steam at low pressure is but little less than at high pressure. For instance, a pound of steam at 125 lb. gage pressure contains 1192.2 B.t.u. while at 10 lb. gage pressure it contains 1160.4 B.t.u. Most engine terminals are at least partially equipped with vacuum return systems but unfortunately it is easier to extend live steam lines than it is the heating mains, consequently in most instances it will be found that the radiation supplied with live steam exceeds the original low pressure installation,

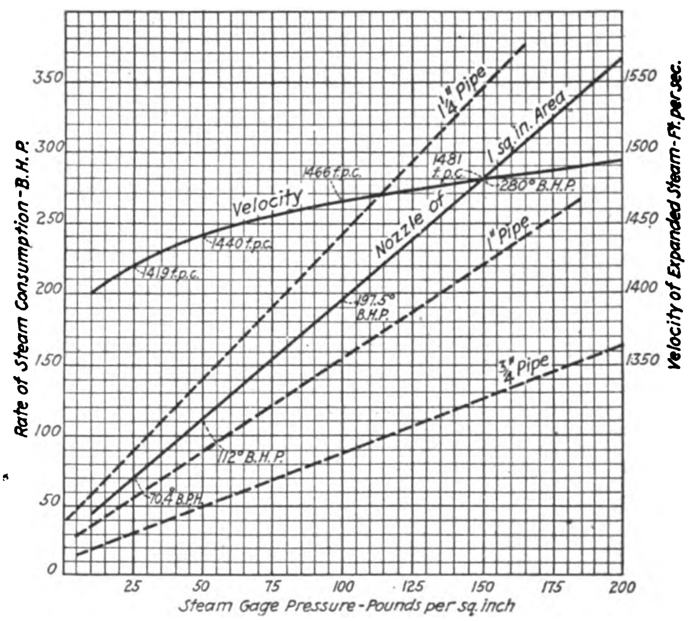

Fig. 1—Rate of steam discharge through nozzles of different size

* Part of a paper read at the annual Master Mechanics Staff Meeting of the C. M. & St. P. held at Milwaukee, Wis., on September 8, 1924.

and further, it quite frequently happens that no traps are provided on the high pressure radiators, in which case the steam is allowed to escape to the atmosphere unimpeded. A radiator full of steam when trapped will give off just as much heat as one where the steam is permitted to blow through to the air.

An illustration of what happens when steam is allowed to blow through a radiator into the atmosphere unobstructed is as follows: A pound of steam at 10 lb. gage pressure will give off 10 B.t.u. and a pound of steam at 125 lb. gage pressure will give off 42 B.t.u., whereas, if properly trapped and allowed to condense, a pound of steam at 10 lb. gage pressure will give up 980 B.t.u. and a pound of steam at 125 lb. gage pressure will give up 1,012 B.t.u. while as a matter of fact, the effect on the room temperature is the same in either case because the radiator will be no hotter in one case than the other, provided the condensation is drawn off properly. In other words, if steam is allowed to blow through the radiator unimpeded,

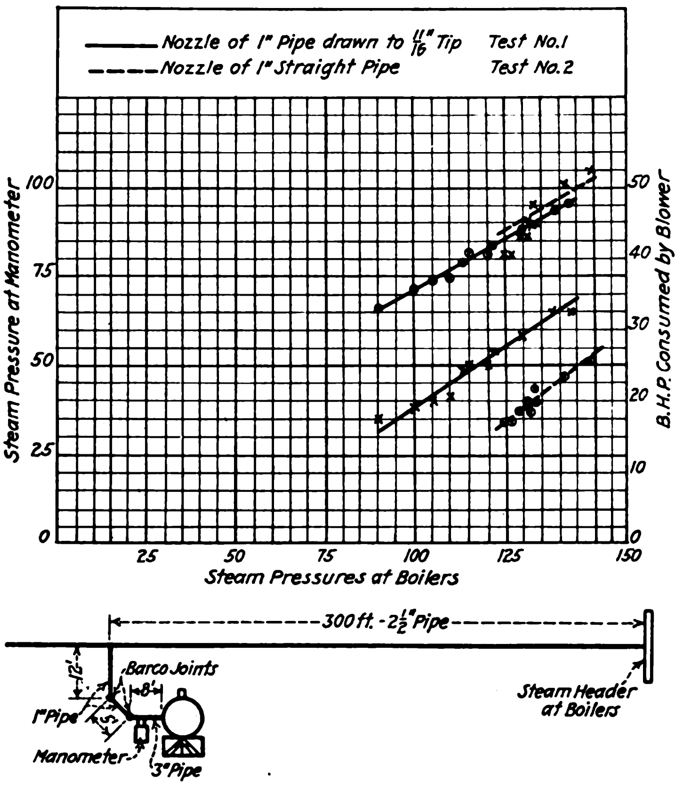

Fig. 2—Actual steam discharge through straight end drawn nozzle tips determined by tests at the Western avenue, Chicago, enginehouse of the C. M. & St. P.

it will require 92 times as much steam at 10 lb. gage pressure and 24 times as much steam at 125 lb. gage pressure to produce the same amount of heat as could be obtained with one pound of steam in either case if the radiators were properly trapped. In addition, there is still 180 B.t.u. in each pound of steam after it has condensed that may be recovered with a properly operated vacuum return system. Bearing in mind that at 10 lb. gage pressure there will be 275 lb. of steam per hour discharged through a ½-in. pipe which, on the basis of 6,000 B.t.u. equivalent per pound of coal, will approximate 50 lb. of coal per hour, it will be evident that this feature has an appreciable effect on the coal consumption.

There are no doubt instances where the installation of a properly installed vacuum return system, which would include all the radiation, would give the same relief as the installation of an additional boiler in the power plant.

Another heavy steam consumer at engine terminals that is not always fully appreciated is the roundhouse blower line. The amount of steam that blows out through the locomotive stack while firing up an engine depends entirely upon the amount of steam that the blower pipe line can carry. Fortunately in most instances the distance from the boilers is so great and the blower pipe line is so small, particularly where it drops down to connect to the front end blower, that the steam pressure has dropped sufficiently to hold the steam consumption to a reasonably small amount. Fig. 1 shows the rate of discharge of steam into the atmosphere for varying steam pressures from pipes of different sizes. The heavy line indicates the amount of steam discharging through a nozzle of 1 sq. in. cross sectional area. The blower arrangement in the majority of the engines consists of a 1¼-in. pipe, which, if there were unrestricted volume back of it, would consume steam at 150 lb. gage pressure at the rate of 345 boiler hp. However, on account of the small pipe sizes used in the blower line and blower line drops, the actual consumption is very much less than 150 lb. of steam.

In order to determine just what this amounts to, some actual measurements were taken recently at Western avenue. The test results are shown graphically in Fig. 2. From these it is determined that with boiler gage pressures between 125 and 150 lb. the steam consumed is between 40 and 55 boiler hp. This will vary with the steam pressure and will be effected somewhat by the distance from the boiler room, owing to the pressure drop in the main pipe line. However, the greatest pressure drop occurs in the small pipe and connections between the blower line and the front blower connections, as this is usually reduced to a ¾-in. pipe connection. From this and other information collected on the subject, it may safely be assumed that the average consumption for blowers is no less than 50 hp. With the blower on for 45 min. this would represent about 225 lb. of coal (6 lb. per boiler-hp. hour).

Turtle-back roof applied to B. & A. suburban cars

Maximum seating capacity with convenient facilities for prompt loading and unloading—Vestibule ends economically constructed

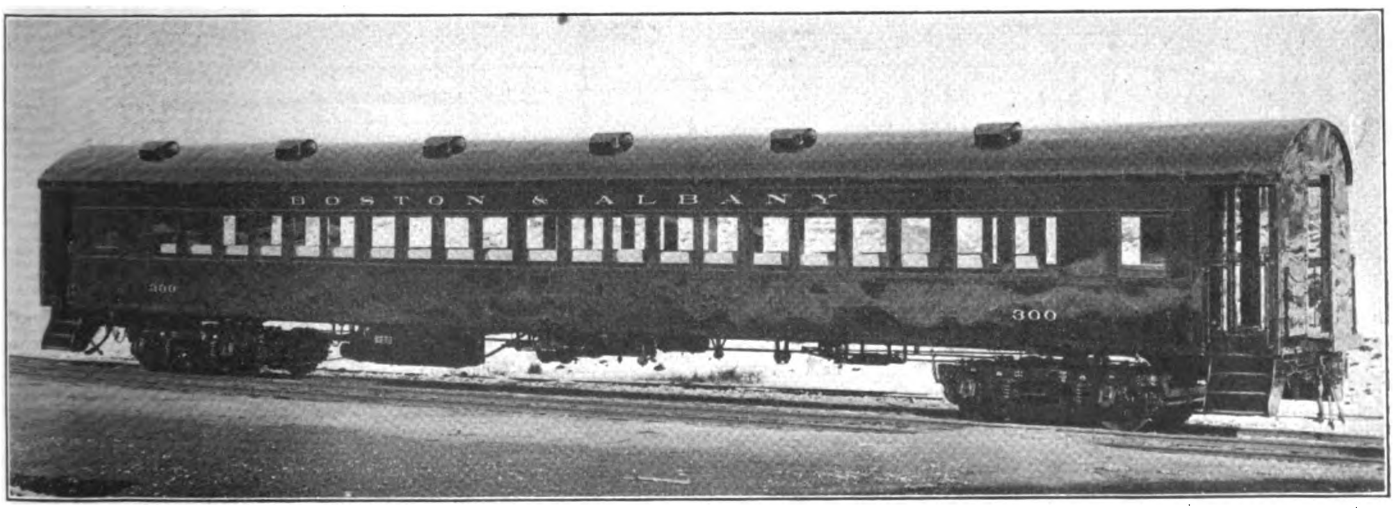
An order of 50 steel suburban passenger coaches built by the Osgood Bradley Car Company, Worcester, Mass., has recently been placed in service by the Boston & Albany. The passenger cars now used on the main line and the highland branch between Boston, Mass., and Riverside, will be replaced by this equipment.

Before designing this equipment the problem of handling suburban passengers in and out of Boston was carefully studied, after which it was decided that the utmost seating capacity with convenient facilities for promptly loading and unloading were demanded by the conditions. Features of the cars which help to attain these ends are the ample space provided at each end of the car for standing room, the wide end doors and wide steps with four treads and the fact that the seats have no arms, which adds considerably to the ease of passage through the aisle and entrance into the seats.

Underframe frame construction equal to that of coaches in through passenger service

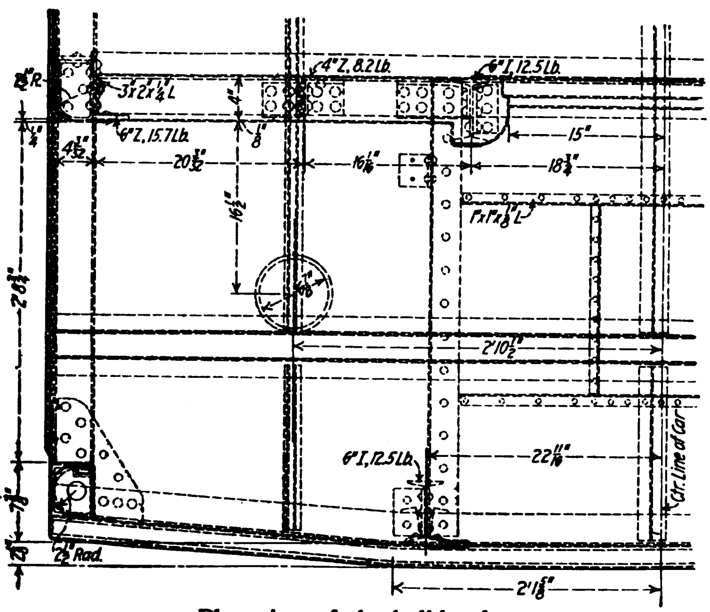
The cars are of steel construction throughout, with steel interior finish. The underframe and superstructure details have been so designed that their strength is equal to that of coaches in through passenger service.

The center sills consist of two 12-in., 35-lb. channels,



Steel suburban passenger coach with seating capacity for 100 passengers

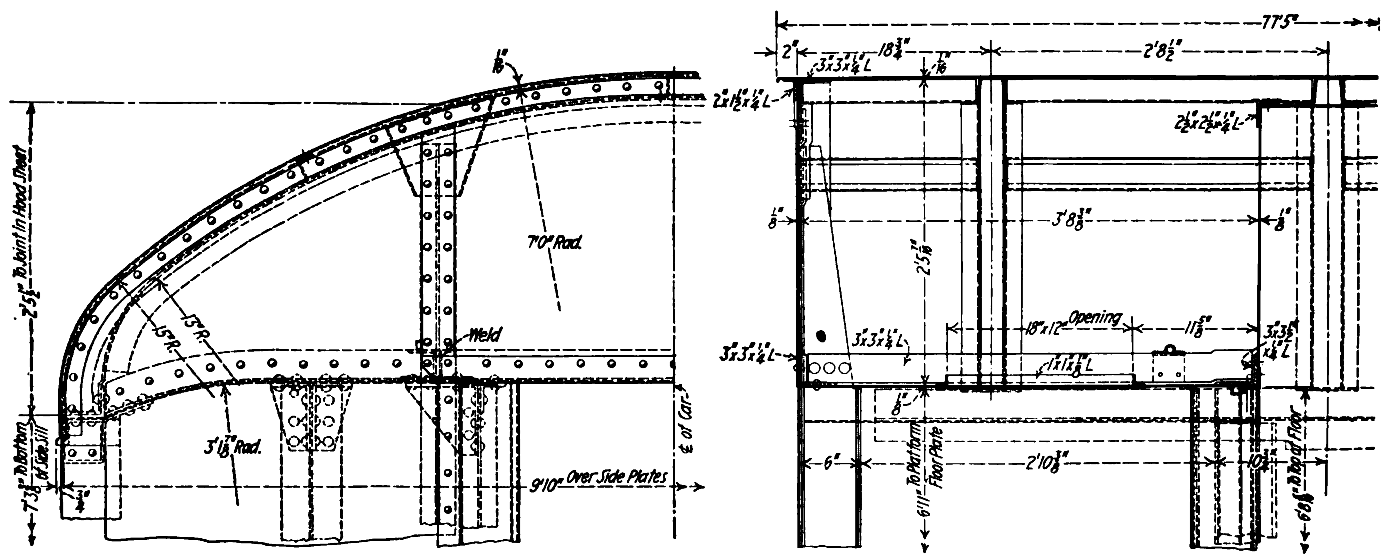
spaced 18 in. back to back and riveted to the bolster castings. Each channel is reinforced at the bottom by a 3½-in. by 3-in. by 7/16-in. steel angle. The cover plate is 28 in. by ¼ in. extending between the bolster centers. Cast steel body bolsters and platforms make up the two ends of the underframe construction. The side sills are 5-in. by 3½-in. by 7/16-in. rolled steel angles. The side and center sills are tied together with three ¼-in., pressed



Plan view of the bulkhead

steel, flanged, crossbearers provided with ¼-in. cover plates.

The 12 floor supports form additional underframe members and consist of ⅛-in. pressed steel channel shapes. Riveted to the pocket in the bolster casting at each end of

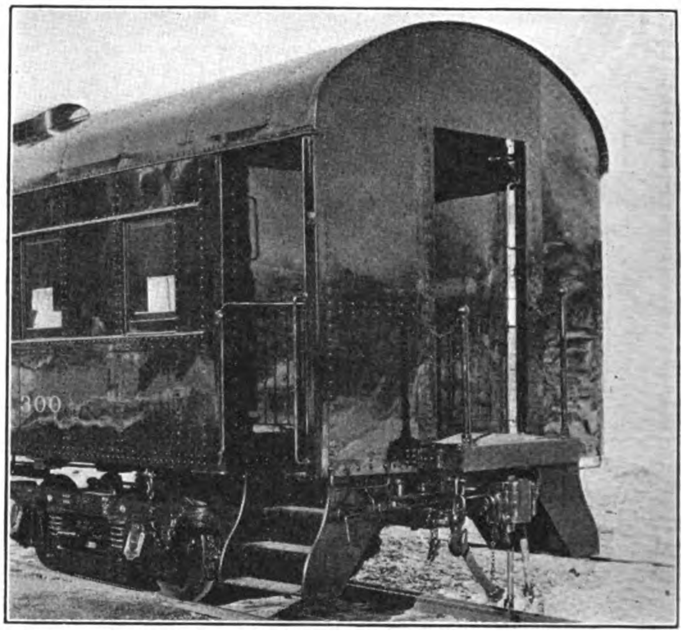


Longitudinal and cross section of the vestibule roof

the car, are two end door posts which consist of 6-in., 12½-lb. I-beams. At each end of the car riveted to the bolster casting are two intermediate end posts made from 4-in., 8.2-lb. Z-beams. The 6-in. Z-beam body corner posts are riveted to the bolster casting.

Turtle-back roof effects savings in materials

The roof is of the turtle-back type. The construction consists of 28 carlines of the flanged channel type made of 3/32-in. steel plate. There are three purlines of ⅛-in. pressed steel, Z shapes, fitted between the carlines. The roof sheets consist of 1/16-in. steel sheets, extending from the side plates in one piece. The roof sheets are butted



Turtle-back roof permits economical end construction of the car

together over the carlines and are made tight by welding. The cars have no hood as the roof sheets extend in a straight line to the intersection with the vestibule end sheets. One of the drawings shows a plan of the bulkhead constructed. The roof is provided with 12 Garland type ventilators, with registers in the interior.

Single windows are used in these cars with the sash fitted with O. M. Edwards window fixtures. The seats are spaced so that each passenger is opposite a window. Over the seats are basket racks of the Adams & Westlake type which will provide ample space for commuters' parcels.

The cars are well insulated, having three-ply of ¾-in., special hair felt which covers the entire inside surface of the outside sheathing on the sides and ends of the car, except above the windows. The flooring is composed of

special ⅝-in. corrugated galvanized steel, laid crosswise of the car and covered with Flexolith. The platform floor is covered with Feralun.

Low-arched, light colored ceiling diffuses light

To facilitate reading, the lighting arrangement of these cars has been carefully planned. Along each side of the low-arched ceiling are placed 26 attractive lamps. The head lining is finished in a cream color down to the frieze moulding. This combination of a low-arched, light colored ceiling, diffuses the light so that the passengers can read comfortably. Current for the lamps is furnished by Gould electric light equipment, and each car is provided with a 225-ampere Edison battery. The steam heating system is of the Vapor type, designed to maintain at all times a comfortable temperature on the interior. The cars are equipped with the New York U. C. air brake equipment.

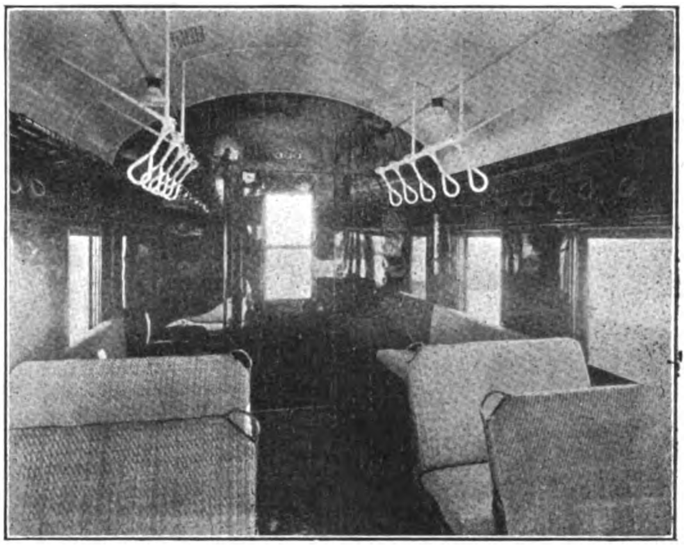
The coaches have seating accommodations for 100 passengers —Ratan seats without arm rests

Four-wheel trucks are used, equipped with the Simplex clasp brakes, and 33-in. forged steel wheels. The small wheels are used to facilitate charging the storage batteries, by their greater number of revolutions. The journals are 5 in. by 9 in.

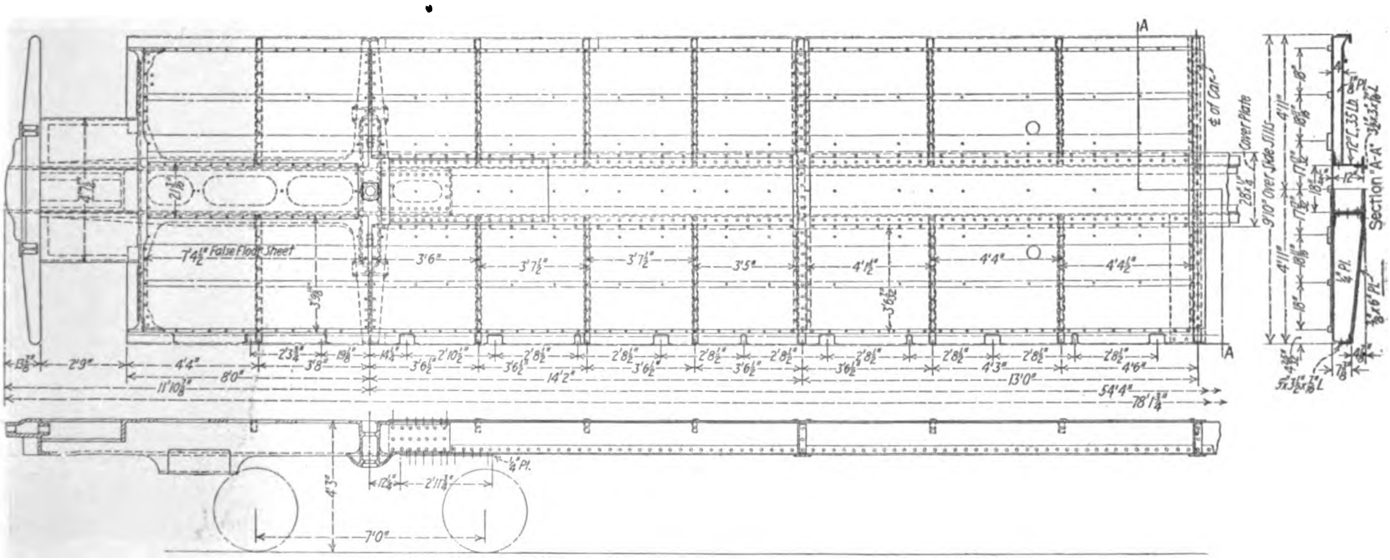
It will be noticed that the end doors have an opening of 2 ft. 6 in. and that considerable room has been provided immediately inside of the doors. The platforms have an opening of 2 ft. 9 in. at the vestibule steps. A standing space of approximately 14 sq. ft. is available. The vestibule steps have four treads and are easy to reach from the platforms at track level.

Weight per seated passenger slightly over 1,000 lb.

The empty weight of these cars is 101,500 lb. With a seating capacity of 100 persons the weight per seated passenger is but slightly over 1,000 lb. The over-all length of the cars coupled is 78 ft. 11¾ in.



Ample standing room and overhead hand straps are provided at the ends of the cars



Underframe construction of the Boston & Albany suburban cars

A WAGE INCREASE of two cents an hour has been granted by the Atchison, Topeka & Santa Fe to its shop crafts employees on all lines.

Enginemen and firemen on the Southern Pacific lines in Texas and Louisiana have been granted a wage increase of approximately 5 per cent, retroactive to September 21, 1924. This increase is in line with similar ones which were awarded previously on the Southern Pacific, Pacific system, and on other western roads.

D. L. & W. Hoboken, N. J. terminal, which handles from 66,000 to 67,000 commuters daily

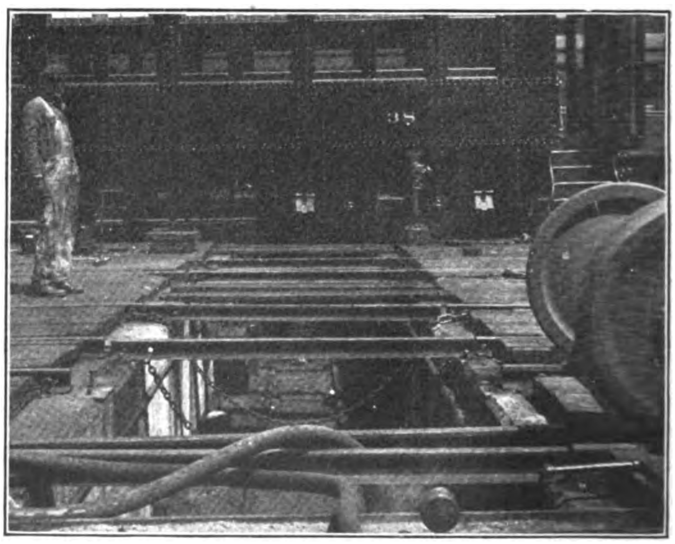
D. L. & W. coach maintenance at Hoboken, N. J.

Adequate facilities and organization have increased the time between shoppings—Paints emulsion cleaned every five months

THE terminal maintenance of passenger equipment is one of the big problems of the car department. Just as it is important to provide adequate facilities and efficient organizations for the proper maintenance of locomotives at terminals, so is it essential to provide the proper facilities and organization for the terminal maintenance of passenger equipment. The principal object of this plan is to increase the length of time between the shopping of cars and, in doing so, keep the number of cars going in the repair shops down to a minimum. In other words, the rate of depreciation of passenger equipment is decreased with the increased efficiency of terminal maintenance.

Blacksmith forge located near repair tracks

The maintenance of passenger car equipment at the Hoboken, N. J., terminal of the Delaware, Lackawanna & Western is based on the above principles. Proper facilities and organization are necessary to handle the cars at this terminal, as 115 suburban trains and 10 main line trains are dispatched every 24 hours. Approximately 450 suburban cars make 700 arrivals and 150 main line cars enter Hoboken every day which gives a total of about 850 car arrivals. Between 66,000 and 67,000 commuters pass through the Hoboken terminal every day.

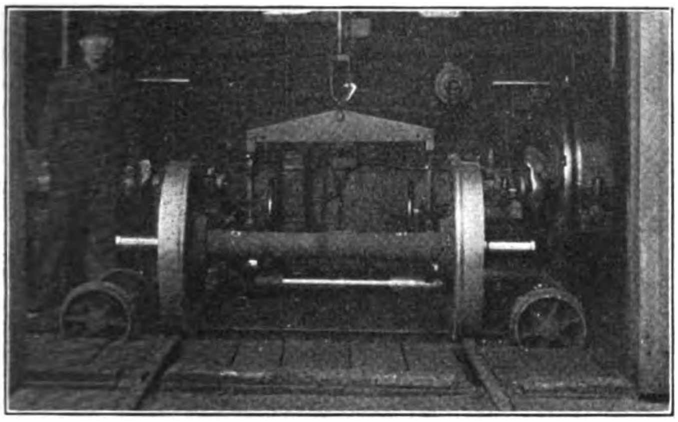


Four track drop-pit located 60 ft. from the wheel lathe

The train and car arrivals have been carefully analyzed by means of graphic charts which show the number of cars arriving and leaving each hour of the day. This graph indicates the rush periods and serves to act as a guide for putting on the maximum working force and the best time of the day to take the cars out of service for repairs.

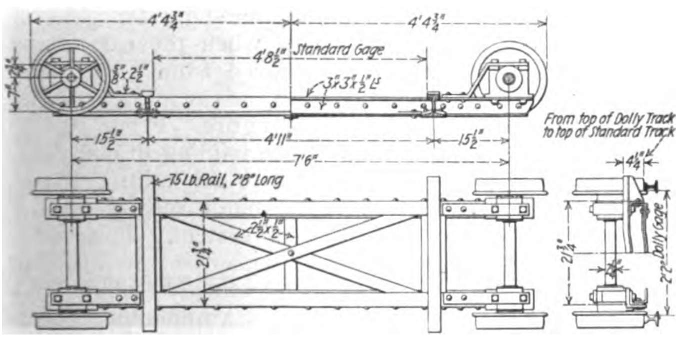
Method of cleaning cars

A schedule has been worked up by which the cars are cleaned on an average of once every five months by an emulsion cleaner. The controlling factors used in preparing this schedule are the condition of the cars, the service they are in and the time out of the shop. The length of the period between general repairs depends largely on the condition of the paint on the car.



Pair of wheels on the dolly truck ready to be placed on the outbound track

To retain the lustre and preserve the paint, the cars are passed through a coach cleaning shop which has two pit tracks with a capacity of six cars. The cars are taken from service after the morning rush hours, passed through the shop and put back in service in time to handle the evening peak traffic. There are six men in this shop who work on a piece-work basis. The exterior of the cars are cleaned with an emulsion cleaner which removes all of the dirt and grime from the paint and gives it a finished appearance. If the interiors of the cars need cleaning, the paints are washed or renovated which returns the paint to its original lustre. Of course, the floors and lavatories are thoroughly scrubbed and cleaned. Cars on the through trains are either emulsion cleaned, washed or repainted, depending on the condition of the paint. Between the working hours of from 8 A. M. to 4 P. M. five cars are passed through this shop without being withdrawn from service. This operation is also carried on in the winter as a temperature of 70 deg. is maintained in the shop.

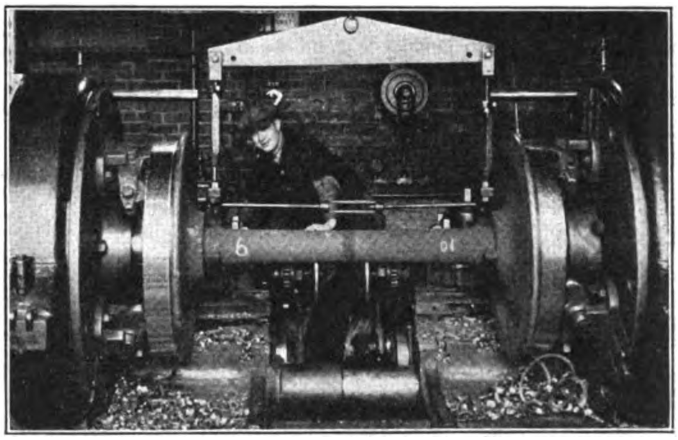


Dolly truck which facilitates the movement of wheels to and from the wheel lathe

Facilities are provided at one end of the coach cleaning shop for the mounting of air, signal and steam hose. During the day a workman from the shop does this work. After the evening rush hours, the terminal car inspectors do this work, as they have plenty of time on their hands between the departure of the evening trains.

Maintenance of car trucks and platforms

All the truck and platform work is done at this point, between the morning and evening rush hour periods without the need of taking the cars out of service. A gang of 12 men is assigned to do the work. A four-track drop pit, which is shown in one of the illustrations, has been provided to facilitate the dropping of wheels. The drop pit is made of concrete and is about 4 ft. deep and 5 ft. wide with a 2-ft. 2-in. dolly truck at the bottom passing under the four tracks. The car truck containing the pair of wheels to be removed is placed over one of the pits. When the wheels are ready to be removed, a small four wheel dolly truck is placed over one of the pneumatic pit jacks and raised up to the wheels. The wheels are raised off the track and the two rail sections are removed which allows the wheels to be lowered into the pit. The truck and wheels are then run along the bottom of the pit to the track which leads to the wheel lathe. The rail sections over this track are removed and the wheels raised above the track level and then the rail sections replaced. The wheels are then lowered and rolled out on the wheel lathe feeder track. This arrangement provides a quick method of removing and replacing wheels.



Pair of steel wheels can be machined on this lathe and placed on the outbound track in 25 min.

A short distance from the drop pits is a blacksmith forge which is completely tooled to handle any kind of repairs which may require a blacksmith. A skilled blacksmith is assigned to this work but since he does not have enough work to keep him busy throughout the day, he helps the general repair gang.

Method of handling wheels

The decision to install a wheel lathe at Hoboken terminal was primarily based on economic considerations. Prior to the installation of the wheel lathe all wheels to be turned had to be transferred to Kingsland, N. J., which is about 7 miles from Hoboken. This operation tied up a considerable amount of wheels and kept cars out of service longer than was necessary, besides the expense involved in moving the wheels between these points. It was figured that the expense involved in transferring the wheels to the distant point plus the capital tied up in extra wheels,

kept on hand for repair work, would pay for a wheel lathe in a comparatively short time. In other words, it was more economical to bring the tool to the work instead of the work to the tool.

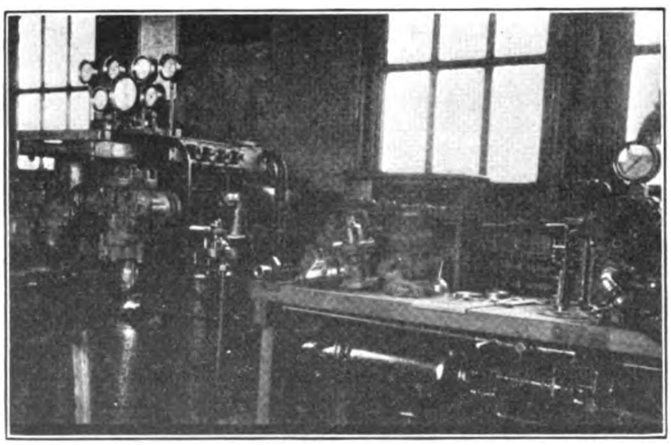
As a result a Sellers wheel lathe, capable of turning steel wheels, was installed. This lathe is housed under a shed which is approximately 60 ft. from the center line of the drop pits. There are two tracks leading to the wheel lathe, one for wheels waiting to be turned and one for turned wheels. These tracks each hold about 15 pairs of wheels. Just at the end of these two tracks and directly in front of the wheel lathe, is a 2-ft. 2-in. dolly truck, which is shown in the accompanying drawing. The distance between the axle centers in 7 ft. 6 in., in between which are fastened two sections of 75-lb. rail, 2 ft. 8 in. long and located 15½ in, from the center of each axle, which makes the distance between the rails 4 ft. 8½ in.

The lathe is placed on a concrete foundation sufficiently below the ground level so that a pair of wheels can be rolled to the lathe and readily placed on its centers by means of an overhead air hoist. After the wheels are turned, they are placed on the dolly truck and moved to the outbound track. By means of this arrangement a pair of wheels can be rolled into the building, placed in the lathe, turned, removed from the lathe and rolled out on the finished wheel track in 25 min.

If a pair of Pullman wheels is needed in a hurry, a reverse movement can be made. The wheels can be run down the outbound track to the wheel lathe, thus avoiding moving all the wheels on the feeder track.

The short distance over which the wheels have to move from the drop pits to the wheel lathe, coupled with the dispatch with which the wheels are handled in and out of the lathe, have reduced the amount of extra wheels on hand to a minimum and delays to cars waiting for wheels to zero.

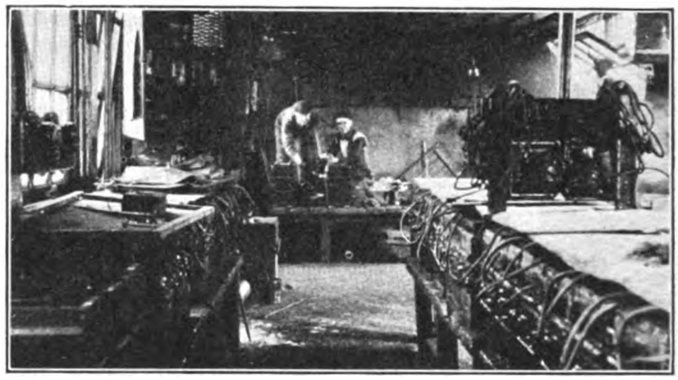
Another advantage obtained by the location of this lathe at the terminal is that a close check can be kept on steel wheels in order to have them turned in time for use in freight service. In the past 36-in. steel wheels worn below the 1-in. limiting mark were scrapped. The A.R.A. rules now permit the use of these wheels in freight service, as there still remains ¼ in. of wearing metal which will give from three to four years of freight service. Full advantage is being taken of this ruling of the A.R.A. at Hoboken with the result that many steel wheels are being diverted to freight service.



U. C. and triple valve testing racks located in air brake room

Maintenance of air brake equipment and steam heat

The majority of the passenger car equipment at this terminal is of steel construction and equipped with the U. C. brake equipment. The schedule for bringing the cars in for cleaning has been so arranged that the U. C. equipment is due for cleaning at the same time. This is an advantage, as the cars can be placed over a pit for the removal of the U. C. equipment, which makes it much easier for the repairmen to remove them because of their heavy weight. Westinghouse test racks for U. C. and triple valves are in the air brake room, which is located in a building adjoining the coach cleaning shop and the repair pits. These test racks should be located at the terminal as considerable expense and time is saved over the practice of sending air brake equipment to be tested at the back shops, which are usually a considerable distance from the terminal. Furthermore, this arrangement keeps the air brake equipment down to a minimum. All air brake governors, reducing and steam heat valves are repaired in the air brake room.



Batteries from all the cars running into Hoboken are repaired in this shop

Battery and car lighting maintenance

The batteries of all the cars running into Hoboken terminal are repaired in the battery repair shop, which is 14 ft. wide and 35 ft. long, and located directly beneath the air brake room. Six men are assigned to battery maintenance, four in the repair shop and two outside inspecting and making minor repairs. The batteries are removed from all the cars sent to the shops for general repairs and repaired and replaced when the cars come from the shop. A battery is removed from a car, torn down, rebuilt, tested and replaced in the car in 33 hr. time, which is considered a good repair figure. From 100 to 125 batteries are given a general overhauling in one year.

A gang of seven men is assigned to car lighting maintenance. They inspect and make minor repairs on the generators and the general lighting system. This force has become thoroughly familiar with the car lighting equipment and is able to locate and remedy trouble in a short time. Repair parts are kept at a minimum. Uniform results are obtained as routine inspection periods are made covering the whole equipment.

Method of cleaning cars in the yard

Considering that there are about 850 car arrivals every day at this terminal, considerable work must be done in the yards and in the train shed. One of the big jobs is the dry wiping of these cars every day. The work is done by gangs in charge of a gang leader. The arrival and departure of the trains have been analyzed so that these gangs can move from one train to the other with a minimum loss of time, the heaviest work being done during the longest layover. This arrangement is essential as all the cars must be wiped once a day, most of which is done on a piece-work basis. The cars are wiped with waste

which was used in the coach cleaning shop for the final polishing of the cars. This leaves a certain amount of the emulsion cleaner on the waste which helps to remove the dirt and polish the cars. The exterior of the cars are dry wiped, except in rainy weather, when they are washed.

Every suburban car is swept, dusted and mopped and the water cooler iced and filled daily. The water coolers are also steamed weekly. Repairs are made to all the hardware and other minor defects which can be quickly repaired.

The plush seats of the suburban cars are vacuum cleaned once a week and the main line cars once a day. This is accomplished by means of a vacuum system which is piped throughout the terminal and in all the offices. Two-inch pipe is used, from which an outlet is taken every 75 ft. The vacuum for this system is maintained by two vacuum pumps each driven by a 40-hp. Westinghouse induction motor. A vacuum of 21 in. is maintained at the plant with one vacuum pump. All the offices at the terminal are cleaned with vacuum cleaners.

Results obtained at Hoboken

The facilities and the organization described in this article were planned to achieve certain definite results. The primary object was to increase the length of time between shopping periods of passenger equipment, without deterioration to the cars and without sacrifice of a favorable general appearance of the equipment. In doing this the number of cars passing through the general repair shop every month would be reduced and thus the working force eventually reduced. The length of time out of the shop for D., L. & W. passenger cars has been increased from 12 to 18 months or over. Thus, if a shop had to give general repairs to 1,200 cars, it would have to handle 100 cars a month on a 12-months shopping basis and on an 18-months shopping basis would have to handle 66 cars a month. The saving effected is obvious.

The results of receiving periodical emulsion cleaning give a more general uniform appearance of trains which reacts favorably to the traveling public.

Decisions of the Arbitration Committee

(The Arbitration Committee of the A.R.A. Mechanical Division is called upon to render decisions on a large number of questions and controversies which are submitted from time to time. As these matters are of interest not only to railroad officers but also to car inspectors and others, the Railway Mechanical Engineer will print abstracts of decisions as rendered.)

Work necessary to justify the charge for cleaning air brakes

On February 27, 1923, the Charleston & Western Carolina cleaned the air brakes on N.O.T. & M. car No. 750 for which it rendered to the Gulf Coast Lines a bill for $5.17. The Gulf Coast refused to pay the bill on the grounds that the work had not been performed according to Rule 60 effective January 1, 1923, the second paragraph of which provides that the charge is not permissable for cleaning the triple valve unless the triple valve cylinder, retaining valve, dirt collector or pipe strainer are all cleaned at the same time. The items listed on the repair card indicated that the dust collector or pipe strainer had not been cleaned. The Charleston & Western Carolina stated that car No. 750 was not equipped with a dirt collector but was equipped with a strainer made solid in the train line tee at the branch pipe connections. It could not be cleaned or become dirty, as dirt or scale would go straight through the strainer and the train line and could not get into the branch pipe. The repairing line also contended that circular D.V. 276 was issued to cover this particular feature.

The Arbitration Committee rendered the following decision: "The charge in question is sustained, in accordance with Circular D.V. 276, dated April 28, 1923. At the date of the repairs, there was no requirement that the billing repair card should show that the car was not equipped with a centrifugal dirt collector."—*Case No. 1325, Gulf Coast Lines vs. Charleston & Western Carolina.*

Car damaged through lack of rider protection

The C. B. & Q. furnished a joint inspection statement, dated July 14, 1923, which contained a list of defects existing on C. & W. C. car No. 3074, and requested disposition under A. R. A. Rule 120. The handling line did not advise the circumstances under which the damage occurred. Later, the C. B. & Q. advised that the C. & W. C. car was damaged in switching service without rider protection. As a result of this admission on the part of the handling line, the car owner declined to authorize repairs, as the damage was the handling line's responsibility under Rules 143 and 120 and Rule 32 Section D, Item 4. The handling line contended that ample evidence had been furnished the car owner that its car had been damaged in fair usage on a practically level track where no rider protection was necessary. The car owner contended that even though the switching took place in practically a level yard, the fact that the impact of two cars coming together broke six sills on its car, indicated that rider protection should have been provided.

The Arbitration Committee rendered the following decision, "The handling line is responsible for the damage to this car as per Rule 32, Section (d), Item 4. Case 1224 is parallel."—*Case No. 1331, Chicago, Burlington & Quincy vs. Charleston & Western Carolina.*

Charge for testing and adjusting safety valves on tank cars

During the months of October and November, 1923, the Shaffer Oil & Refining Company tested the safety valves of 17 cars belonging to the Johnson Oil Refining Company. Each car was equipped with two safety valves. Bills were rendered against the car owner for this work with a labor charge of four hours per car, two hours for adjusting the valves to a 20-lb. pressure and two hours for the testing. The labor charges were assessed according to A. R. A. Rule 107, Items 288 and 288B. The car owner returned the bills to the repairing company for correction stating that only two hours labor should have been charged for each car in accordance with A. R. A. Rule 107, Item 288B. The car owner stated further that the testing and adjusting should be considered as one operation as safety valves must be tested after being adjusted to show that they have been adjusted correctly. The repairing line contended that the two operations were separate, inasmuch as the valves were removed from the car and put on a test rack. If the spring is properly adjusted to 25 lb. pressure, the valve is considered O.K. If not properly adjusted, the valve has to be removed and the spring adjusted until it releases at 25 lb. This makes it necessary to take the valve off and on several times to make the proper adjustment.

The Arbitration Committee rendered the following decision: "The contention of the Shaffer Oil & Refining Company is sustained."—*Case No. 1328, Johnson Oil & Refining Company vs. Shaffer Oil & Refining Company.*

One day's output—Eight completed cars

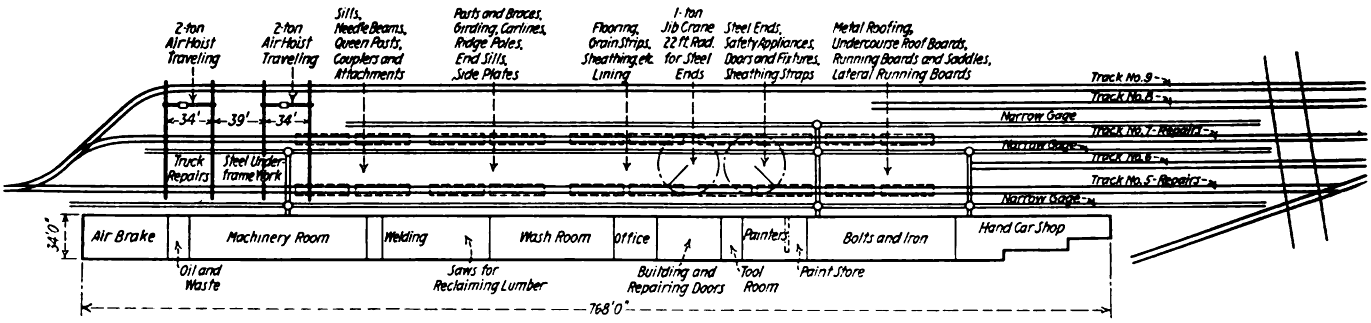
Burlington rebuilds eight box cars a day at Aurora

Successful application of station-to-station method and production system has resulted in increased output

At the Aurora, Ill., car repair shops of the Chicago, Burlington & Quincy an extensive application of the station-to-station method has been in operation for several months which has two features of unusual interest: First, the fact that the station-to-station method has been successfully applied to a rebuilding operation where the cars are not completely dismantled and, second, a simple production system which not only increases the earnings of the men engaged but serves as well to speed up production. Work on this program was started on November 25, 1924, and, up to April 2, 1925, with two rebuilding tracks working, 681 cars had been completed.

The cars being rebuilt are 40-ft., 80,000-lb. capacity box cars with wood superstructure, side and intermediate sills and steel center sills. In the rebuilding operation they are fitted with two-piece corrugated steel ends and metal roofs.

The present rebuilding operation is carried on on two parallel tracks with identical work being performed at adjacent locations as the cars are moved from station to station. The output averages four cars per track for each working day, a total of eight finished cars per day. By this method a car is completed and ready for service at the end of the fourth day from the time it is placed on the stripping tracks.

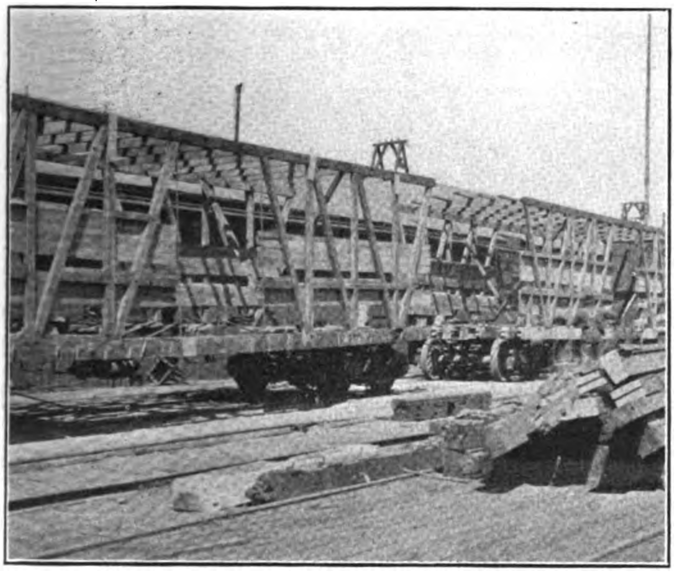


Layout of repair tracks showing the location of the different stations

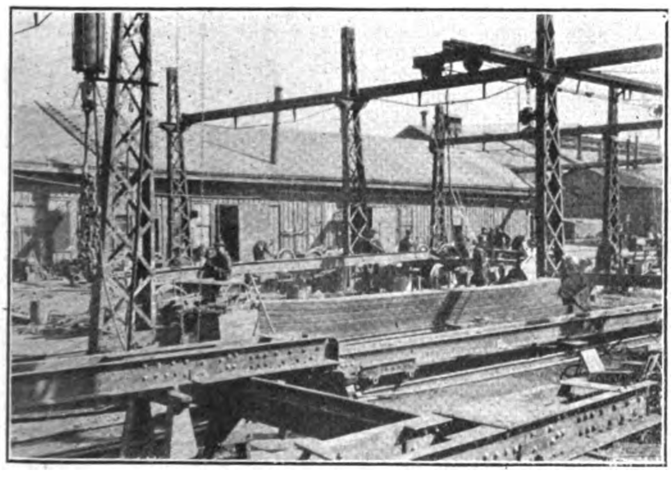
At the present time the average force employed on the entire stripping and rebuilding operation consists of 146 men classified as follows:

25 helpers and laborers on stripping tracks.
82 freight car repairers on the two rebuilding tracks.
1 steel car repair man } On truck channels.
1 steel car helper
13 steel car repairmen } On repairs to steel center sills.
6 steel car helpers
2 steel car repairmen } On fabrication of steel ends.
4 steel car helpers
3 air brake repairmen.
5 painters.
3 door men.
1 car oiler.

Before putting this repair system into operation a careful study was made of the various operations and the time required for each and a schedule was prepared providing a fixed time allowance for each operation. The total time allowance for all operations required in complete stripping and rebuilding program is 203½ man-hours per car. At the present time the work has progressed and been systematized to such an extent that the average time per car has been reduced to approximately 144 man-hours. A production system is in effect whereby if a gang is able to complete their particular operation in less than the time allowed by the schedule it results in a proportionate increase in the amount paid them for that particular operation. This system is remarkably simple and efficient in operation. The fact that it is possible for one man to keep all of the time records of the total force employed in connection with the complete rebuilding operation is an indication of the simplicity of the time and production system. The production feature functions in such a manner that if a gang on a certain operation is able to complete that operation on a number of cars within a given period in less time than the schedule allows, they are paid at the rate of the allowed time per car for the actual number of cars completed. For example: Suppose on a certain operation two men were allowed 1 hr. 30 min. per car and their hourly rate was 62 cents. They are actually able to complete their operation on 12 cars in 13½ hrs. However, they would be paid for 12 cars at the allowed time of 1 hr. 30 min. each, or a total of 18 hrs. at the hourly rate of 62 cents. In this manner their hourly rate for 13½ hours would be actually increased to 82.6 cents.

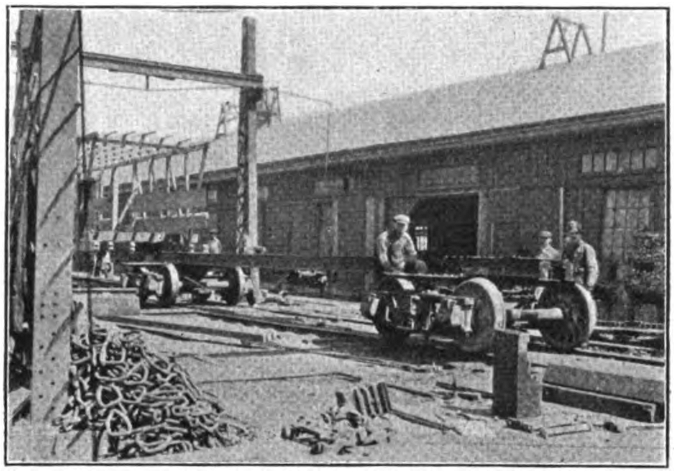


Stripping operation completed—Ready for rebuilding



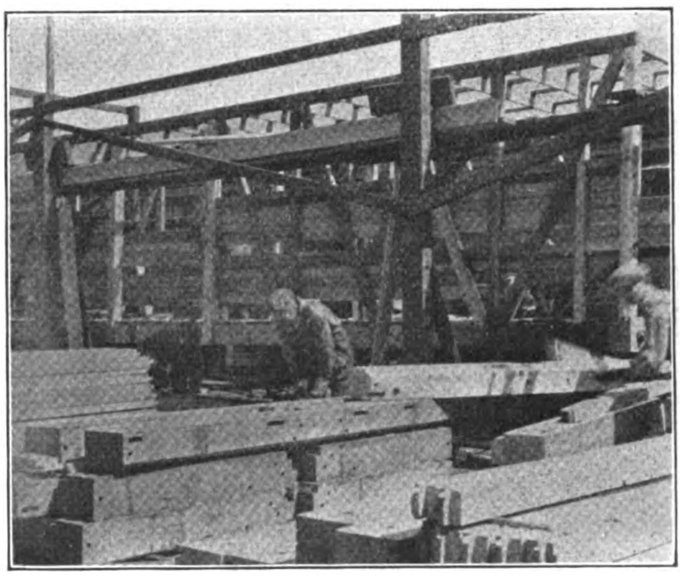
Truck and steel center sill repair station showing overhead cranes

The fact that the rebuilding operations are conducted on parallel tracks sets up a spirit of friendly rivalry between adjacent gangs at the different stations and this has enabled a substantial reduction in the time required to complete the rebuilding of a car as well as a general increase in the earnings of the men.



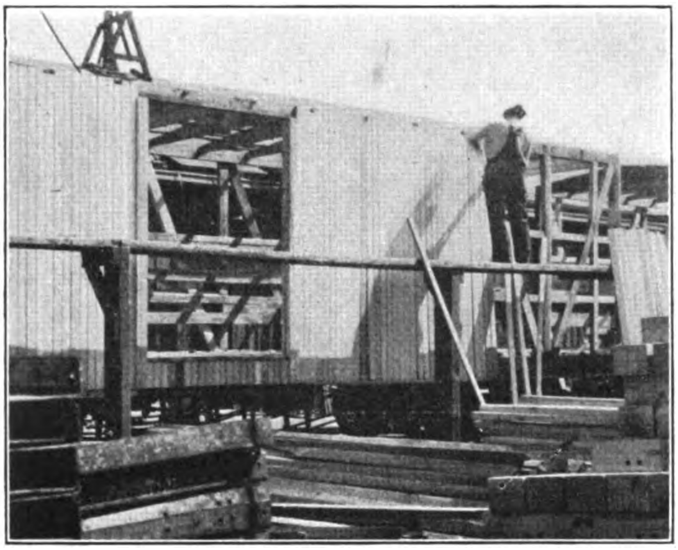
Trucks and sills repaired and ready to be returned to car

In general, a given number of cars to be rebuilt are placed on the stripping tracks each morning. After the stripping operations are completed the cars are moved by tractors and placed two at a time on each of the two rebuilding tracks. The first rebuilding operations consist principally of the jacking up of the car body and the removal of the trucks and steel center sills for repairs and the application of cover plates. An interesting feature of this operation is the manner of removal of the trucks and center sills from two cars at a time. Both cars on one track are jacked up and after the trucks and center sills



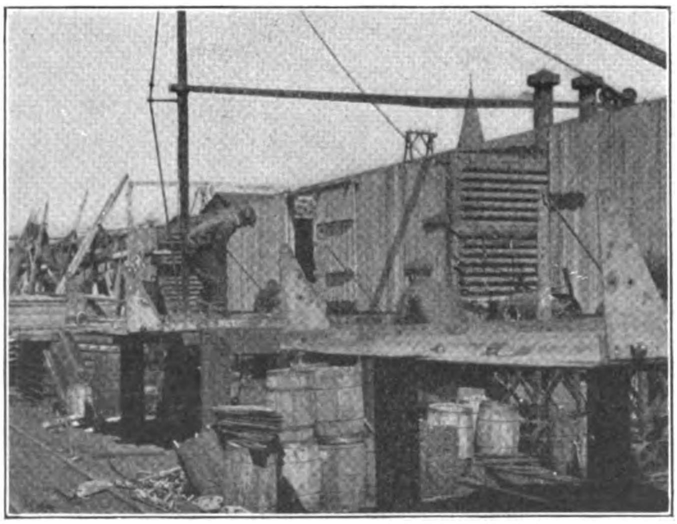
The framing of the car completed

are run out from under the car nearest the truck repair station the trucks and sills from the second car are removed from under the car and follow the first set, passing under the first car on the way to the truck repair station. Overhead crane service is provided at the truck and steel center sill repair station and the air brake repair and test room is located adjacent to this station. When the work at this station is completed the car is moved to the next station where the work on the body framing, flooring and sheathing, etc., is carried on. Adjacent to this station is the door shop where three men turn out an average of 16 complete side doors and 16 running board



Framing completed—Applying the side sheathing

extensions each eight-hour day. The fabrication and application of steel ends is also made at this location. From here the cars are next moved to the stations where all roof work is completed and from there to the stations where the first and second coats of paint are applied and finally all stencilling is done and final inspection made.



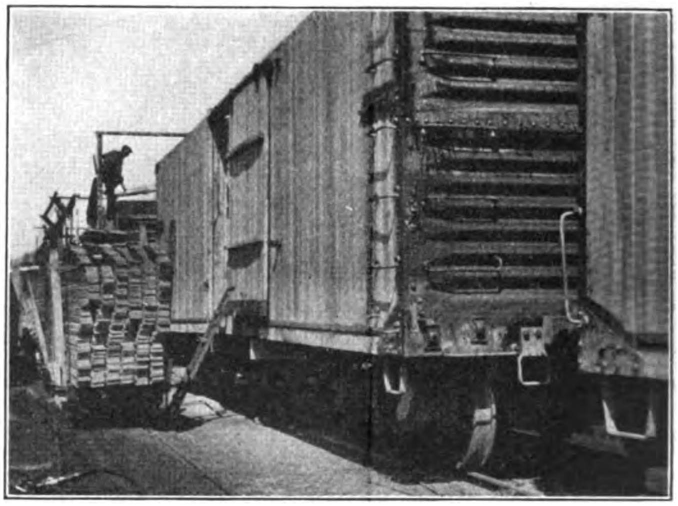
Fabricating the steel ends

Rigid inspection is also made at the completion of each operation.

The general layout of repair facilities makes it possible to effect an unusually economical scheme of material distribution. Material for the various operations is concentrated at each station, a separate gang checking material at all times and providing material from the main storehouse, car machine shop, blacksmith shop, and mill to replace that which is used. Tractors with trailers and trucks on narrow gage tracks are used to transport this material.

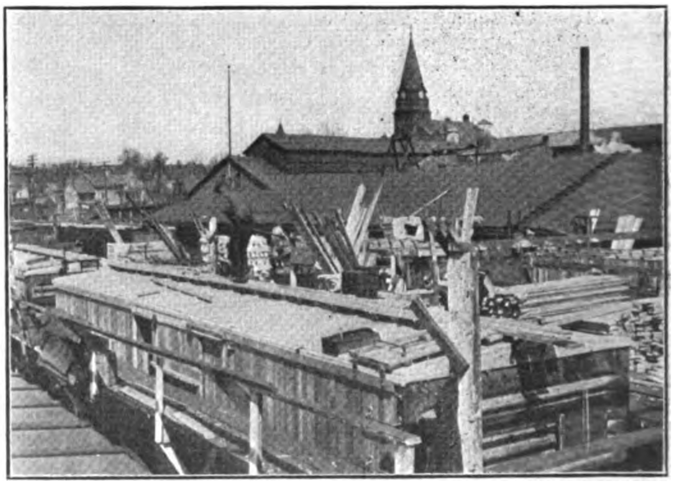
Details of operations at each station

Position No. 1—Stripping—Operations: Remove running boards and roof, brake shaft castings, all fascia, side and end doors, door



Car body completed ready for moving into position where roof is applied

tracks and fillers, door brackets, front and back stops, corner plates, grab irons, sill steps, sheathing and sheathing straps, corner end and side door posts, end plates, tie rods and buffer lugs, door lintel strips, nailing strips, necessary flooring, lining, grain strip and girth, threshold plates, cleaning nails from all framing not removed and the preparation and bracing of car for moving.



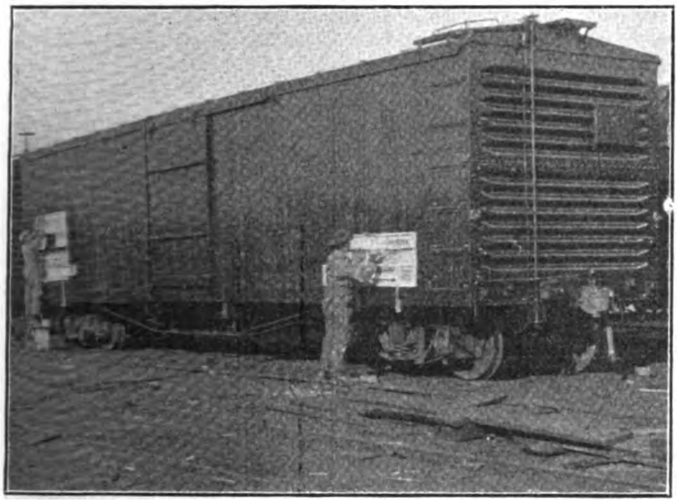
Roof repair position—Note elevated platforms and material

Remove box and column bolt nuts, end sills, buffer blocks, couplers, pin lifters, brake step, turnbuckles, truss rods, needle beams, body bolsters, all brake connections, pipe clamps, release rods; drive up post rods when side sills are to be removed and apply the necessary cleating of posts and braces.

Position No. 2—Rebuilding—Operations: Jack up car and remove trucks and steel center sills. Remove and replace side sills, intermediate sills or splices. Remove and replace truss rods, bolt truss rod saddles to sills, frame old needle beams, remove and replace lever carriers, floating levers and brake rods, air cylinder, needle beams and castings; replace trucks and steel center sills and body bolsters and jack car body down.

Position No. 3—Rebuilding—Operations: Tear down trucks and rebuild complete, including channels, bolsters, arch bars, springs, journal boxes, brasses and wedges, wheels, brake beams, brackets, hangers and pins, levers, bottom rods, brake shoes and

keys and dust guards. Men at this position assist in removing trucks and steel center sills from under the car and help take combined steel sills off the trucks, apply couplers, followers, springs, friction castings and tie castings. They also assist in replacing trucks and steel center sills under the car. Spring channels are also repaired at this position by a separate gang of two men.



Painting finished and ready for stenciling

Position No. 4—Rebuilding—Operations: Straighten steel sills; apply cover, lap and gusset plates, body bolster and truck center plates, needle beam clips; line up broken sills and apply channel patches. Remove and replace draft castings and body bolsters. Cut up scrap sills, and do all necessary burning, bolting up, reaming, heating and driving rivets. The men assist in handling steel sills off and on trucks.

Position No. 5—Rebuilding—Operations: Apply end sills, corner posts and lugs, side door posts, intermediate posts and side braces, end and side plates and rods, carlines and anchor lugs, purlines and ridge pole, renail old purlines, tighten carline lugs, sill steps, sheathing girth, ladder posts, anchor rods for steel ends, carline and ridge pole bolts.

Position No. 6—Rebuilding—Operations: Apply and nail side sheathing complete. Apply and nail flooring, complete.

Position No. 7—Rebuilding—Operations: Apply side doors, side door stops, open door stops and blocks, door brackets, tracks and fillers, door hasps on stops and doors, side plate door headers, grab irons, brake step, sheathing straps, side plate anchor rods, uncoupling levers. Bore holes. Adjacent to this position is the door shop in which three men are employed on side doors and running-board extensions.

Position No. 8—Rebuilding—Operations: Rivet metal ends together including the application of gusset plates. Apply metal ends. Bore holes and apply bolts through middle and bottom gusset plates; intermediate tie rods, apply truss rod nuts, turnbuckles and block and tighten up. Apply buffer blocks, carry irons and end sign boards.

Position No. 9—Rebuilding—Operations: Apply side and end lining. Bolt nailing strips to steel ends, post strips, grain strips, lining blocks, clean nails off inside the car and apply threshold plates.

Position No. 10—Rebuilding—Operations: Apply metal roof complete including all filler battens, longitudinal running board, running board extensions, brake shaft and bracket, saddles and brackets, side and end fascia. Apply all washers, lock nuts and nuts on all roof bolts inside the car, lay bottom course diagonally, set nails, end plate tie rods: straighten car, bore holes and apply bolts in top gusset plates and end plates.

After all rebuilding operations are completed the cars are given two coats of paint by the spray method and all stenciling is done. When this is completed final inspection is made and the cars are ready for service.

Hand brake power for freight cars

A discussion of the recommendations contained in the report of the A. R. A. Committee on Brakes and Brake Equipment

By Robert H. Blackall

THE recommendations contained in the report of the Committee on Brakes and Brake Equipment of the American Railway Association, Mechanical Division, which was made at the convention held at Atlantic City, N. J., June 11 to 18, 1924, were ordered submitted to letter ballot of the members. The letter ballot circular, No. D. V.-375, was mailed at Chicago, October 18, 1924, and the ballot was closed on November 18, 1924. It was recommended by the committee that the hand brake wheel or hand brake ratchet lever, brake staff at the chain, and the hand brake leverage between the brake staff and cylinder shall be so proportioned that a force of 125 lb. at the rim of the brake wheel of three inches from the outer end of the hand brake ratchet lever develop an equivalent load W at the brake cylinder piston of not less than 2,500 lb. and 3,950 lb., respectively, for cars having 8-in. and 10-in. cylinders. Inasmuch as the views of the writer, which are based upon practical tests with the dynamometer, do not coincide with the results assumed in the report, a discussion of some of these results and various points connected with the subject in general may be of interest.

According to the formulas given in the report, the pull on the chain at the brake shaft would be $W = \frac{125L}{r}$ in which $r = M + K$. M is the radius in inches of the brake staff drums, and K, the distance, in inches, from the face of the brake staff drum to the center line of the brake chain.

The instructions in the report, using a 7/16-in. brake chain as shown in Fig. 1, give $K = \frac{1}{2}$ in. Using the brake shaft drum shown in Fig. 2, $r = 1\frac{1}{4}$ in., $L =$ the diameter of the brake wheel, or the distance from the center of the shaft to the end of the ratchet lever, and $W =$ the work performed.

Referring to Figs. 2, 3, 4 and 5, it will be seen that the distance from the center of the shaft to the center of the chain is $1\frac{1}{4}$ in., 1 9/16 in. or $1\frac{3}{8}$ in., according to how the chain happens to be winding on the drum at the time of full application. This maximum difference is but 5/16 in., yet in an actual dynamometer test it will be found that, with one man, there is often a considerable variation which is accounted for principally by this difference in the distance from the center of the shaft to the center of the chain.

The instructions in this report assume that the center of the hand is 3 in. from the outer end of the lever, which distance approximates a hand 6 in. in width. As a matter of fact we believe this distance is more nearly 2 in.

With a dimension of 19 in. from the center of the shaft to the end of the lever, and subtracting 3 in. as directed,

we would have 16 in., or the same as the value L for a 16-in. diameter brake wheel. On this basis the value for the ratchet lever referred to in the report would develop a chain pull exactly the same as with a 16-in. brake wheel, which is not borne out by dynamometer tests.

If the method suggested of taking 3 in. off of the distance from the center of the shaft to the center of the lever is followed when using a 28-in. club, we will have, referring to Fig. 6, practically the same condition as we would have with a lever 20 in. long.

If this method of reasoning holds good, it is equivalent to saying that practically no more braking power can be obtained by the use of a 28-in. club than with a wheel alone, which we know is not the case.

A test was made on May 10, 1920, with three brakemen in the presence of seven observers, most of whom were engaged principally in office work. The results of this test are shown in the table, from which it will be seen that the maximum chain pull obtained with a 16-in. wheel was 1,280 lb. against an average of 1,098 lb. Using a 28-in. club on a 16-in. wheel a maximum pull of 2,400 lb. was obtained by one of the brakemen, the average being 1,930 lb. A maximum chain pull of 2,500 lb. was made by the writer with an 18-in. leveraged ratchet and the average was 2,084 lb. With a 24-in. leveraged ratchet the maximum chain pull was 2,700 lb., which was also obtained by the writer, and the average was 2,308 lb.

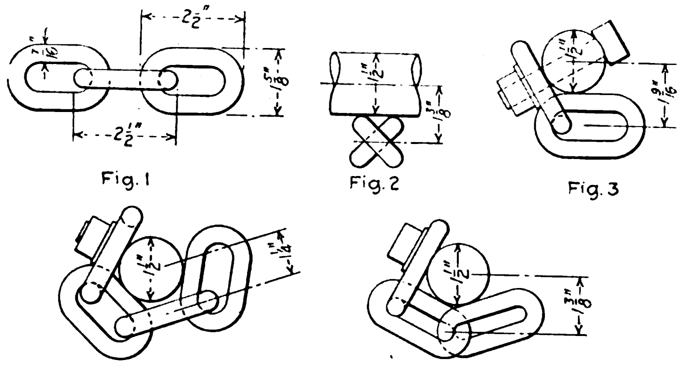


Fig. 1 Fig. 2 Fig. 3

Fig. 4 Fig. 5

Drawing showing different windings of the chain around the brake staff drum

It will be noted that the use of the formulas recommended by the committee give a value of 1,600 lb. for the 16-in. wheel whereas the maximum chain pull in this test was 1,280 lb. and the average 1,098 lb.

According to the formulas the ratchet having 19 in. from the center of the shaft to the end of the lever should have given a pull of 1,600 lb. whereas the maximum was 2,500 lb. and the average 2,084 lb.

In studying this table it will be noted that there is a reading given for both maximum and "dog," and that the variations in these readings vary all the way from 200 lb. to 700 lb. The average pull was approximately 300 lb. The maximum reading means the greatest pull that was obtained in each test and the "dog" reading refers to the amount to which the chain pull dropped back when the shaft was allowed to revolve backwards until the pawl or "dog" engaged the ratchet wheel. This emphasizes the necessity for having as large a number of teeth as possible in the platform ratchet commensurate, of course, with the strength.

The minimum number of teeth used at present for new equipment is 16 and it would seem that it would be working towards greater efficiency of the hand brake to make this number 25. The writer has seen this number of teeth in a gear and it had ample strength. Another interesting point developed by this test was that instead of having a shieve to double the power of the chain pull, this pull was never within 10 per cent of the theoretical doubling that was supposed to result and it was sometimes less.

From data resulting from dynamometer tests it would seem correct to use in the formula an average pull at 2 in. from the end of a lever as 170 lb. and at the edge of a brake wheel as 100 lb. and the average distance from the center of the shaft to the center of the chain as $r = 1\frac{1}{4}$ in.

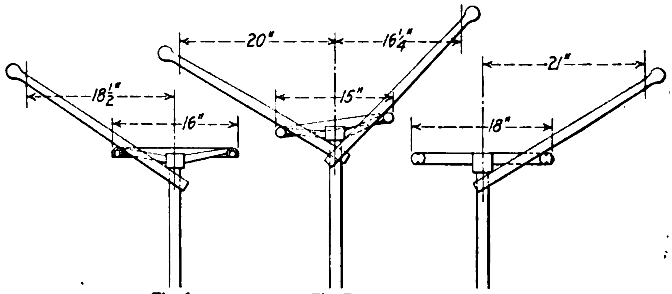

Fig. 6 Fig. 7 Fig. 8

Drawing showing the various lengths of leverage obtained with a 28-in. club on 16-in., 15-in. and 18-in. hand brake wheels

There has been considerable agitation for the use of a booster in connection with the hand brake. Several devices placed on the market are quite ingenious and most of them will do exactly what is claimed for them with the slack in the brake rigging a predetermined amount. However, the pull does not always remain constant when this slack varies. The great objection to practically all boosters is the initial cost and the fact that as long as a brake wheel is used, the club will be used also. This means excessive braking power on these cars and trouble will result if the strength of the brake step is figured only for the power developed by the wheel and booster. It also has to withstand the power developed by the use of a brake stick.

The following example can be cited in order to show that this conclusion is not theory. About 1904, the writer designed a gear multiplying mechanism which was placed on about 1,000 ore cars. After this gear had been in use for some time it was found necessary to use a short leverage ratchet so as to prevent the brakemen from using a club on the hand wheel. Trouble was experienced afterwards because of friction in the gears when the end of the car bulged. The final result was that all of these boosters were removed and replaced by a ratchet which gave a predetermined amount of power.

Straight Pull On Chain		Meyers	Coulter	Peck	Courtney	Blackall	Clark	Emery	Straight	Peden	Taylor	Average

24" Lever	Dog	2000	1300	2200	1500	2300	1800	2200	1920	2100	1900	1922

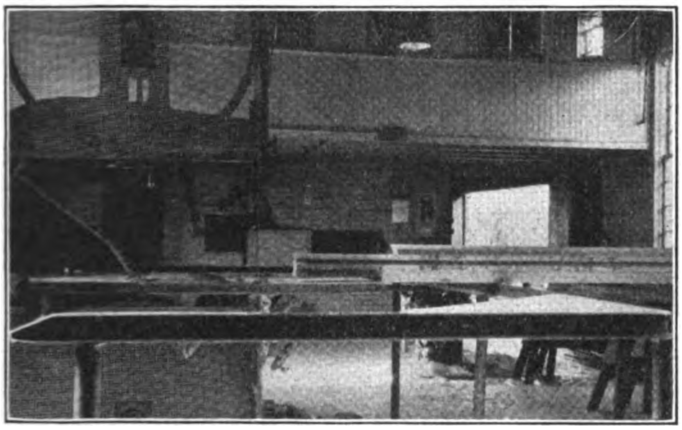
Table showing the maximum chain pull obtained in tests on various types of hand brakes

If the committee desires simply to establish an arbitrary method of figuring the hand brake power, it would seem advisable to employ the results of a dynamometer test as a basis. The formulas give too low a chain pull for all but the brake wheel, and this is too high. The lower the brake chain power the greater the necessity for multiplying this power in order to obtain the same chain pull as that developed by the air brake with 50 lb. cylinder pressure. The result will be more chain to wind up and there is hardly sufficient room at present for the chain to be taken care of properly. Because of this it would seem advisable to approximate more nearly the actual power applied at the rim of the brake wheel or to the end of the ratchet lever and thus get an efficient hand brake with a minimum amount of chain to be taken care of.

It will be of interest to note that the horizontal distance or leverage, of a 28-in. club as shown in Fig. 6 is 18½ in. This is the same as a ratchet lever having a distance of 20½ in. from the center of the shaft to the end of the lever and taking off 2 in. for the distance back to the center of the hand.

Cutting large pieces on a band saw

PRACTICALLY every wood shop has occasion at some time to cut large pieces of lumber on a band saw. The carpenter usually finds it somewhat difficult to perform such work as notching side posts and diagonal braces at the ends, for box and refrigerator cars on a band



A rail placed at the same height as the band saw provides additional support for large pieces

saw of the ordinary type without using a horse or trestle to hold up the other end. Quite often the side post or diagonal brace falls off the horse while the notch is being cut and breaks the saw. The arrangement shown in the illustration has been devised so that long pieces may be readily handled on a band saw without any possibility of accident due to the overhanging end falling off a trestle or other support. It consists essentially of a light rail bent as shown and placed at the same height as the table of the band saw. Triangular shaped filler boards are placed in each corner so that the operator may swing the work to any position desired without liability of it falling down inside the rail as it is swung around a corner. There is sufficient clearance between the rail and the table to allow plenty of room for the operator to handle small pieces. Another advantage in having such an arrangement is that a truck can be placed along side of the rail and each piece can be moved endwise across the rail to the saw and cut with a minimum amount of lifting and handling.

Device for cutting out holes in dust guards

THE usual practice in cutting the holes in dust guards is to chuck the guard on the face plate of a lathe and feed the tools to the work. The method used for doing this work at the Kingsland car shops of the Delaware, Lackawanna & Western is the reverse; i.e., the cutting tools are mounted on the face plate and the dust guard placed in a suitable holder and fed to the tools.

The method of mounting the tools in the face plate

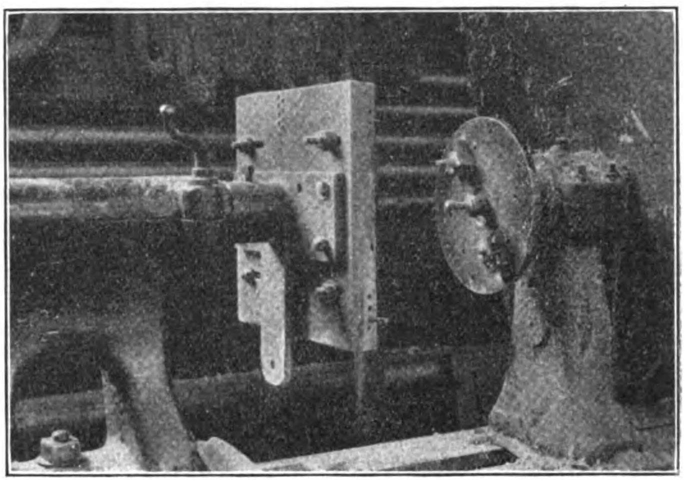


Fig. 1—Arrangement of adjustable cutting tools on the face plate of a lathe

is shown in Fig. 1. The tools are ground to a width of ¼-in. and placed in the toolholders which are adjustable for the purpose of cutting any diameter of hole required for any size of axle. The piece cut from the dust guard is pushed from the hole by a device extending from the lathe spindle. Its primary purpose is to warn the operator that the cut has been finished and that the dust guard should be set back to prevent the tools from digging into

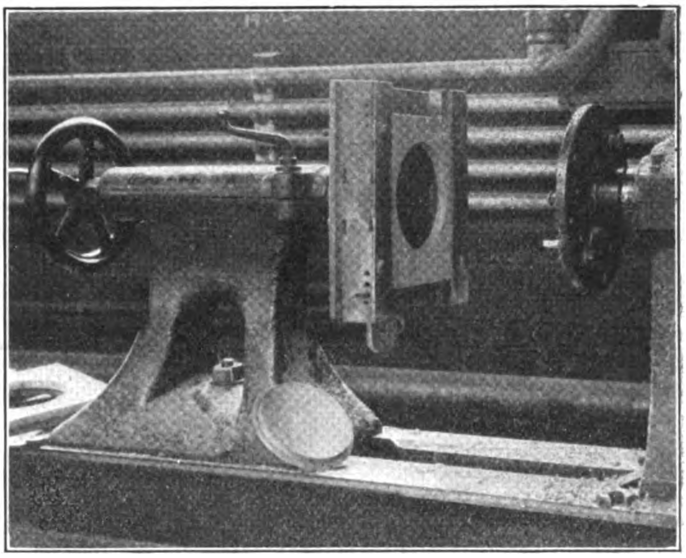

Fig. 2—Adjustable holder for holding various sizes of dust guards

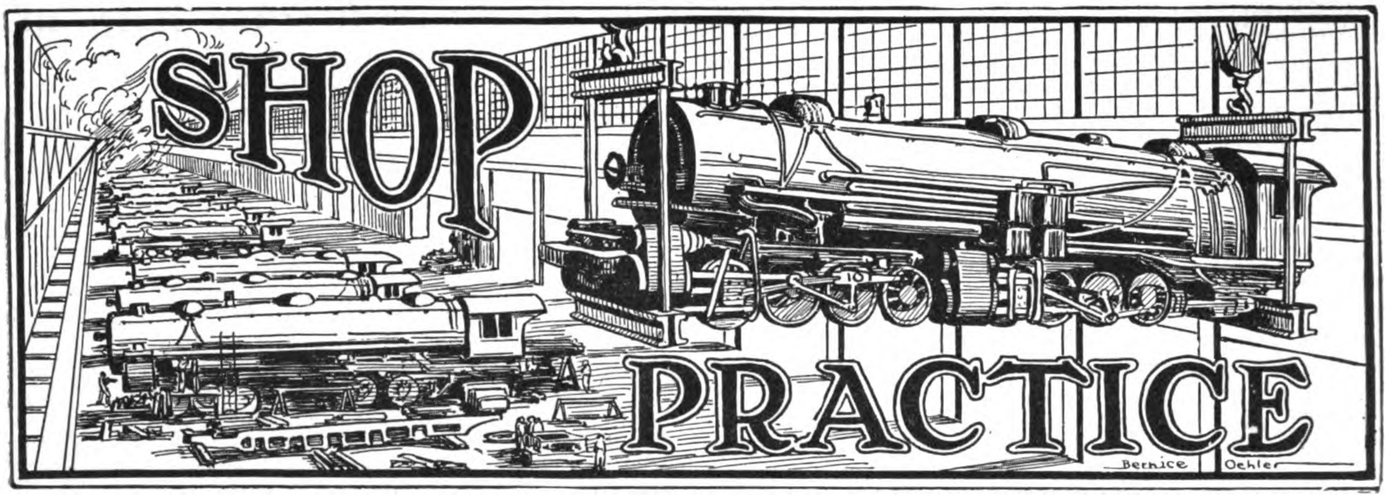
the rear of the dust guard holder. The device consists of a bolt which fits in a bushing and has a nut and washer on one end and a spring at the other.

Fig. 2 shows the method of holding the dust guard. With this arrangement dust guards can be machined with great rapidity. The actual time to complete one piece is 45 sec.



Booster inspection and maintenance

Instruction of enginemen in handling boosters and close attention to lubrication are important maintenance factors

THE locomotive booster has proved an important factor in the increased utilization of the steam locomotive. Like many other appliances found on the modern locomotive it presents a new and somewhat different maintenance problem. A study of this problem on some of the railroads which have a large number of boosters in service brings to light the fact that the real solution of the booster maintenance problem lies in the prevention of trouble, rather than in the repair of the equipment.

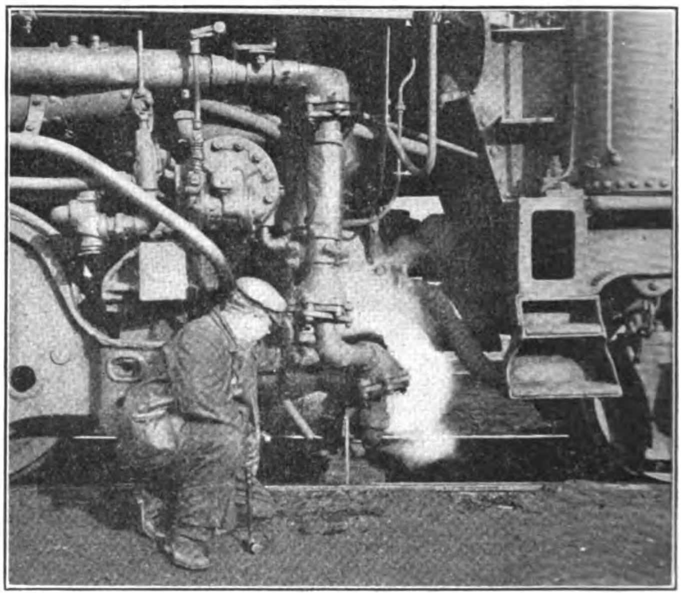
The Lehigh Valley, particularly, has been successful in the operation of booster equipped locomotives, and has 60 in service at the present time—50 Mikados in freight service and 10 Pacifics in passenger service. Two facts stand out rather prominently in studying the conditions on that road, viz.: first, that since the first booster was placed in service in March, 1923, there has not been an engine failure which could be charged to the booster and, second, that not one of the 60 boosters in service has yet been dismantled for a general overhauling. Some of these booster equipped locomotives have made more than 100,000 miles and the majority have made from 35,000 to 50,000 miles.

It has been found that the most successful way in which boosters may be maintained is to provide a separate organization to look after this work. Consequently, at each engine terminal where booster locomotives are cared for there has been assigned one machinist whose principal duty is to look after the booster equipment. These men are responsible for inspection and maintenance and render reports to the chief locomotive inspector, a system officer.

Much of the success of the Lehigh Valley in the operation of boosters may be attributed to the fact that when the first booster equipped locomotive was placed in service on the road, a great deal of stress was placed on the importance of properly instructing the men. As a consequence, classes were instituted in which special instruction pertaining to booster operation and maintenance was given to traveling engineers, enginemen and shop men. The traveling engineers made up the first classes of instruction in order that they might qualify to act as instructors of the enginemen.

Inspection

When a locomotive reaches the terminal at the end of its run, a thorough inspection of the booster is made while on the pit. While it may appear to be relatively unimportant, the first thing done by the inspector is to clean



A convenient method of checking the height of booster cylinder cocks

off, with an air hose, all of the coal and ashes that may have accumulated on top of the booster casing. This not only serves to make the top of the booster casing readily accessible in case it is necessary to remove the crank case cover for any reason, but it also lessens the possibility of dirt and ashes working into the mechanism.

The second step is to close the idler cock and idle the

booster engine. While doing this the inspector makes a careful inspection of all parts of the booster to make certain that there are no oil leaks. One of the principal points at which oil leaks occur is where the booster engine piston rod passes through the casing frame. There is an end cover plate here in which a ⅝-in. round packing is used as a wiper to prevent the loss of oil. This packing frequently becomes worn or deranged so that it is important to renew it if necessary.

While the booster engine is being idled, the inspector observes whether it is running at normal speed, to determine whether or not the preliminary throttle valve is functioning properly. While the inspection of the booster equipment is being made, it has been found advisable to set the independent brakes on the locomotive to prevent any possibility of the locomotive being accidently moved. The cut-out cock to the clutch cylinder is now opened and the booster latch is thrown in. This cut-out cock has been previously referred to as the idling cock, because of the fact that when it is closed the booster latch may be thrown

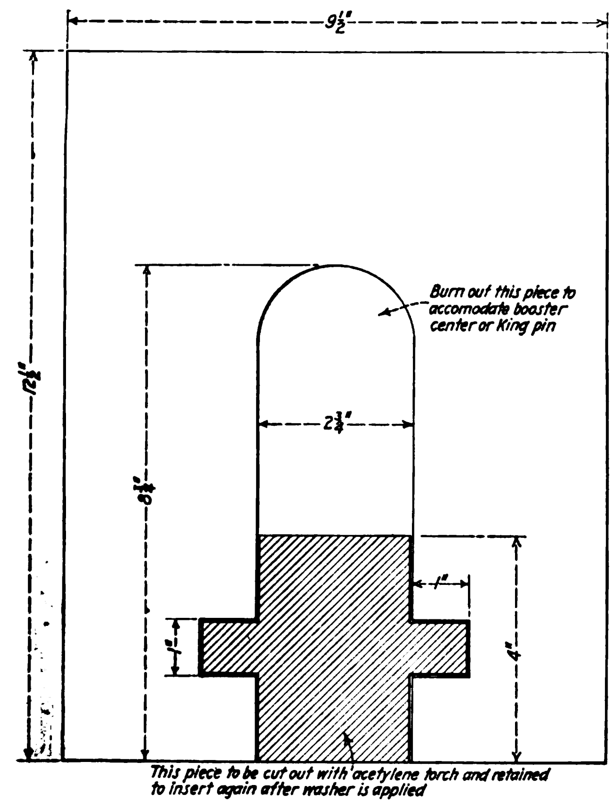


Plate washer for raising booster engine, the thickness of which can be made to suit conditions

in and the preliminary throttle valve will serve to supply steam for idling the booster engine without the clutch cylinder acting to throw the idler gear into mesh with the gear on the trailer axle. With this cock open and the booster latch thrown in the piping system to all the air control valves is filled with air under pressure so that a thorough inspection may be made with a torch to ascertain whether or not there are any air leaks in the control piping system. It is extremely important that a thorough test for air leaks be made because of the fact that a leak in the piping may cause some part of the air control system to fail to function properly while on the road.

At this point of the inspection it has been found advisable to observe the actual time required to close the cylinder cocks. Under normal operation the cylinder-cocks are automatically closed by building up pressure in the main steam inlet pipe, which acts on the main piston in the dome pilot valve. This piston, in raising, opens a small valve in the head of the dome pilot valve, which permits air to pass through the cylinder cock timing check valve and timing reservoir and causes the cylinder cock operating cylinder to actuate the closing mechanism. With the idling cock open the booster latch on the reverse lever should be thrown in and out several times to observe whether or not the main booster throttle valve is opening properly. The pet-cocks on the booster crank case should be opened to observe whether or not the oil in the crank case is at the proper level and oil should be added if necessary. The main locomotive throttle should be opened a sufficient amount to provide pressure in the booster steam line so that any possible steam leaks in the line or at the ball joints may be discovered.

The height of the booster above the rail should be measured and a plate washer applied if necessary. A clearance of five to six inches above the rail at the back cylinder cocks should be maintained in order to eliminate the possibility of any damage to the cylinder cocks from obstructions along the track. A very convenient method of checking this height has been found as follows: Directly over the rail on the inlet and exhaust manifold will be found a flat shoulder. By taking measurements it will be found that when this shoulder is 11 in. above the rail the clearance at the back cylinder cocks on the booster engine will be 6 in. One of the illustrations shows a simple yet effective method of making a plate washer to

Loco. No.__________

Lubrication				Repairs Made	
Date	Crank Case	Amt. Oil Added	Axle Bearings	Date	Description

Example of form used in keeping permanent record of booster lubrication and repairs

raise the booster engine. It is made from steel plate of the desired thickness and the crossshaped key cut out with an oxy-acetylene torch. The booster engine is jacked up to a height of at least twice the thickness of the washer and the washer inserted around the center pin. Then the key which has been cut out is dropped into the opening in the washer and the booster lowered into place. It is important that the inspector examine the cylinder cock rigging thoroughly to make sure that all parts operate freely. Enginemen's work reports frequently contain an item to the effect that the cylinder cocks on the booster do not close. Invariably this is found to be due to the fact that some of the rods on the cylinder cock rigging have become bent by striking something so that they prevent the rigging from operating freely. The full pressure and full power on the booster engine cannot be obtained with the cylinder cocks open and the importance of having them closed at the proper time is evident.

It is not only important that a thoroughly inspection be made at the end of every locomotive run, but also that an accurate record be made of each inspection. A permanent record form, which is illustrated, is kept for each locomotive, on which the inspector enters the date of inspection, a notation as to the condition of the oil in the crank case and the amount of oil added, if any. A column is provided in which the condition and attention given to the axle bearings is reported. On this form is also entered a record of any repairs which may have been made

to any part of the booster equipment. Inasmuch as these forms are made out by the booster maintenance men and inspectors at every engine terminal to which booster equipped engines are regularly assigned, the chief locomotive inspector who has supervision over this work is able at all times to know the condition of every booster on the road as well as to know what parts of the equipment require the greatest amount of attention. In this way these parts may be given special attention.

In testing booster equipment while the locomotive is on the pit, the cylinder cocks cannot be closed automatically without opening the main locomotive throttle valve, which as a general practice is not to be recommended. Therefore, in order to close the cylinder cocks manually the inspectors are provided with a small steel wedge which may be inserted under the spring seat of the upper valve in the dome pilot valve. This serves to close the valve which permits the air pressure to pass into the pipe leading to the cylinder cock timing check valve and timing reservoir and in this way the cylinder cock operating mechanism will work the same as though it was being worked automatically by the operation of the main piston in the dome pilot valve.

Opinions differ as to the proper time which should elapse after the booster engine has started to operate before the cylinder cocks close. The manufacturer recommends that a period of 20 sec. be established. But, on the Lehigh Valley, it has been found advisable to change this period of closing on different classes of locomotives to suit their particular operating conditions. Consequently, the practice has been established of setting the timing mechanism so that 10 sec. on locomotives in passenger service and 30 sec. on freight locomotives will elapse before the cylinder cocks close. The reason for this is that the booster on passenger locomotives is used only to facilitate the smooth starting of heavy trains, and consequently, it is desired to have the full power of the booster available immediately at starting. Inasmuch as a pressure of only 30 to 40 lb. can be built up in the booster engine cylinders when the drain and cylinder cocks are open, the time of closing on passenger locomotives has been reduced in order that the full boiler pressure may be available with a minimum loss of time. On locomotives in freight service where the booster is used at starting for a greater period of time it is not so important that the cylinder cocks close quickly.

Maintenance of booster equipment

Overhauling of preliminary throttle valve—Experience has proved that the greatest source of trouble in any part of the air control equipment will be found in the preliminary throttle valve and it has been found that if this valve is thoroughly overhauled every 30 days, very little trouble is experienced. A record is kept on the inspection and repair form previously referred to, of the exact date on which the preliminary throttle valve is overhauled and these records are periodically checked up to see that this work is performed at least once every 30 days. The principal operations in overhauling the preliminary throttle valve are grinding in of the steam valve, freeing the rings in the piston grooves, and a thorough cleaning and lubrication of the parts with a mixture of graphite and valve oil. Inasmuch as the practice of removing this valve at such frequent periods has been established, it has been found convenient to apply a union in the steam pipe on each side of the valve so that by breaking the joints at these unions it can readily be removed.

Throttle operating cylinder—This part of the equipment gives very little trouble and outside of a thorough examination and cleaning approximately every 90 days, very little attention is required.

Main throttle valve—The seat in this valve should be reground once each six months. In reassembling, the valve proper should be assembled in such a manner that it has freedom of movement on the valve rod. This can be assured by backing off the nut on the top of the valve rod a sufficient amount to allow the valve to adjust itself to the seat. While this work is being performed, the main steam valve should be re-packed if necessary.

Dome-pilot valve—This valve should be taken apart at least once each three months and the piston rings examined to see that they are free in the grooves. The spring should be examined to make sure that it is in good condition, and the outside valve should be ground in.

Cylinder cock operating cylinder—The piston ring in this unit should be thoroughly examined and cleaned at least every six months.

Reverse lever pilot valve—At least once each three months the spring in this valve should be examined and the inside and outside check valves reground.

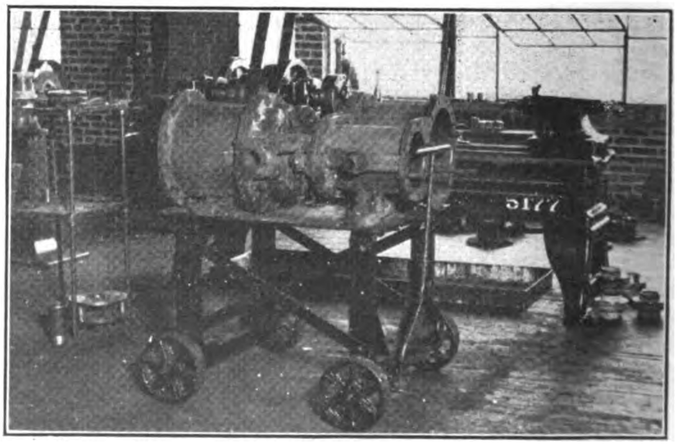
Conclusion

In considering the facts brought out by a study of conditions on the Lehigh Valley and the experience gained in maintaining booster equipped locomotives over a period of more than two years, the whole problem seems to bring out the vital importance of three factors—the thorough instruction of enginemen in the handling of the booster, proper lubrication and, finally, eternal vigilance in the inspection of boosters, together with the recording of information on inspections and repairs in such a manner that the supervisor in charge of this equipment may anticipate and prevent trouble rather than to make extensive repairs after damage has been done.

It may be well to mention the fact that the Lehigh Valley has made adjustments in the tonnage rating of all booster locomotives in order to take advantage of the full additional hauling capacity, the average increase in tonnage rating of booster equipped locomotives being about 10 per cent above that of locomotives not so equipped.

Portable bench for repairing air pumps

ONE of the numerous devices designed to expedite production in the air brake department of the Finley shops of the Southern Railway, North Birmingham, Ala.,



A portable bench designed to expedite repair work on air pumps and feed water heaters

is a portable bench used in the work of repairing air pumps, one of which is shown in the illustration. An account of the system used in the operation of the air brake department was included in a description of the Finley shops, published in the March issue of the *Railway Mechanical Engineer*.

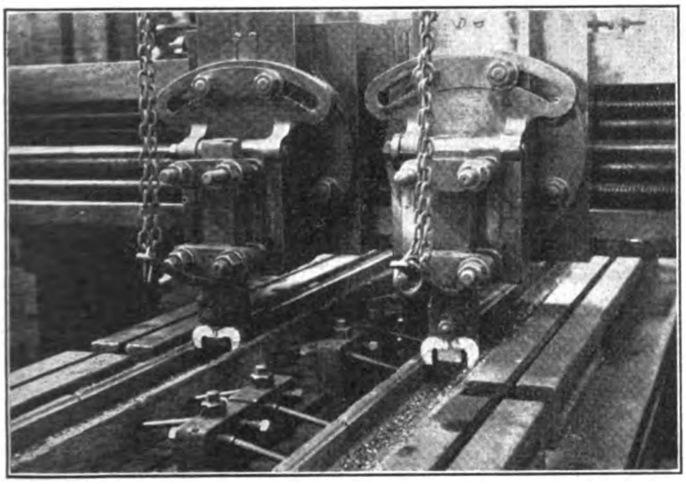
The frame of the portable bench or wagon is built of flat bar iron, securely braced to insure a rigid construction. The top is in one piece and is provided with holes so that a pump of any size may be bolted to the bench. With this bench pumps may be easily moved by the mechanic from bench to lathe and vice versa or to any other place desired. A portable bench of similar design is also being developed for feed water heaters.

Tools for planing driving box shoes and wedges

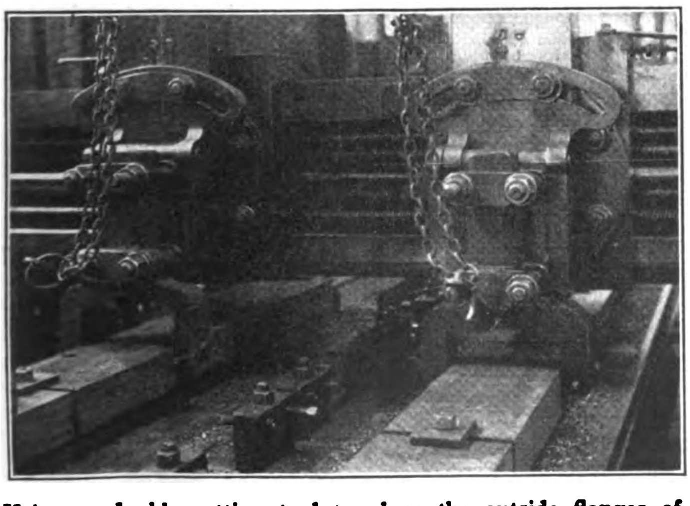
By E. A. Murray

Shop superintendent, Chesapeake & Ohio, Huntington, W. Va.

TIME and labor factors are usually the prime motives behind the development of means to improve machine operations. Such was the case in designing the tools, shown in the illustrations, which rough cut and finish shoes and wedges in two operations. After a set of castings have been laid off to driving box sizes, they are set up in two rows in a double head planer. They are first finished on the inside for the frame fit by planing down the inside of both flanges at the same time, using a double tool. The castings are then turned over, placed on a mandrel and clamped in position when both flanges are planed outside simultaneously with another double tool, which is shown in one of the illustrations.



Planing inside of flanges with a double cutter



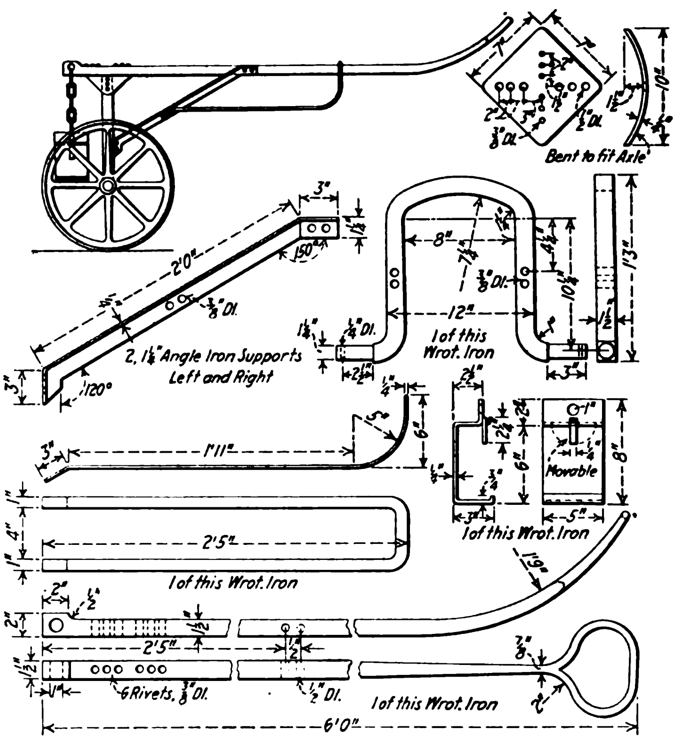
Using a double cutting tool to plane the outside flanges of driving box shoes

It will be noticed that both of these tools are made of unusually heavy material which greatly increases their weight and would naturally cause a heavy drag on the finished work on the return stroke. This objectional feature has been overcome by releasing these tools during the return stroke of the machine by the use of a pneumatic operated cylinder, which is connected to the tool post by suitable levers. The air is admitted to and exhausted from the cylinder by a lever which is connected to the reversing mechanism of the planer.

Two-wheel truck for handling rods

By E. A. Miller

A CONVENIENT truck for such work as handling rods from the blacksmith shop to the rod department is shown in the drawing. All of the parts, with the exception of the wheels, can be made in the blacksmith and machine shops. The axle is made from 1¼-in. wrought iron bar bent to the shape shown in the drawing. The handle is forged from 1½-in. wrought iron round bar and is curved up at the end so that it will be at a more convenient height for the workman. The rods are slung on a wide carrier attached by means of a chain as shown in the assembly view. A detail of the rod carrier is shown at the right of the drawing immediately above the detail of the handle. It is made of ¼-in. wrought iron and is 3 in. by 5 in. at the base with a ¾-in. lug to prevent the rod from falling off.



Drawing showing the assembly and details of a truck for handling rods

A versatile tool for locomotive repair shops

Horizontal boring, drilling and milling machine handles a wide range of work—Serves as a balancing medium in the shops

By Leroy R. Gurley

RAILROAD shops, particularly engine terminal shops and small back shops turning out 10 to 15 class repairs a month, handle repair work on a job rather than on a production basis. The machines in these shops are called on to handle a great variety of repair parts. These parts require many machine operations, such as boring, drilling, milling, facing, turning, shaping, planing and tapping. To provide single-purpose

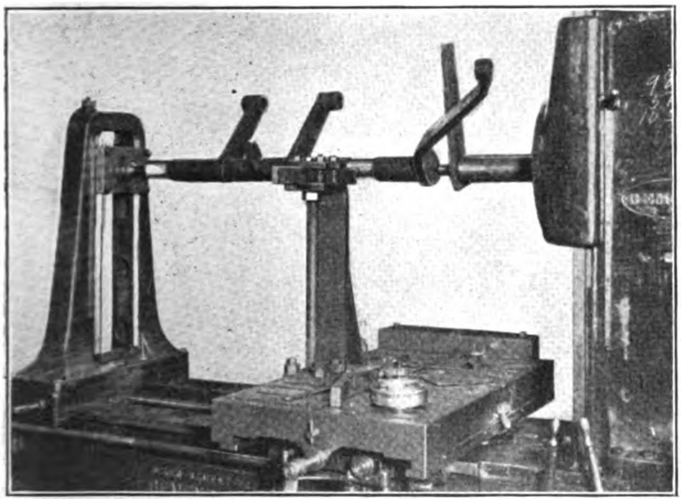

Fig. 10—Turning the bearings on a reverse shaft arm

machines for all of these operations is often impracticable. If a part to be machined requires several operations and production quantity is necessary, it is advisable to purchase a single-purpose machine for each of these operations, which would mean doing the several operations on many parts at the same time much more quickly than if all the operations were to be finished on one machine, one part at a time. But, in the small shop, where only a few parts of a kind are needed, a machine which will do as many of the operations on one part at one set-up as possible, is the most suitable.

A machine of this type is used in a somewhat different capacity in the large back shops. Owing to the fact that three different operations can be performed on this machine at one set-up it is used as a balancing machine to handle the overflow from the single purpose machines when they are crowded with work. It is also used to advantage when a regular machine breaks down. The back shops frequently have to handle large, irregular parts which can not be readily set up on the regular machines, or if they can be, it would not be practical to take the machines off from the regular repair work which they are assigned to handle. Therefore, large repair parts are assigned to a machine of this type owing to its versatility and the large platen, which is ordinarilly a feature of the horizontal boring, drilling and milling machines found in the average railroad shop.

Parts handled on the horizontal boring, drilling and milling machine

The horizontal boring, drilling and milling machine is well adapted for machining locomotive repair parts which require more than one operation. Its general design permits it to be used for machining parts at one set-up which would ordinarily require considerable trouble to set up on a single-purpose machine for but one operation.

Every railroad shop receives its share of parts such as those shown in Table I. Of course there are many parts which can be machined only on single-purpose machines regardless of the size or location of the repair shop. In examining Table I, however, it will be noted that the majority of the parts listed requires drilling, boring and milling, all three of which can usually be performed on this type of machine with one setting, and all the different cuts will be accurate in relation to each other. This elimination of the time consumed in changing the work

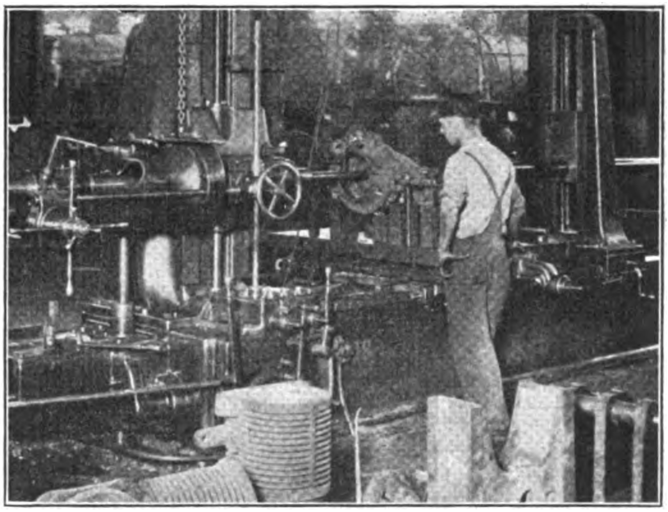

Fig. 11—Boring and facing a throttle box at one set-up

from one machine to another and the necessary resetting that would be required results in a saving in costs.

The machining of steam pipes is one of the most awkward jobs encountered in the railroad shop. Owing to its irregular shape, it is difficult to set up. Fig. 6 shows a machine of this type facing the joint of a steam pipe with the aid of a facing attachment. This effects a saving in time and labor by permitting the steam pipe joint to be faced and the flange bolt holes drilled and counterbored at one set-up. Machining crossheads is a common repair job in the railroad shop. Wrist pin and the piston fits are being faced, drilled and bored with one set-up by using

a swiveling table. Fig. 12 illustrates the method of doing this work.

Another job which the foreman dreads to see come on the floor is the turning of the bearings on a reverse shaft arm of a Walschaert valve gear, as shown in Fig. 10. In order to handle this set-up two centers were used, one to fit the taper hole in the spindle and the other to fit a bushing in the outboard support. The reverse shaft is placed on the centers and is driven with a carrier, the same as in ordinary lathe practice. The method of mounting the cutting tool, which is fed to the work by hand, is clearly shown in the illustration.

Locomotives frequently require new valve chamber bushings. This is a job which may be done at the engine terminal or at any locomotive repair shop. Part of the machine work on them requires that they be bored out and the ports milled to size. Fig. 7 shows the method

Table I—List of repair parts which can be machined on a boring, drilling and milling machine in the small railroad shop

Air compressor cylinders—boring, facing and drilling in one setting.
Air compressor center head—boring and tapping.
Bell standards—boring and drilling.
Booster engine cylinders—boring, facing and drilling.
Brasses, crown—boring, drilling and facing for lateral.
Brasses, journal box—boring and facing.
Brasses, main rod—boring, facing and milling flanges.
Check valves—boring and milling.
Crossheads—facing, drilling and boring wrist pin and piston rod fits in one set-up, using a swiveling table.
Crosshead shoes—milling.
Cylinder heads—back, guide fit—milling, one setting with swivel table.
Center castings, truck—boring.
Cellars—driving box—milling.
Deck castings, front—bored.
Driving boxes—bored, faced, filled, drilled and milled.
Eccentrics and straps—milling, tongue and groove.
Fulcrum castings—boring.
Fulcrum straps—boring.
Feed water heater cylinders—boring.
Flue sheets—boring dry pipe hole.
Gear frame, Walschaert valve gear—boring and facing.
Grate shaker cylinders—boring, facing and drilling.
Jaws, truck—milling.
Key seats, in axles—milling.
Link hanger brackets—boring, milling and drilling.
Link supports—boring.
Main rods—milling and drilling.
Tie head, steam pipe—milling and drilling.
Nozzles, exhaust—facing.
Piston rod extensions—boring, facing, turning and drilling.
Power reverse gear cylinders—boring, facing, turning and drilling.
Rocker boxes—milling and boring.
Smoke stacks—turning, facing and drilling.
Steam chest bushing—boring and milling.
Steam pipes—facing and drilling.
Side rods—boring and milling.
Stoker engine cylinders—boring, milling and facing.
Stoker troughs—boring.
Slide valve false seats—milling ports.
Slide valve steam chest—facing, boring and turning.
Straps, main rod—milling and boring.
Trailing trucks, roller seats—milling.
Throttle box—boring and facing.
Throttle standpipe—boring and facing.
Truck bolster—reboring worn pin holes.
Tumbling shafts—milling (with a gang of cutters) and boring.
Valve chamber head and valve stem crosshead guide—boring, facing and drilling.
Valve chamber bushings—milling port holes.

of boring a valve bushing, while Fig. 1 illustrates how the ports are milled to size. All the ports can be milled at one setting by means of a swiveling table.

The operations of boring and facing a throttle box are done at one setting on this type of machine, with the finished surfaces in true alinement. Fig. 11 illustrates the method of setting up the job and the boring of the preliminary lift valve seat. After this operation, the main valve seat may be faced, if necessary. Something of the use which is made of these machines is indicated by the repair parts on the floor waiting to be machined.

How the machine can be used in the large shop

In the large repair shop it is the practice to issue shop orders calling for the machining of certain parts in lots which are to be distributed to engine terminals and smaller shops. By carefully analyzing locomotive parts to be machined, it will be found that there are many requiring several operations which are not called for in large enough quantities to permit organization of the work on a production basis. Typical examples of such work is the boring of booster, stoker, feedwater heater, grate shaker and power reverse gear cylinders. These parts, some of which are too long to be handled on an internal grinder, are being finished on the horizontal boring, drilling and milling machine in number of shops. Fig. 13 illustrates the method of setting up grate shaker cylinders on a machine of this type for facing both ends,

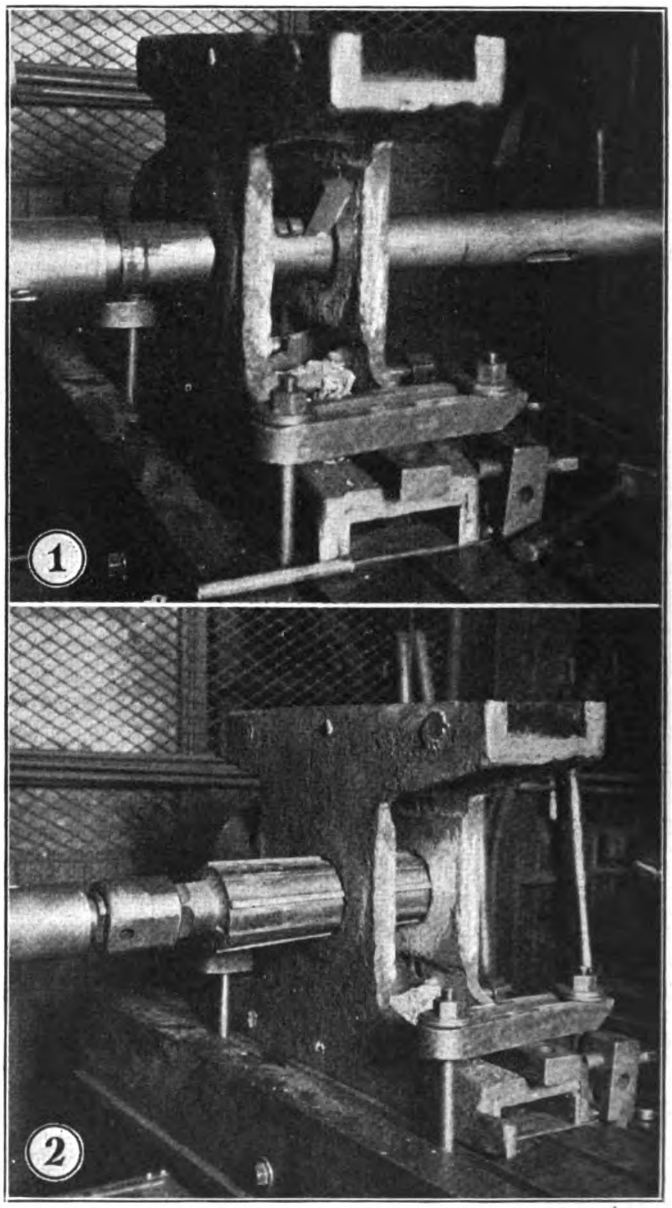

Fig. 12—(1) Facing the inside face of a wrist pin fit; (2) Reaming the wrist pin fit

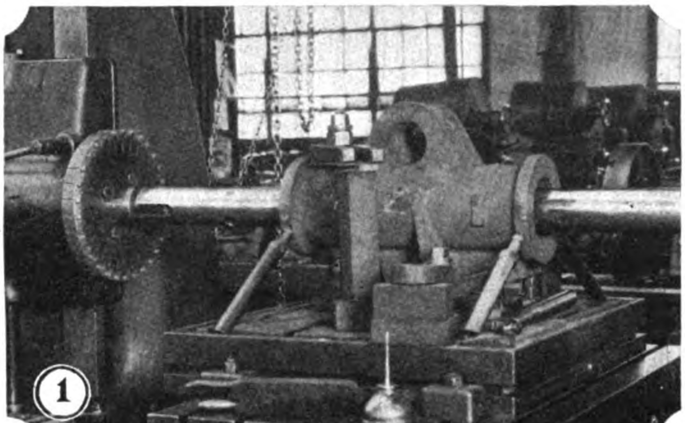
rough and finish boring the cylinders and then, by turning the swiveling table 90 deg., boring the top of the casting. Steam pipe T-head jobs are also done on this machine. Fig. 14 shows a T-head being bored out and milled for the tube sheet connection at one setting.

Many other repair parts are machined in the large shops which this machine can handle effectively in single pieces or small job lots, such as valve gear frames, link support brackets, steam pipe joints, piston rod extension guides, etc. Fig. 15 shows three link brackets being bored at one set-up.

Handling the overflow from single-purpose machines

One of the important jobs of any large locomotive repair shop is the machine work necessary on driving boxes. They are generally passed through the shop on a schedule which often cannot be maintained due to the lack of sufficient machine tools to handle an unusual volume of driving boxes. The horizontal boring, drilling and milling machine is often called on to handle the overflow of work from these machines as it is capable of doing all the machine work on the boxes which the specialized tools will do. Fig. 5 shows a machine of this type machining a driving box and grease cellar at one set up. Fig. 9. shows another machine boring a crown brass, and Fig. 16 shows the milling of grease grooves in a driving box crown brass.



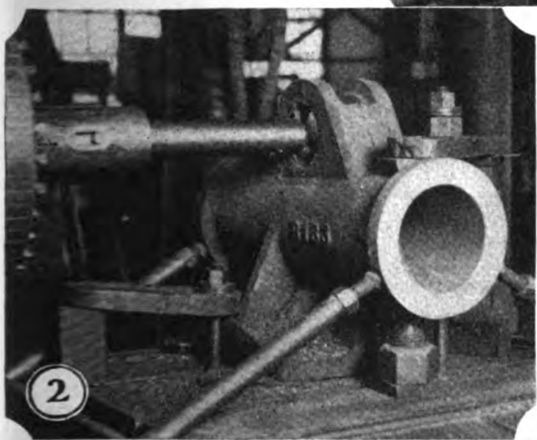


Fig. 13—(1) Boring grate shaker cylinder; (2) Boring operating shaft bearing; (3) Milling cutter facing end of cylinder; (4) Swiveling table makes it possible to perform all operations with one set-up.

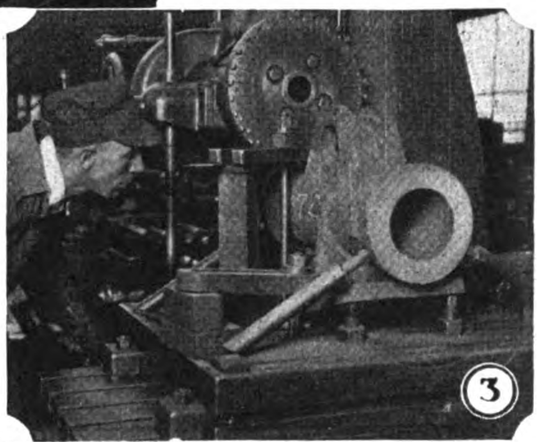

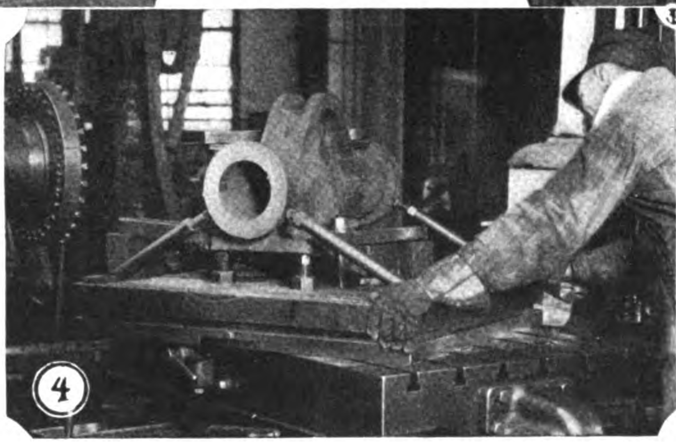

An additional example of the adaptability of this machine to handle the overflow of specialized machines as well as its versatility is the milling from the solid of the back end of a main rod. Fig. 17 shows a machine of this type milling out the back end of a main rod in two cuts in 4 hr. 30 min. from floor to floor. Fig. 2 shows the same machine boring out, in three operations, the main crank pin bit of a main rod strap. Table II shows the time required to machine other repair parts on a machine of this type. The last column of the table, which shows the time to complete the work, includes the time from floor to floor.

A machine of this type in the large repair shops has been used to advantage in reboring the cylinders of air compressors. The four cylinders of a cross-compound compressor can be quickly bored at one set-up. This method eliminates time and labor required for dismantling in order to rebore the cylinders separately. Furthermore, the machining of four cylinders at one set-up assures perfect alinement of the cylinder bores. The compressor head joints can also be faced or the stud holes drilled without changing the work. Fig. 3 shows a machine of this type boring out the cylinders of a cross-compound compressor.

Unusual job handled in the large shops

The horizontal boring, drilling and milling machine is called upon to handle some unusual jobs in the large shops. Fig. 4 shows a machine boring out the dry pipe hole in a front flue sheet. This job was the result of the failure of a machine in the boiler shop which regularly handled this work. Another unusual job is illustrated in Fig. 18 which shows a machine of this type milling the keyseat in a locomotive driving axle. Fig. 19 shows a machine boring out the back end brass of a side rod, which operation requires high cutting speed due to the soft metal.

The maintenance and repair of machine tools and shop equipment leads to the machining of many jobs other than locomotive repair parts. These jobs are often cumbersome parts which cannot be readily machined on some of the other types of tools. Furthermore, the other machine tools in the shops are usually engaged in their routine operations on locomotive repairs. Thus, the versaltility of the horizontal boring, drilling and milling machine enables it readily to handle these odd jobs. The machining of air hoist and vacuum pump cylinders, the masthead of a walking crane, as well as the various parts of machine tools are examples of such work which are handled by this machine. Fig. 8 shows a machine of this type boring out the air cylinders of a pneumatic pit jack.

The place of this machine in the railroad shop

There are several factors that should be considered before placing a machine of this type in the small shop or

at an engine terminal. First, the work should be analyzed to determine whether there is enough available to keep the machine busy. The work which can be handled only by such regular machines as the lathe, planer, shaper and drill press should be first eliminated from this list. These

Table II—Time required to machine locomotive repair parts which the boring, drilling and milling machine can handle in the railroad shop

	Material	No. of operations	Kind of operations	Time to complete Hrs.	Min.
Valve chamber bushing	Cast iron	6	Milling 6 ports	1	0
Air compressor cylinders	Cast iron	4	4 cylinders rough bored for bushings	3	30
Air compressor cylinders	Cast iron	4	4 bushings finished bored complete	4	0
Side rod	Steel	7	6 roughing cuts and 1 finishing cut	2	0
Engine truck center casting	Steel	2	Reboring pin holes for bushings with two settings	0	35
Milling shoe and wedge to line	Steel	1	Milling away ½ in. of stock	0	30
Side rod strap	Steel	1	Milling to layout marks	1	0
Valve gear crosshead arm	Steel	2	Face off electric welded shoulder	0	15
			Rebore pin hole	0	10
Valve gear rod	Steel	1	Reboring pin hole	0	20
Eccentric rod	Steel	1	Reboring pin hole	0	15
Main rod	Steel	2	Milling out solid end with two cuts	4	30
Crosshead	Steel	4	Bore and ream piston rod and wrist pin fits	5	0
Trailer equalizer	Steel	2	Drilling to holes	0	36
Locomotive driving box	Bronze	3	Setting up	0	30
			Rough bore	0	6
			Finish bore	0	4
			Chamfer	0	3
Back valve chamber head	Steel	1	Reseating worn seat	0	40

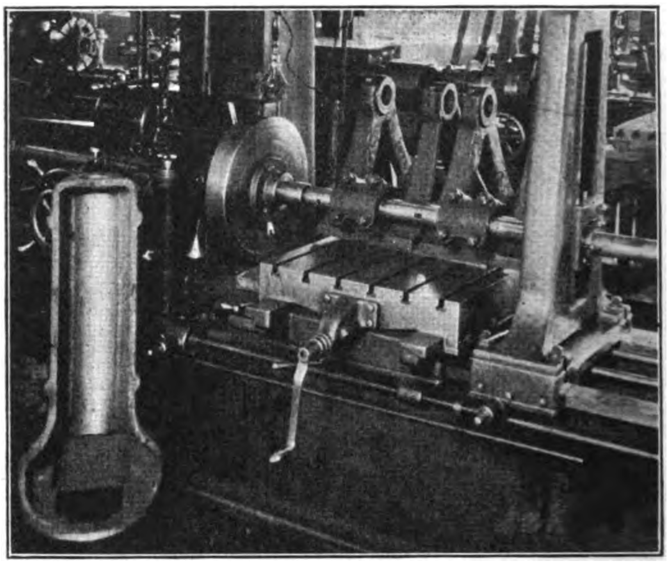

Fig. 15—Boring three link brackets at one set-up

machines are indispensable in every railroad shop. The balance of the work should be considered from the standpoint of the number of operations which can be performed at one set-up, thus saving time in transferring the work

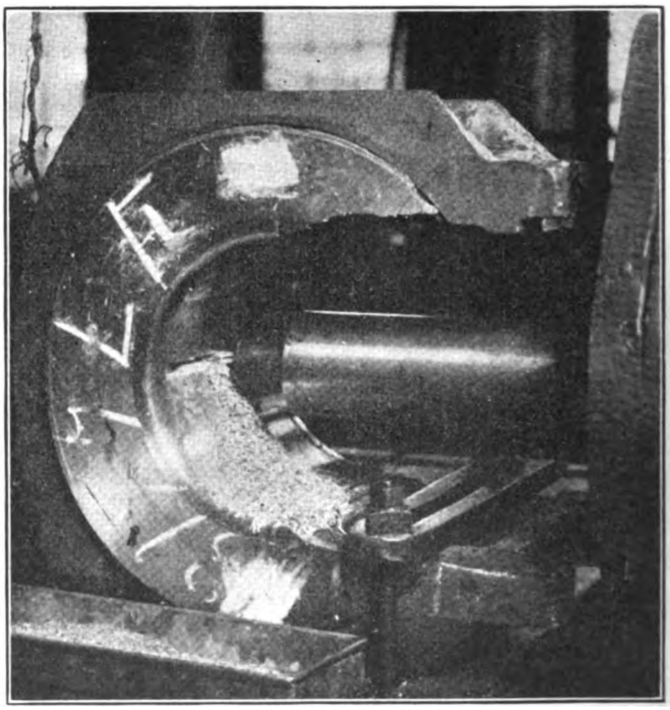

Fig. 16—Milling grease grooves in a driving box crown brass

from one machine to another. If it is found that there are enough such repair parts to keep the machine busy, then its purchase is justified. It would be a poor investment to purchase a machine of this type if it would have to stand idle a large part of the time, or be used on operations which can be performed as effectively on the single-purpose machines with which the shop is already provided.

It is well to keep in sight the fact already pointed out concerning the balancing function which this machine serves in both the larger and smaller shops. It is well to have in the shop a machine which can be used when the single-purpose machines are crowded with work or

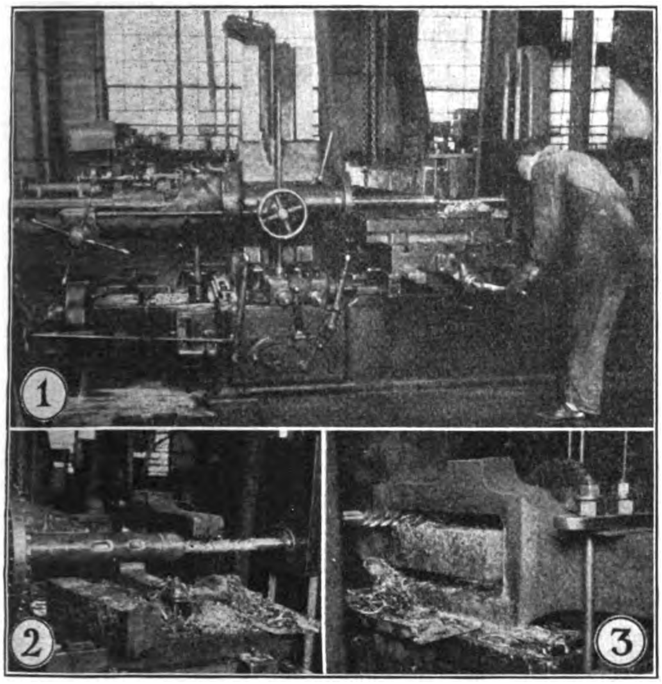

Fig. 17—(1) Starting to mill out the back end of a main rod; (2) Starting the second or finishing cut; (3) Ready to remove the block at the end of the first cut

a machine breaks down. The maximum of such protection can be provided with a minimum investment, by a multiple purpose machine, which can be used to good advantage in emergency.

The use of this machine in the large repair shops must be considered from a somewhat different angle. Repair

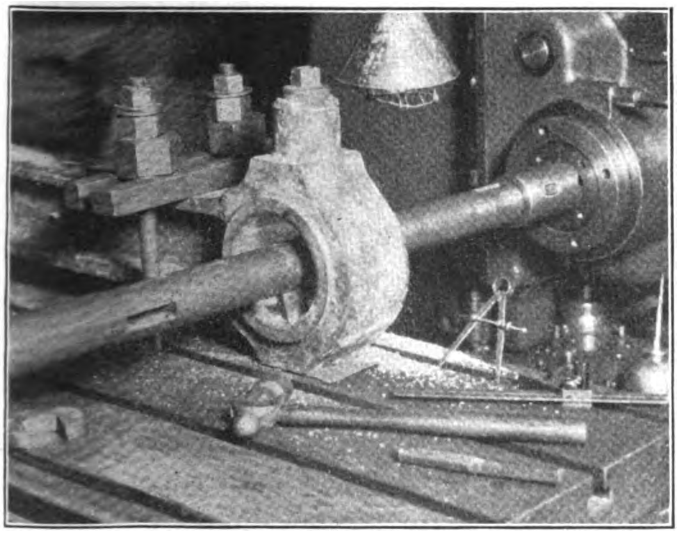

Fig. 19—Boring out the back end of a side rod brass

parts pass through the smaller shops in such limited numbers that it is not practical to install single-purpose machines to handle the work. In the larger shops the conditions are just the opposite as there are sufficient repair parts to warrant the installation of single-purpose machines. However, many parts which have more than one operation performed on them at one set-up, but which are never finished in large runs, can be machined

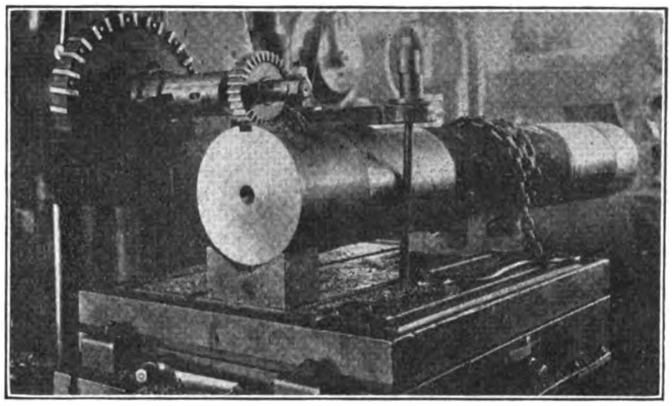

Fig. 18—Milling the keyseat in a locomotive driving axle

economically on a horizontal boring, drilling and milling machine.

Testing rack for brake cylinder packing leathers

By E. A. Miller

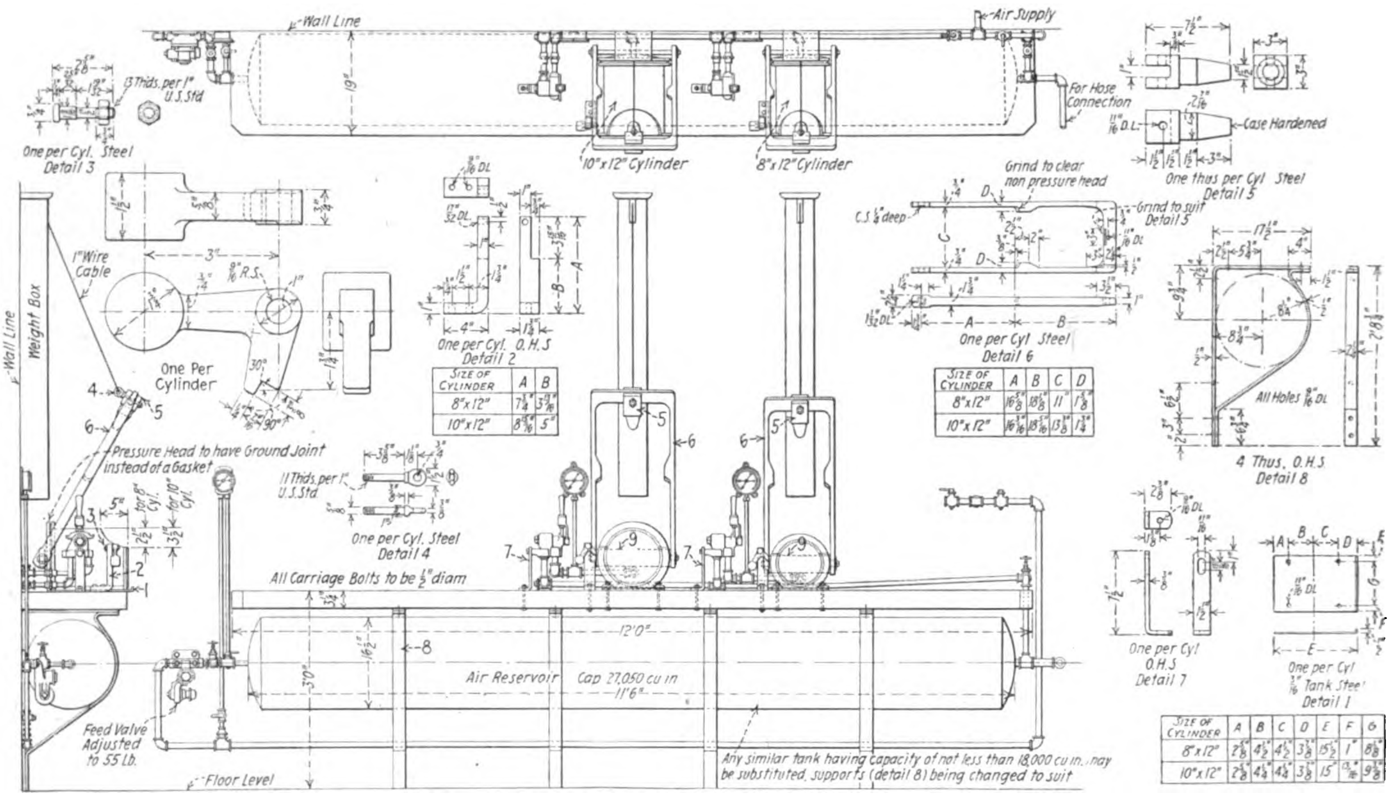
The testing of brake cylinder packing leathers is one of the essential jobs connected with the maintenance of air brake equipment. To eliminate the usage of worn and leaking leathers it is imperative that they should be thoroughly tested on a suitable testing rack. The rack shown in the accompanying illustration is apparently well suited for this work.

The equipment is placed on and under a table, 1 ft. 7 in. wide by 12 ft. long and 33 in. high, which is built against the wall. Bolted to the table are two air brake cylinders, one 8 in. by 12 in. and the other 10 in. by 12 in. whose pressure heads have a ground joint instead of a gasket. Over each cylinder is a movable yoke, which when lowered in position serves the purpose of holding the piston in place against the testing pressure in the cylinder. The yokes are counterbalanced by a weight enclosed in a tubular covering, and connected to the yokes by a 1/8-in. wire cable. Beneath the table is a 16 1/2-in. diameter reservoir, 11 ft. 6 in. long which has a capacity of 27,050 cu. in. It is charged from the main air line, in which there is a stop cock, through a feed valve which is adjusted to 55 lb. A two handed air gage, shown to the left of the table, is used; one pipe being connected to the main air line and the other to the pipe leading to the reservoir for the purpose of indicating its pressure. From the right hand end of this cylinder, a pipe leads up and back of the two cylinders on the table which supplies air to the cylinders through the back heads. A lever valve controls the supply of air and a gage is placed between it and the cylinders.

The top front end of the 8-in. cylinder is cut away 2 1/2 in. on its diameter and the 10-in. cylinder 3 1/2 in. and both cut back 5 in. on a curve as shown. This is done to permit the easy entry of the packing leather at the face and pushing it back into the increasing periphery of the cylinder until fully entered. Then it is pushed back as far as necessary to allow the yoke to be pulled down in a line with the center of the cylinder. The inside of each yoke is ground to permit it just to clear the non-pressure head and is then held in place by a latch which swings out of

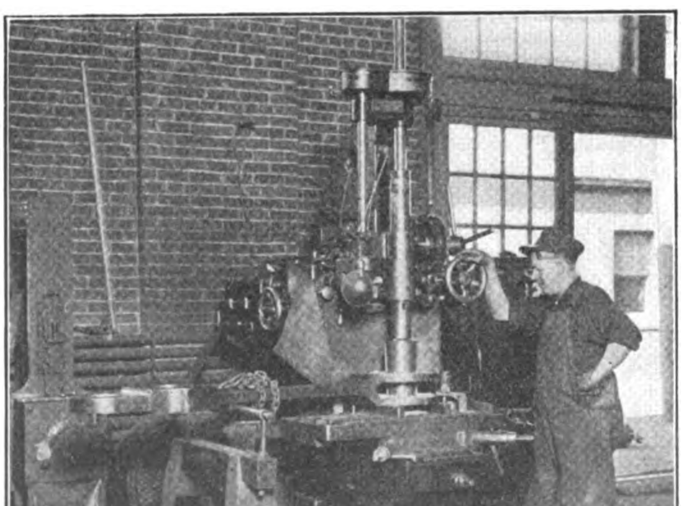
place to allow the yoke to pass and return to place due to the weight at the end of the bell crank of the latch.

After the piston is in place, the air is allowed to enter the back end of the cylinder until the reservoir pressure is 55 lb. The air is then shut off and the rate of leakage is indicated by the cylinder gage. This test being completed, the valve is opened and the air is exhausted to the atmosphere. The piston and rod are pushed back to allow



General arrangement and details of testing rack for brake cylinder packing

clearance for lifting the yoke after which the piston is quickly removed and another put in and tested. This arrangement permits the continuance of the work at a good speed.



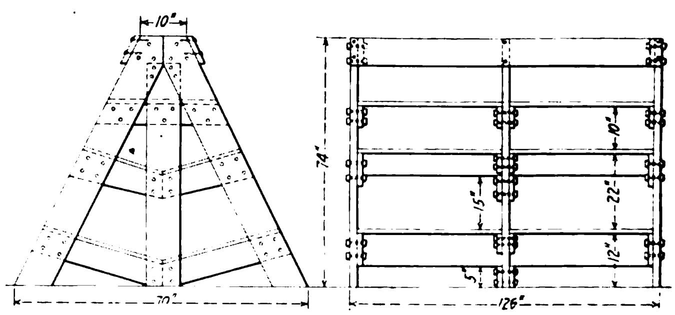
Reaming an unusually large side rod knuckle pin hole

Storage rack for arch brick

By Joseph Smith

ARCH brick piled on the floor of an enginehouse takes up considerable room and there is also danger of the bricks becoming broken, due to the piles being knocked over or bumped into with trucks and heavy tools. The rack shown in the sketch is convenient for storing arch brick in enginehouses as well as in the erecting shop. The ends and center piece are made of 2-in. by 6-in. timbers, bolted together by ½-in. bolts. Planks, which serve as shelves, are spiked to the cross pieces, as shown in the sketch.

This rack is placed in a central location in the en-



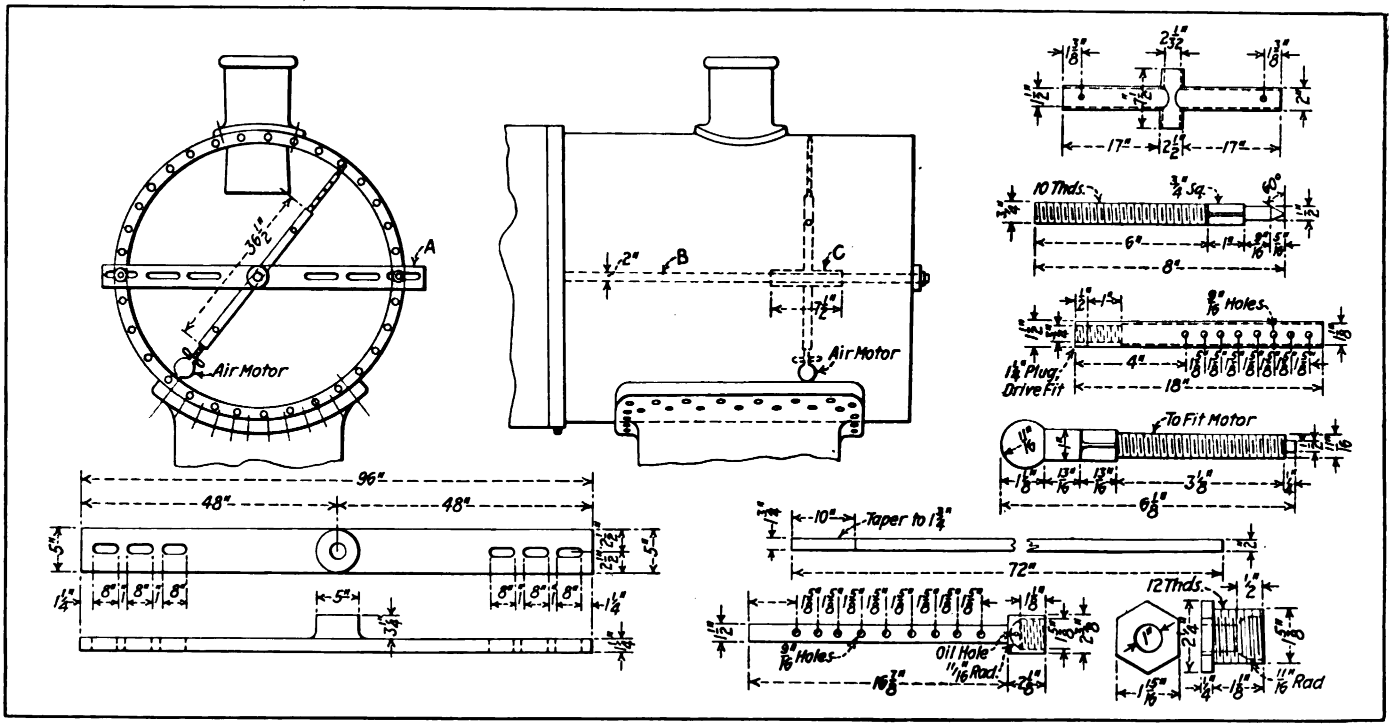
A rack for storing arch brick in the engine house

ginehouse. It will accommodate about 650 bricks of the various types and is kept supplied by a laborer. It is convenient for the hot worker and eliminates the necessity of having to go to an outside storehouse in inclement weather. As brick is taken from the rack, an order blank is filled out and placed in a metal container on the rack. These orders are periodically collected by the stores department.

Device for drilling saddle bolt holes

THE customary method of holding the air motor in position when drilling cylinder saddle holes is with an "old-man." Its use necessitates changing its position many times which requires considerable time and labor. It is often a problem to know where and how to fix or bolt it in order to drill certain holes. The device shown in the illustration does away with the "old-man" and makes the job a one-man operation.

The cross-arm *A* is fastened to the front end studs so that its center is near the center line of the boiler. Shaft *B* extends from the cross-arm to and enters the end of a flue or flue sheet hole, near the center line of the boiler. Sleeve *C* fits and slides on shaft *B*. It has two extensions, one to the motor and the other to the front end shell to act as a brace.



General arrangement and details of a device for setting the air motor when drilling saddle bolt holes

With this arrangement it is easy to swing and fasten the motor to any position thus permitting the drilling of all saddle bolt holes with one set-up. This device was developed in the Grand Rapids, Michigan, shops of the Pere Marquette.

Methods of selecting and training supervisors*

By G. P. Hodges

Division master mechanic, C. M. & St. P., Mason City, Ia.

I BELIEVE all supervisors should be selected, whenever possible, from the ranks. Of course, there always will be a time when it will be necessary to go outside for specially trained men. However, I advocate the practice of selecting your man from the ranks for it creates a better feeling with the rank and file as much depends on them to bring success to any industry. With any large railroad, it should not be difficult to find the right kind of timber for promotion to a minor supervisory position. Any supervisor who cannot find such material in his organization for promotion to a more responsible position, has neglected some of his duties as a supervisor.

A college education is not really essential, but a man should have a fairly good education, and if he is the right kind of man he will soon educate himself along the lines of his work. The late James J. Hill, once said, that he considered an educated man one that knew about all there was to know about the business he was engaged in.

The man you are considering for promotion, in the first place, should not even be considered until he has conclusively proved his ability in his former position. He must be ambitious, and a tireless worker. He should possess good judgment. This qualification is about as essential as anything else, for it is on this point that the most of us fail. If we all would think just a little more and decide to use good judgment, instead of at times, doing things without thinking of what will be the final outcome I am sure that those in a supervisory capacity could set a very good example for the men under them. Of course, I don't mean to insinuate that we don't think and use good judgment, in fact, I would be very much offended if some one stood up and told me I didn't use my head, but at the same time, we will have to admit that some of the things we do, perhaps look to our superiors as if we didn't have a head or if we have one, we didn't use it. So be sure that the young man you pick for promotion is a thinker, and thinks before he leaps. He should also have a pleasing personality, be persistent and have patience. He must also be a leader of men and must not be egotistical, as it does not work well with the rank and file. They resent egotism. As a rule, each man has to be handled just a little different. Many a man that we termed a "poor man" could have been made a "good man" if he had been handled right at the start.

As soon as I am attracted to a young man that looks promising to me, I watch him, inquire about him

*A paper presented before one of the Master Mechanics' meetings held on the Chicago, Milwaukee & St. Paul.

from the foreman, find out what kind of a citizen he is outside of the plant and, when I see him occasionally, I stop and talk to him about his work. I also try to find out if he is loyal to the company or, in other words, is interested enough in his work to be fair-minded in his dealings and will do just a little more than he is paid to do something a little out of line with his schedule. If I find him loyal as a workman, it can be generally figured that he will be loyal as a supervisor. After determining these facts, I ask him if he thinks he would care to become an enginehouse foreman. If he states that he desires to get ahead, I send him application blanks to be filled out, after which they are filed in my office, awaiting an opportunity for promotion. Of course, I do not go to extremes in this. I generally keep about four applications for enginehouse foreman and two applications for traveling engineers on file. In picking a traveling engineer if the man is a first-class engineman and thoroughly understands machinery and the air brake, then the only thing he has to prove is his ability to handle men.

We want only broad-gage men in supervisory positions. There is no place on a railroad these days for narrow men. They must be able to weigh the questions fairly, whether they involve friend or enemy, and at all times be absolutely honest in their decisions. This is the only way to get along with men and do justice to the company you work for.

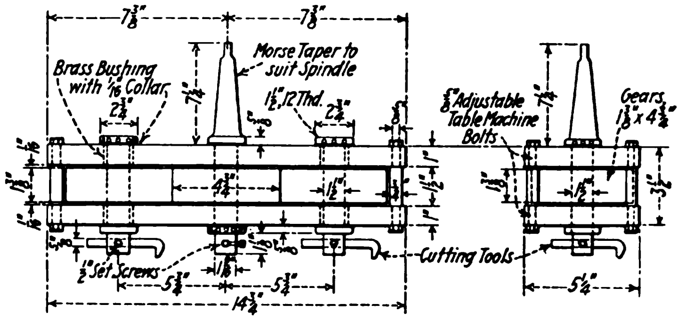
Merits of training schools for supervisory positions

I do not believe that a system of training can be inaugurated until the men are really familiar with the work. Most men get trained in the hard school of "experience." If the man you pick is working at a place where a slip foreman or a lead boilermaker is used, try and get him in one of these positions and with the right kind of supervision over him, he will, within a very short time, prove whether he is the man you want. If he does not prove successful, it is best to drop him out of the supervisory positions. There is no use dragging along with him as he will only prove a burden to himself and to the company.

It occasionally happens that we promote a night foreman to a day foreman, only to find out that he knows very little about the day work. Who is responsible for this? No one but the master mechanic and the day foreman; they have been neglecting their duty. I have all the sympathy in the world for a night foreman. He works in the dark and is generally kept in the dark. He generally has a very small force for the amount of work to be done; seldom ever sees any of the officers, quite often never sees the letters of instructions that are sent to the day foreman nor anything else pertaining to the running of the railroad. If anything goes wrong it is generally blamed on the night foreman. I seldom, if ever, go to an enginehouse but what I try to get to see the night foreman and talk things over with him. I also insist that certain instructions be given to the night foreman and have him acknowledge receipt of them to the day foreman. Most all circular letters that I send out have to be turned over to the night foreman to read, in fact, I try to have him made acquainted with all the facts that the day foreman gets.

Driving box oil grooving device

THE driving box oil grooving device, shown in the sketch, is designed to save time and labor as well as to obtain uniformity in all of the oil grooves on the shoe and wedge faces of the driving box. It is operated by a Morse taper shank designed to fit the drill press spindle. A driving box is placed on the table of the drill press, the taper shank of the grooving device is fitted into



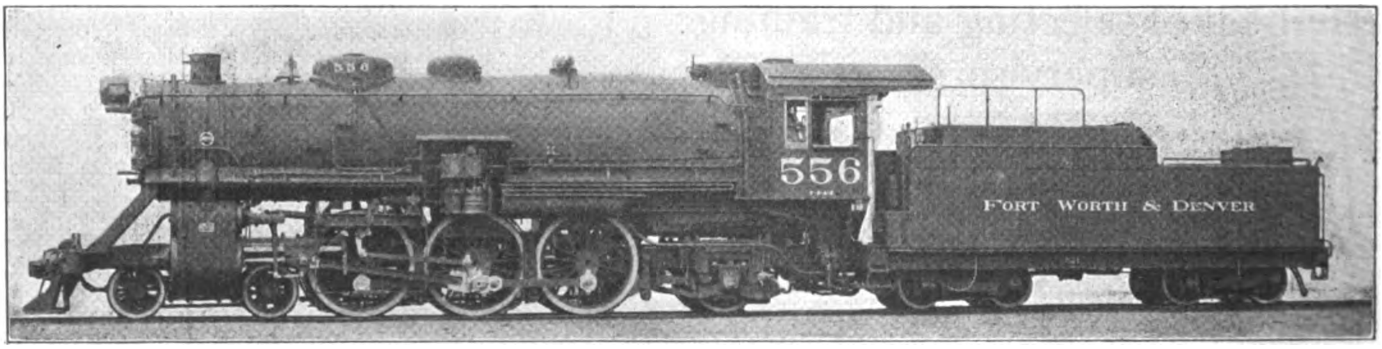
A device which will cut oil grooves on shoe and wedge faces to uniform depths

the drill press spindle, which is lowered to the shoe or wedge face of the box.

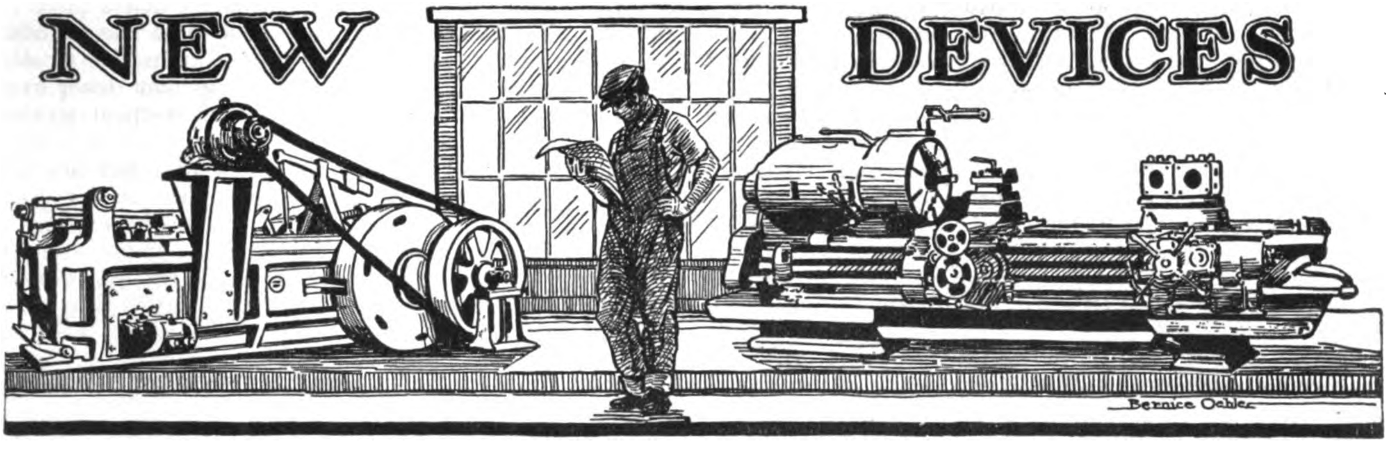
The cutting tools are turned by two gears which are held in a frame made of one-inch steel plate, 5¼ in. wide by 14¾ in. long. The center gear is rotated by the drill press spindle which meshes with the two gears that operate the cutting tools. By referring to the sketch, it will be noted that allowance has been made on the cutting tool gear shafts for the adjustment of the bottom plate.

The cutting tools are adjusted by means of the ⅝ in. adjustable machine bolts to suit the depth of the groove to be cut on the shoe and wedge face. The grooves are then cut to the required depth by the cutting tools which are turned by the three 1⅜ in. by 4¾ in. gears, shown in the sketch.

The principal advantage of this device is that all grooves have the same uniform depth which facilitates proper lubrication. This is practically impossible when the grooves are cut by hand.



Oil-burning Pacific type for the Fort Worth & Denver, built by the Baldwin Locomotive Works



Piston designed for gasoline rail car service

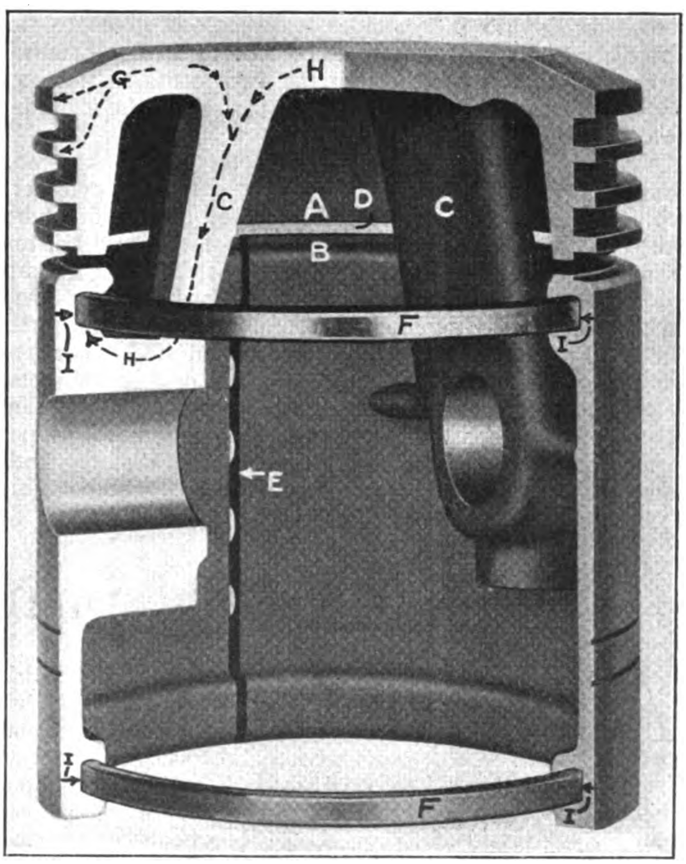
A NEW development which is assuming substantial importance in the railway field is the growing utilization of internal combustion engines as a source of motive power for major purposes. The gasoline hand car and track speeders have been a familiar sight for several years, and the gasoline passenger coach for rail service, while not so common as yet, is expanding its range of usefulness consistently.

This new field of service has brought the builders of automotive equipment face to face with a group of new problems, for the conditions encountered are radically different from those met by an automobile in road service. The automobile operates most of the time with throttle only slightly opened, being subject to full load only spasmodically and for short periods. The railway motor car, on the other hand, is driven on full throttle for many miles at a stretch without any chance to cool down or renew the oil film.

Thus a high temperature is built up and maintained without relief for long periods. But upon approaching a station or after topping the crest of a hill, the throttle is closed without declutching and the car coasts forward with little or no dimunition of speed. The engine continues to rotate and the pump circulates cold water over the cylinder walls at the same rate that it was flowing when working a full throttle, but combustion no longer occurs to produce heat. The cylinder walls are quickly chilled by this douche of cold water, and contract upon the piston, which cools much more slowly because not in direct contact with the water. In many cases this effect proved sufficiently drastic for the cylinders to bind the pistons fast, wrecking the motor and putting the unit completely out of commission.

In attacking this problem it became apparent that a practical method of controlling expansion and of governing the time of heat travel was essential to satisfactory performance. Extensive research in metallurgy eventually developed a method of producing an alloy of aluminum, copper and nickel in certain proportions, which assisted materially in solution of the difficulty. This alloy is particularly high in conductivity of heat, transmitting the calorific energy 3½ times as rapidly as cast iron does. Furthermore, this metal is very light and produces a piston weighing less than half as much as one of the same size made of iron, yet it actually wears longer than iron, is very hard, very tough and is not affected by the highest temperatures existing in a motor's combustion chamber.

But while these qualities made such an alloy very useful, the necessity for finding a way to regulate expansion was emphasized, for aluminum alloys expand twice as rapidly as cast iron when subjected to heat. Alloy pistons



Sectional illustration of a rail motor car piston

A. Piston head; B, Skirt; CC, Strut bars connecting the head to the piston pin bosses and transmitting the force of explosion direct to the connecting rod; D, Slot separating the ring belt from the skirt; E, Wave slit; FF, Steel bands controlling the skirt expansion; G, Path of heat travel from the outer portion of the piston head to the cylinder wall; H, Path of heat travel from the center of the head to the steel band controlling the skirt diameter; I, Direct path of the chill from the cylinder wall to the steel band.

for automobiles had been made with large clearances between pistons and cylinder walls when cold, so as to avoid the piston's becoming too large when heated. This had the disadvantage of giving poor compression in a cold motor,

with attendant oil pumping, drifting of gasoline to the crank-case to dilute the lubricant, and excessive wear.

But trouble more important than these is that caused by the fact that after the piston had expanded under heat to fit the hot cylinder, it did not cool as quickly as the cylinder walls cooled when drenched with cold water as the throttle was closed. The cylinder contracts more rapidly than the piston and seizure follows.

In order to overcome the problem of unequal expansion, a piston has been designed to take advantage of the conductivity of the improved alloy, known as Nickel-metal, which distributes heat rapidly from the centers of highest temperature to the cooler areas. In order to make the control of the heat more definite the head of the piston is completely separated from the skirt by a slot under the bottom ring. The head is attached to the piston pin boss by two substantial struts or bars of oval section. These transmit the pressure directly to the boss and the piston pin instead of putting the load on the skirt first and then on the outer end of the pin. The skirt carries practically no load at all, acting merely as a cross-head. The skirt, being entirely separated from the head, is comparatively cool and constitutes a capacious reservoir into which the heat of the piston head may be drained.

The struts supporting the head are cast in a location half way between the center of the piston head and its periphery. The heat of the outer portions of the head flows directly to the cylinder walls and is given to the circulating system for radiation. The heat of the central area is drawn down through the two struts to the cool skirt, where it is dissipated and passes to the cylinder walls.

A means of controlling the diameter of the skirt was sought in order to eliminate seizing when the cylinders chill and contract, also to gain precisely correct fit under all variations of temperature and do away with piston slap and oil pumping. In meeting this problem, advantage was taken of the fact that aluminum and iron will neither weld together nor combine chemically under heat. Two circular bands of low-carbon steel, about ¼ in. less in diameter than the piston, are cast in the metal —one near the top of the skirt, the other near the bottom. By means of splitting the cores, wave slots of proper width are provided on opposite sides of the skirt to allow space to compensate for expansion of the alloy. This slot is given a serpentine shape so that in case a piece of grit or other hard material should get into the cylinder and lodge in the slit it will be shifted from side to side and not cause damage by traveling up and down over the same path each time and causing a vertical scratch on the cylinder wall.

The steel bands are surrounded by alloy but are not fast to it, becoming in effect simply two tracks upon which the nickel-metal slides as the increasing expansion causes movement. The steel bands are of ample strength to prevent any enlargement occurring in the direction of the diameter, so the expansion is compelled to take place circumferentially, the metal sliding around on the steel bands partially to fill the wave slots on each side. Thus, the only expansion in diameter is that permitted by the expansion of the steel bands themselves, which is practically the same as that of the cylinders instead of that of the nickel-metal which is twice as great.

By having the head separated from the skirt, the desired control of heat travel and of rate of expansion and contraction is attained. To reach the steel band which governs the diameter of the skirt, the heat must travel from the center of the piston head down the struts to the pin boss, out the boss to the skirt, and up the skirt to the band. The result is that the heat of combustion, generated in the head of the cylinder, is transmitted to the cylinder walls more quickly than to the steel band of the skirt, so that there is no danger of the piston expanding more rapidly than the cylinder.

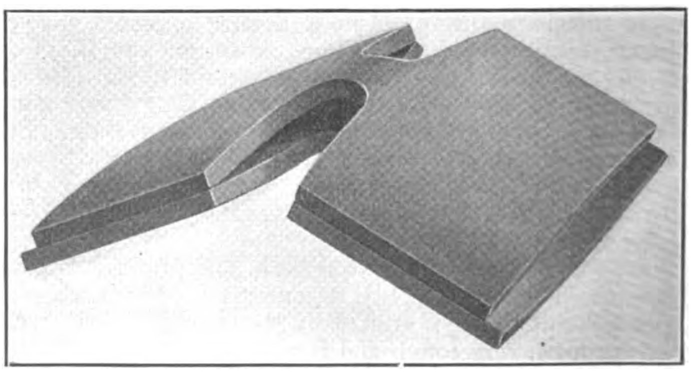
When the throttle is closed and production of heat ceases, and the flow of cold water cools the cylinder walls, the chill is imparted to the steel band immediately because only ⅛ in. of metal separates the band from the cylinder walls. Therefore, the diameter of the piston contracts quickly, remaining free of the cylinder walls as they cool.

It will be noted that this design causes heat to travel a circuitous route to reach the controlling steel band, while heat is conducted from it directly to the cylinder walls. Thus, is obtained the desired result of a piston which expands slowly under heat and contracts quickly under chill.

Pistons of this type are now being used with satisfactory results in a number of gasoline rail coaches. It has been placed on the market by the Butler Manufacturing Company, Indianapolis, Ind.

A friction spring bolster cushion

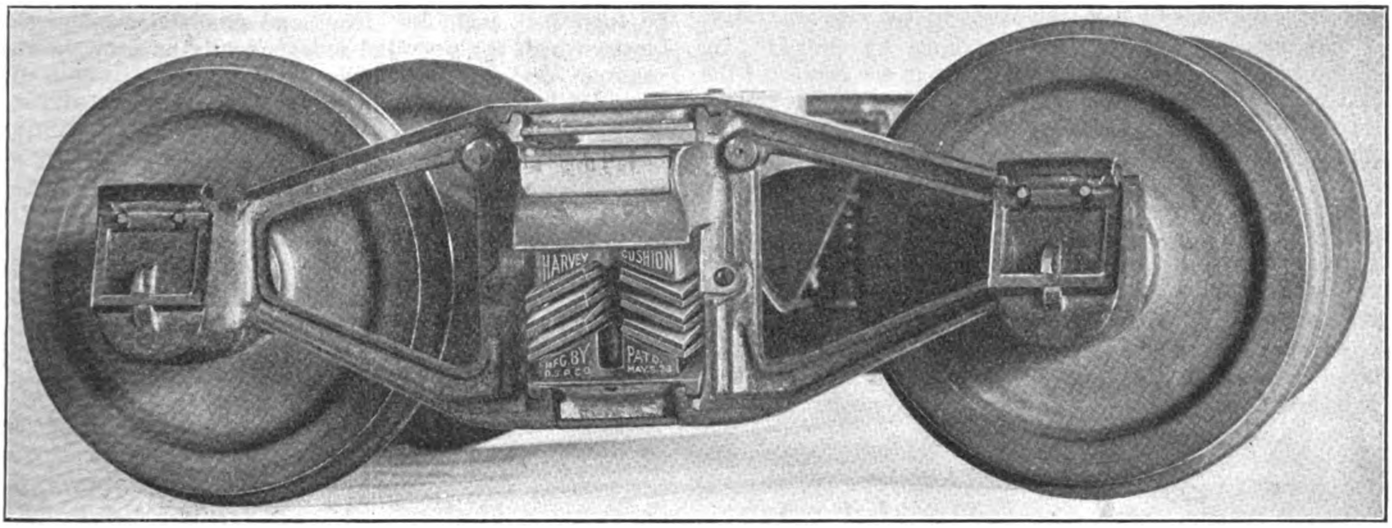
A FRICTION spring truck bolster cushion, which replaces truck springs of the ordinary type, has been developed by Frost Railway Supply Company, Detroit, Mich. This device known as the Harvey, friction bolster cushion consists of a top and a bottom malleable iron casting, called caps, and a series of concave and convex plates of spring steel. The plates and spring caps have angles sloping from the center outward, the top cap being concave and the bottom cap being convex. All plates and caps have the same angle with the horizontal. Each plate is cut out along the center axis into two sections which are joined by a narrow strip of the metal. It is this center portion or neck that is bent to give the two sections of each plate the correct angle to the horizontal. The whole assembly of plates and caps is held together by two long rivets. When the assembly is loaded, the lower heads of the rivets move down in pockets provided in the lower cushion cap. Only the ends of each pair of cushion plates are in contact on each side of the cushion. Each pair of plates is in contact with the next pair at the middle, and the top and bottom pairs are in similar contact with the top and the bottom casting.



A pair of the cushion plates

Thus it will be seen that as a load comes on the cushion each set or pair of plates bends closer together. Owing to the angle on the two sides of the cushion, the ends of each pair of plates must slide on each other. This slipping of the two plates that make up each pair is sufficient to produce several hundred foot pounds of absorption when the cushion is compressed and released. This absorption is said to be sufficient to stop the lateral rocking of the car. This rocking which is quite often caused by the time of vibration of the car body synchronizing with the passing of low joints, causes the bolster to move up and down on the side frame, when equipped with coil springs, as much as 1½ in. in the full capacity of the springs. In road tests of the Harvey cushion the maximum movement of the bolster up and down on the side frame is said to have been less than ⅜ in., which means that the rocking of the cars was very much reduced.

These springs are made to interchange with the ordinary nests of springs, so that they involve no change of standards. They are supplied in two classes, one for cars of 50 tons and under, and one for cars of over 50 tons. They can also be furnished for locomotive tenders.

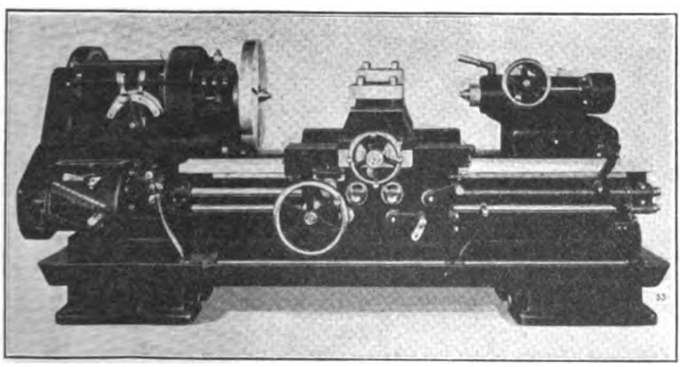


Application of the Harvey friction bolster cushion, showing how the complete assembly is held in place between the truck bolster and spring plank

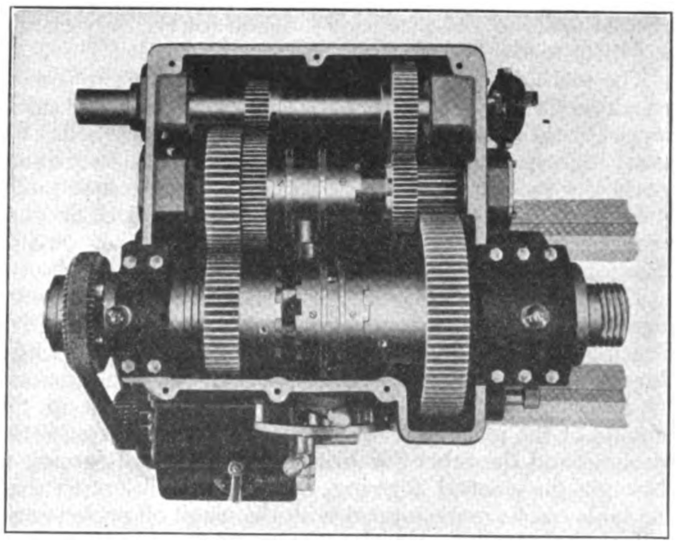
A Monarch heavy production lathe

The Monarch Machine Tool Company, Sidney, Ohio, has recently added to its line of tools a geared or cone head super-production lathe. The headstock gears are made from chrome nickel steel with face widths ranging from 2 in. to 3¼ in.

The auxiliary shafts in the headstock are mounted in a double row of heavy ball bearings. The spindle end thrust is also taken against a heavy ball thrust bearing. The sliding gears and clutches operate on large squared sections of the auxiliary shafts and spindle. Four or eight mechanical changes of spindle speeds are obtained by means of two levers on the front of the headstock which operates in a bath of oil. Either a constant or an adjustable speed motor drive can be furnished. The spindle bearings are exceptionally large—the front spindle bearing is 6½ in. in diameter by 10 in. long.



Monarch 26-in. by 10 ft. lathe



Four-speed geared headstock with auxiliary shafts mounted in heavy double row ball bearings

A 20 or 25-hp. constant speed or 3 to 1 variable speed motor can be mounted either on the floor at the rear of the headstock or on top of the headstock. The drive is through a silent chain to a large friction clutch sprocket

on the initial driving shaft. A constant speed motor of approximately 850 r.p.m. or less should be used. The friction driving clutch is capable of transmitting full power to the lathe and is operated by a lever at the right hand wing of the apron. An additional lever is attached to the apron enabling the operator to start, stop or reverse the lathe electrically, and in case of a variable speed motor, to secure any spindle speed electrically from the operator's position at the front of the lathe carriage.

The massive tailstock is held down by four 1¼-in. clamp bolts. There is also a rack cast in the center of the bed to help support the tailstock and keep it from sliding on the bed. It is provided with a hand-wheel and rack pinion for ease of moving. The thrust of the tailstock screw is taken against a heavy ball thrust bearing, between the shoulder of the screw and the end of the tailstock. The travel of the tailstock spindle is conveniently arranged for the operator by means of a pair of mitre and spur gears, bringing the hand-wheel to the front of the tailstock.

All apron gears and studs are of heat treated steel. The large cross and longitudinal feed frictions are operated by a large ball handle, which is a great convenience in operation as it prevents feed slippage under the heaviest cuts. All apron bearings are oiled from one central oil reservoir. All gears in the quick change gear box and feed mechanism are of heat treated steel. Operating shafts are made of a special grade of high carbon alloy steel.

The carriage has been designed for strength and durability. The cross bridge is 14 in. wide and takes a bearing on the front flat of the bed. Any type of tool rest can be furnished, including front and rear independent tool blocks which are operated independently or brought to a common center at the will of the operator. They are provided with automatic diameter stops.

The machine is built in 26-in. and 30-in. sizes. The following are the principal dimensions for the 30 in. size: Swing over the carriage, 20¼ in.; distance between centers, 3 ft. 4 in.; hole through the spindle, 2⅛ in., standard, 3 in. maximum; taper of the center, No. 6 Morse; range of threads per inch, quick change 1½ to 23; range of feeds per inch, quick change 7½ to 115; number of threads and feed changes, 32; tailstock spindle diameter, 5 in.; carriage length, 36½ in.; size of lathe tool, ⅞ in. by 1¾ in.; speed of geared head driving pulley, 150 r.p.m.

Betts double housing guide planer

THE Betts Works of the Consolidated Machine Tool Corporation, Rochester, N. Y., has recently completed several heavy duty planers of special design for one of the locomotive builders. These machines are used for planing locomotive guides and similar work, where, in order to get maximum production, it is desirable to cut in both directions. In order to accomplish this purpose two sets of housings are used, each carrying a crossrail on which are mounted two heads. As the two crossrails face each other two of the cutting tools are constantly at work. One set of housings is bolted to the bed in the usual manner. To accommodate the varying lengths of the work, the other set is adjustable along the bed by means of suitable slides, screws and nuts. A separate motor is used for moving this set of housings to the desired position and provision is made for securely clamping them to the bed.

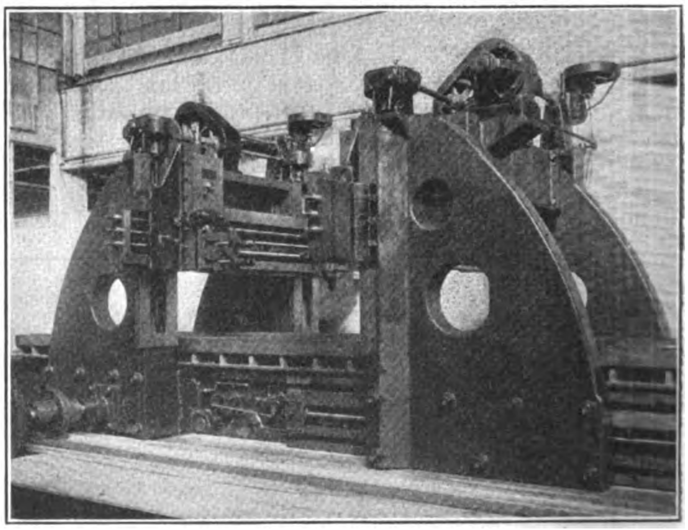
The main drive is by means of a 50 hp. reversing motor which has a speed range of 250 to 500 r.p.m., the entire range being used for cutting only; in other words, the usual high return speeds are dispensed with. The driving gears and rack are all steel, of wide face and coarse pitch, suitable for transmitting the high power required in connection with the heavy cuts that are usually taken on this class of work.

The table tracks, driving gears and driving gear bearings have forced lubrication in connection with a positive filtering system which insures an ample supply of clean filtered oil to these important bearings. Two pumps are used, driven by an independent motor mounted on the outside of the machine, one for forcing the oil through the machine and the other for bringing it back and forcing it through the central filtering unit. In addition to this, the table tracks are equipped with the usual oil pockets and rollers.

All four heads have electric feed and power rapid traverse. Both the feed and traverse are actuated by two electric feed motors, one for each set of uprights, and these same motors also furnish power for raising and lowering the crossrails.

The crossrail is clamped to the housings at both the inside and outside edges and is carried back between the housings a sufficient distance to provide ample rigidity when the tools are cutting close to the center of the table. The table is of the box type construction, and is gibbed to the bed for its full length to prevent any tendency to rise due to heavy cutting, which is an important feature on planing machines of this size.

The bed is of the box section type made with wide distance between the table tracks, and carries the dead shafts on which the driving gears are mounted.



Planer, designed with two sets of crossrails to cut in both directions

The capacity of the machine is 57 in. between the housings, 31 in. under the crossrail and 20 ft. between the table pockets. Convenient push-button stations are used for controlling the various motors. This arrangement permits easy operation of the planer and is such that the operator does not have to move any great distance in order to stop the machine.

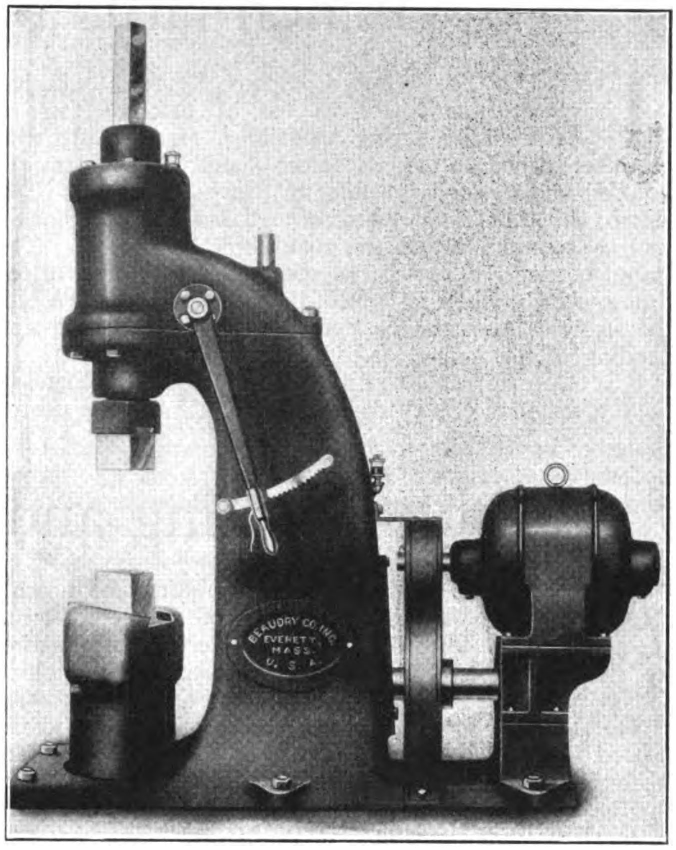
The Beaudry upright air hammer

THE Beaudry Company, Everett, Mass., has recently added to its line of blacksmith hammers an upright air-operated hammer. The compressor piston can either be driven by a belt-driven pulley or a motor. In operation the piston, when ascending, compresses the air above it and this flows into the ram cylinder, sending the ram upward with great speed. When near the top, air is trapped, forming a cushion, which causes the ram to rebound, and this, combined with the suction of the descending compressor piston, produces the hammer blow. The anvil which absorbs this blow is separate from the hammer frame and is supported on its own foundation, eliminating shocks to the hammer frame.

When equipped for belt drive, no countershaft is necessary as the hammer has a tight and loose pulley, the belt being shifted to the loose pulley only for long stops. The blow is regulated to suit the work by the foot treadle from a light, sensitive tap to the heaviest blow. The ram is held suspended when not working or when clamping the work for bending. Bars of any length may be worked either way of the dies.

The ram is designed so that the greater part of its weight is concentrated in a bar of large diameter, practically unbreakable, and is guided by passing through both the upper and lower cylinder heads. The head is entirely separate from the bar and can be readily removed when necessary to separate the ram from the cylinder, otherwise it is held securely to the ram by a wedge clamping ring. As the cushioning of the ram is done entirely by air, the use of springs or rubber cushions is avoided in this design.

The hammer is made in six sizes, with the weight of the rams ranging from 100 to 1,200 lb. The lift of the ram of the largest size is 26 in.; the number of blows, 110 per min.; the size of the motor, 40 hp., and the weight, 30,000 lb.



Beaudry upright, air operated, motor driven hammer

Portable electric circular hand saw

A PORTABLE, electric, circular hand saw adaptable for cutting car flooring, roofing and for general use about a car shop has recently been placed on the market by the Michel Electric Hand Saw Company, Chicago. It also can be used for cutting fibre, hard rubber, insulated cables, brass, light gage metal and many other materials.

Portable, electric, circular hand saw for the car shop

The body of the tool is made of No. 12 aluminum, which makes it light in weight and easy to handle. Every part of the tool is machined and is interchangeable. It has a cutting capacity of 2 in. in hardwood and will also cut many other materials requiring an equal power. It will groove or cut to any desired depth, up to 2½ in. Various attachments can be used for beveling or other purposes.

The motor used is of the universal type especially designed for this kind of a tool. Two types of motor are furnished, one for 110 volts a.c. or d.c. and the other for 220 volts a.c. or d.c. which are air cooled by forced ventilation. The saw is equipped with a trigger switch, the purpose of which is to insure safety, as the operator's finger must be held on the switch in order to keep the motor running. The motor, fan and shafts are dynamically balanced in order to eliminate vibration while in operation.

When first starting to make a cut, the front guide is rested flatly on the material to be cut before starting the motor. It is always advisable to keep the cutter away from the material until after the motor is started, then the saw blade is fed into the material always keeping the

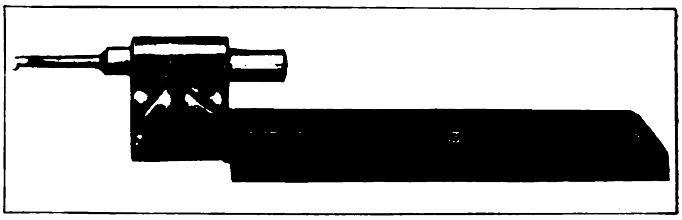
finger on the trigger. After the cut is completed, the trigger is released and the tool removed for a new cut.

The tool is known by the trade name of Skilsaw and is equipped with two 8-in. saws and 15 ft. of extension cord fitted with a plug which fits in any standard light socket.

Bench lathe boring toolholder

The J. F. Smith Tool Company, Dayton, Ohio, has recently added to its list of machine tools a bench lathe boring toolholder. It is made with an offset turned on the end of the shank which is straight knurled and has a large fillet to provide strength. The clamp, which fits over the offset and also holds the boring tool, is countersunk on the shank side to clear it. The clamp is made in two parts, with screws binding in the center, which, when tightened, draw the clamp down into the straight knurl on the shank, preventing slipping and bending of the toolholder.

It is easily adjusted to different heights and is made to hold ¼-in. bars of any desired length. With the use of this holder an operator is enabled to keep his bar on center and parallel with the hole being bored. It is 4 in. long with a 5/16-in. by ½-in. shank.



Toolholder suitable for boring small holes

Bolt-pointing and threading machine

A machine for automatically pointing and threading bolts that range in size from ¾ in. by 1 in., to ¾ in. by 6 in., has been placed on the market by the Economy Engineering Company, Willoughby, Ohio.

The operator fills the hopper located above and to the left of the machine, as illustrated in Fig. 1. A double-blade feeder, which is shown at the bottom of its stroke in Fig. 1 and at the top in Fig. 2, is automatically forced upward through the pile of bolts in the hopper and, on its way, gathers certain bolts the shanks of which fall between the blades. These are then suspended by their heads on the blade edges till, at the top of the stroke, the edges slop downward to coincide with a chute reaching from the hopper to the working section of the machine. The bolts then move down into this chute by gravity and the blade feeder returns to the bottom of its stroke and repeats to keep the chute supplied.

On the side of the chute near the lower end, there is an escapement that, by the operation two rods which alternately project into the path of the bolts, allows one bolt at a time to slide to the end of the chute where it is picked up by a transfer mechanism and carried to the chuck. This transfer mechanism is located, as illustrated in Fig. 2, at the lower end of the chute. It consists of a pair of cam-actuated spring fingers, which grip the shank of the bolt and deliver it to the chuck jaws, where the fingers are opened and returned for the next bolt that has been released through the escapement. The chuck jaws are operated by a cam-actuated toggle arrangement, illustrated in Fig. 2 at the left end of the machine. While a bolt is being placed for threading, the turret is locked against rotation.

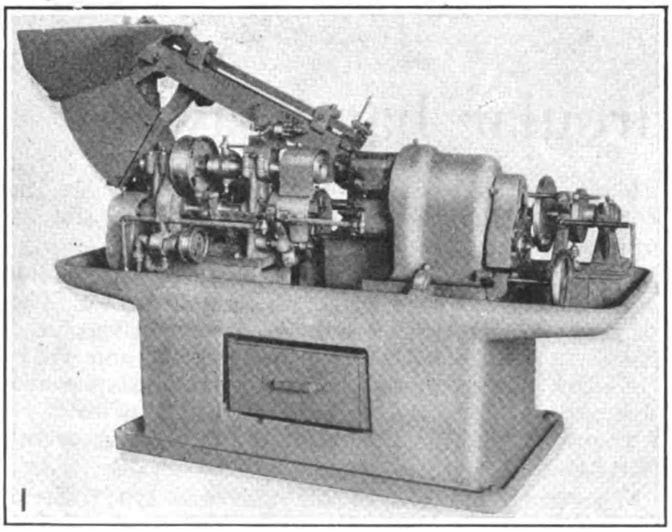


Fig. 1—Economy bolt-pointing and threading machine

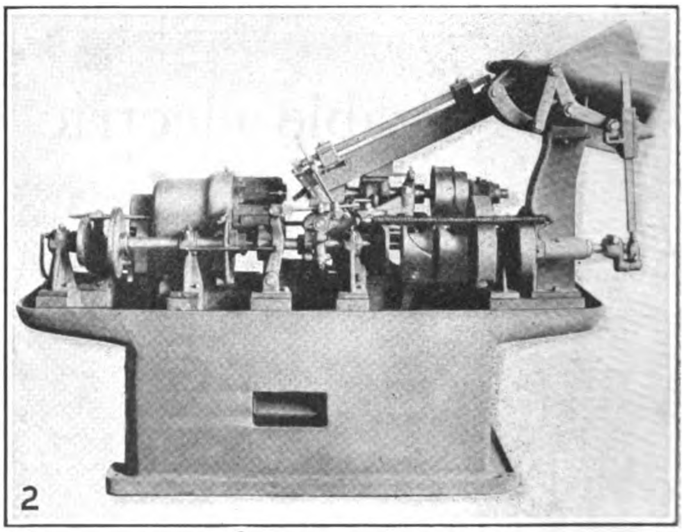

Fig. 2—Rear view of the machine

When the bolt is gripped in the jaws, the turret is released and immediately indexed 120 deg. to come into position with the pointing head which is located, as illustrated in Fig. 1, in the upper center next to the lower end of the chute. This movement also brings the blank that has just been pointed into place for threading in the dies which can be seen in Fig. 1 below the pointing head. The completely threaded bolt is carried around at the same time to the loading station and dropped out as the chuck

jaws are opened to take the next bolt from the feeder.

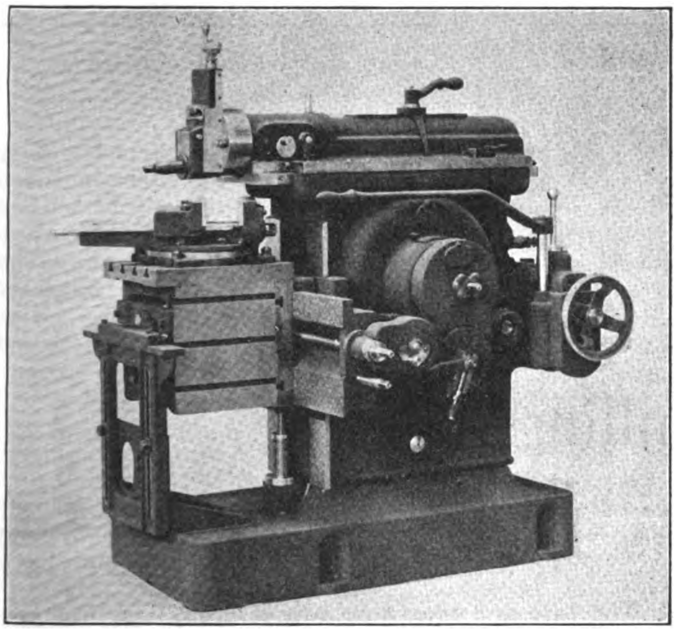
The pointing head and threading die are both fed forward by springs to reduce the possibility of jamming. Cams return them from the work. In the case of the threading die, there is a heavy spring for starting the thread that operates only for this part of the operation, when it comes against a stop and a light spring carries the head forward, overcoming only the drag of the moving parts. At the end of the stroke a cam opens the dies and returns the head to the starting point where another cam comes into action to close the dies, and then advances the head to position for the heavy spring to start the dies on the next bolt as it is indexed into position.

Change gears are provided to get the best ratio between speeds and feeds for a given size of work. The cams are arranged so they can be replaced to suit varying lengths and the turret head can be moved back after its clamps are loosened, to accommodate the longer sizes.

A capacity on ¾-in. by 1¼-in. U. S. standard bolts of 660 an hour is said to be attained.

Heavy duty back geared shaper

THE Stockbridge Machine Company, Worcester, Mass., has put on the market a 16-in. heavy duty, back geared shaper suitable for toolroom and die work. A gear box drive with a high ratio gearing provides ample power for heavy roughing cuts. The gear box is of the selective sliding type which works on the automobile shift principle.



Stockbridge 16 in., heavy duty back geared shaper

There are four changes of speed in the gear box and, with the back gears, eight changes in all are obtained. The gears are steel, heat treated and can be run in either oil or light grease.

The machine is driven and stopped by an automobile type of clutch which, when the machine is stopped, can be locked against any possibility of starting. This clutch is operated by a horizontal lever, which is extended to the front of the machine within easy reach of the operator. The ram can be moved back and forth, when positioning it, by this lever. A hand wheel is also provided on the side of the machine for hand setting the ram.

The base has been made of unusual depth for the purpose of strengthening it with deep ribs. A table support for the knee is carried on the base. This support gives a full width knee when in any position on the bar.

The cross feed will move the saddle in either direction by moving a handle to the right or the left without changing the position of the feed rod. The feed can be reversed without stopping the machine. It always operates on the return stroke of the ram and never feeds on the cut, thus eliminating the possible danger of breakage.

All the driving parts are heavily constructed. The vise is built to eliminate the overhang of the front jaw. It is also designed to keep the work as close to the top of the table as possible, the body of the base standing only 4½ in. from the top of the table. The jaws are 12 in. by 2½ in. and open to 12 in. The ram can be furnished with an automatic down feed.

Multiple spindle automatic screw machine

THE illustration shows a four spindle automatic screw machine of compact design, occupying a floor space of 116 in. by 42 in. and with a view of utilizing the full capacity of high speed tools, all of the machine members have been designed to insure permanency of alinement. This precaution is essential, due to the requirement of maintaining the dimensions of the product of automatic screw machines within close limits.

As this type of machine quickly accumulates many chips, a liberal amount of space has been provided between the tools and the chip pan. A further provision for the chips has been made by arranging the bed casting of the machine so that when the space directly under the tools has been filled with chips, any further accumulation is deflected by an inclined surface inside the bed at the center legs so that the chips can slide across into a compartment at the right hand side of these legs.

A door in the right leg of the machine gives access to a cabinet which accommodates the spindle speed change gears, which furnish seven changes of speed, ranging from 210 to 751 r.p.m.

A convenient feature of this machine is the design of a lever for opening and closing the chucks. As it is shown in the illustration, this lever is hanging straight down where it is out of the operator's way; but when it is required to put a new bar of stock into the chuck, or to release the chuck for any other reason, it is swung up on its pivotal support into a horizontal position. When so held, the rear end of the lever enters the space between the flanges on the chuck operating thimble, and then the hand lever is swung sidewise to open the chuck. When stocking up the machine, the spindle turret is indexed to bring successive spindles into the position where they can be engaged by this hand lever.

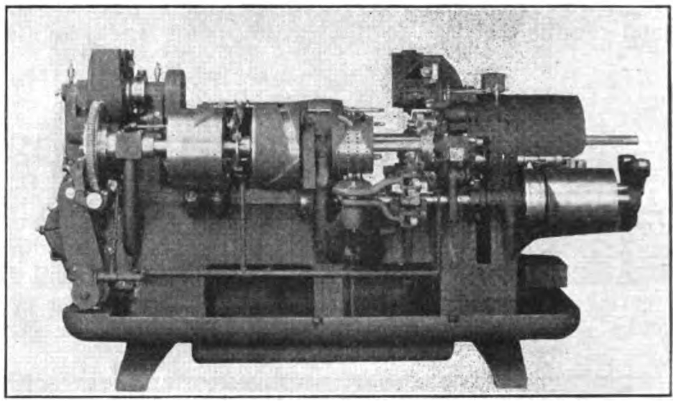
Of particular interest in the design of this machine is the arrangement of the high speed mechanism for effect-

ing indexing movement, and the low speed feed for controlling the working movements of the machine. There are two complete sets of gears for accomplishing these two classes of movement. For the high speed idle movements power is transmitted from a driving pulley, through bevel gears and a vertical shaft to a second pair of beveled gears and thence through spur gears to a worm meshing with a worm wheel on the feed cam shaft. These high speed gears are always running, but when the indexing movement has been accomplished, a clutch is automatically tripped by adjusting pins on the face of the worm wheel thus preventing further transmission through this drive.

The low speed drive for accomplishing the work feed movements is taken directly from the spindle driving gears. As a result, all feed movements, as expressed in inches per spindle revolution, remain constant regardless of how the spindle speed may be changed. From the spindle change gears, power is carried through suitable gearing to a pair of bevel gears which transmit to a vertical shaft, at the lower end of which there is a worm meshing with a worm wheel. From this worm wheel the drive is through a cone of spur gears and then through an intermediate gear controlled by a lever to a cross shaft which carries a ratchet.

Lubrication is an important feature. Oil is carried from the pump by individual tubes and delivered directly to the tool points where it is required. This eliminates the use of pipes above the turret. Attention is called to the fact that the oil pipes are of the telescopic type, so that they move back and forth as the tools advance to or recede from the work. As a result, the delivery of oil is always at the tool point. This is especially important in the case of the threading spindle, because by carrying the oil through the spindle and delivering it to the center of the die, the oil accomplishes the double purpose of lubricating the casers and washing out the chips.

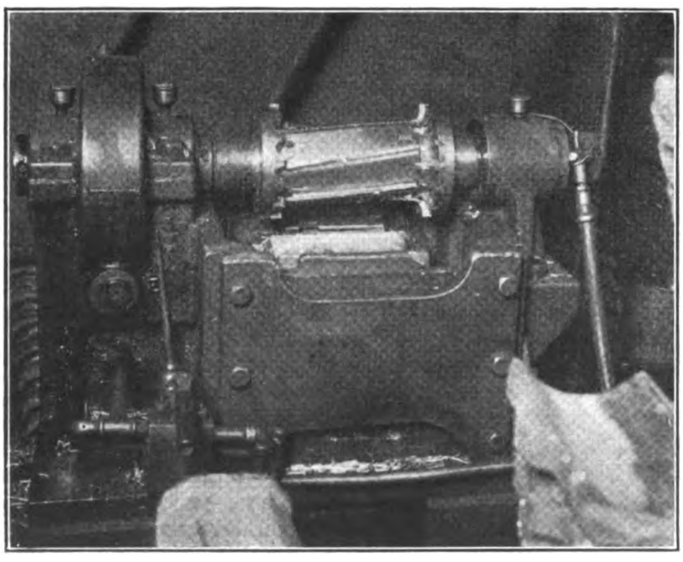
The machine has a capacity for handling 1½-in. round stock, 1¼-in. hexagonal stock, and 1 1/16-in. square stock. The maximum length of feed is 8 in. and the maximum milling length 6 in. The range from the turret face to the face of the chucks is from 7 11/16 in. to 13 11/16 in. The diameter of the turret holes is 1½ in. The machine may be equipped for either individual motor or belt drive. Where the individual motor is employed it may be either alternating or direct current, 10 hp. constant speed, running at 1,800 r.p.m. This machine is the product of the Cleveland Automatic Machine Company, Cleveland, Ohio.



Cleveland automatic screw machine well provided to take care of the chips

Journal brass milling machine

An essential job in connection with the maintenance of rolling equipment is the machining of new or second-hand journal brasses. These brasses must be machined accurately or serious trouble is liable to develop in the form of hot boxes caused by uneven bearing pressure. A machine has been patented by S. R. Parslow, 1276 Hague avenue, St. Paul, Minn., essentially for milling journal brasses to conform to the American Railway Association standard dimensions of length and thickness.



Machine for milling journal brasses which automatically clamps the brass in the chuck jaws and feeds it to the cutters

The base and the frame are of heavy cast iron construction. The carrier, which moves vertically to bring the brass against the milling cutter, is provided with four guides with proper adjustment for slack and is properly lubricated. The carrier is operated by an 8-in. air cylinder underneath the frame of the machine. An adjustable screw is provided in the piston rod of this cylinder which provides the correct amount of material to be machined from the brass.

The brasses are held by two pivoted chuck jaws operated by an air cylinder through powerful toggles. Each brass is located by standard lugs. The design of the machine is such that it will not start unless the brass is properly located in the chuck jaws. A safety feature which tends to reduce injury to the work and the machine.

By turning the operating valve, a friction clutch is engaged that starts the milling cutter to revolve and the chuck to close in and down on the brass, holding it securely and centrally with respect to the milling cutter. While this operation is taking place, the chuck carrying the brass is moved upward against the cutter until it reaches the proper thickness, then the operating valve is automatically reversed and the chuck drops back to its loading position.

Three-piece, inserted blade spiral cutters made of high speed steel are used. Some of these cutters have run as long as six months with a single grinding and at

the same time have turned out a desirable quality of work. Owing to the automatic nature of the clamping and operating mechanism, it is claimed that 120 brasses can be finished in an hour. The machine, which is belt-driven from a 3-hp. motor, will take brasses from 2 in. by 7 in. to 6 in. by 11 in.

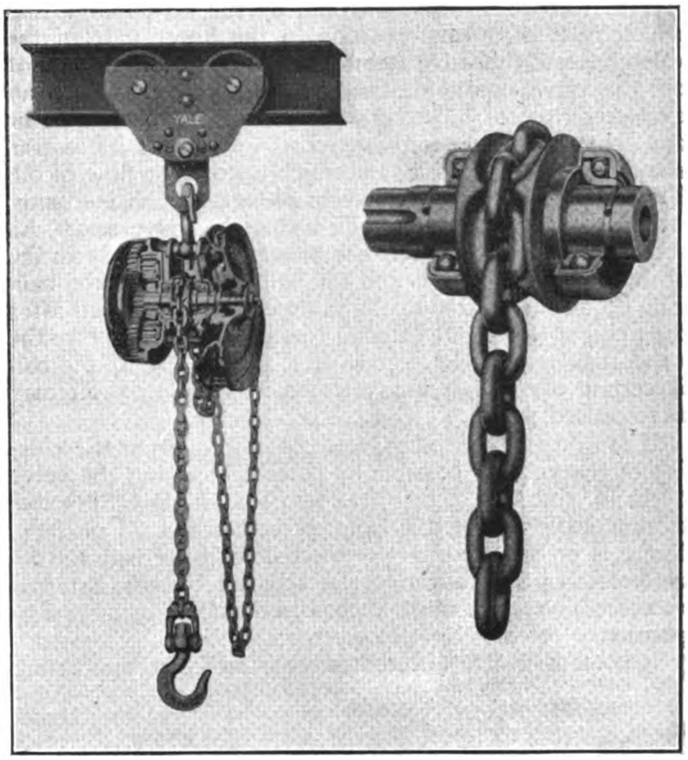
A ball-bearing spur geared chain block

An interesting development in hoisting equipment has just been placed on the market by the Yale & Towne Manufacturing Company, Stamford, Conn., in the form of a new ball bearing, spur-geared chain block. The design provides for two chrome alloy ball bearings to support the load sheave shaft, arranged so as to take the entire weight of the load and, in addition, to withstand the shock of all thrust and overload surges. The bearings are enclosed in small chambers so designed that by means of steel and felt washers dust and grit is prevented from entering.

The sectional view of the block in the accompanying illustration, shows the location of the massive steel load sheave carried on two ball bearings, each containing vanadium steel balls. The top hook, crosshead, suspension plates, load sheave, electric-welded load chain, detachable shackle, bottom crosshead and hook are all steel, so that the load hangs on a line of steel from hook to hook. It is claimed that the mechanical efficiency of this block has been increased over six per cent by the introduction of ball bearings at the points where they carry the full load.

In order to obviate the danger so common in hoisting, a great deal of attention has been given, not only to the size of the parts in the make-up of the chain block, but to the material entering into these parts. It is considered bad practice to put castings in any part of a chain block where they come in tension. It is considered better practice to use steel forgings, wherever parts come in tension in sustaining the load.

An additional feature is the continuous lubrication of the bearings, driving pinion, shaft and driving gears. This chain block is made in all capacities from ¼ to 20 tons.



Chain block provided throughout with ball bearings

Insulation for refrigerator cars

A somewhat unusual development has taken place in the field of refrigerator car insulation, with the advent of what is known as Dry Zero, manufactured by Johns-Manville, New York. This product is the result of intensive study and research work in the theory of heat transmission, in the effort to produce a light and efficient insulation particularly suited for refrigerator cars, where weight is a matter of prime importance.

In arriving at this new product, it was the aim of the manufacturer to find a material in which could be combined to the greatest possible extent, the following essential qualities which are desired by all refrigerator car operators.

The qualities are: the highest possible insulation value; light weight insulant; low moisture absorption; immunity from effects of impact, vibration and torsion; simple and inexpensive application; non-interference with and possible simplification of standard frame construction, and permanence of the insultant and its qualities.

It is claimed that these seven features have been included in the new insulating material. According to tests made by the Bureau of Standards and the Armour Institute of Chicago, Dry Zero insulation has a thermal conductivity of 5.66 B.t.u. per sq. ft. The 2-in. blanket which is principally used for refrigerator car insulation weighs less than 6 oz. a sq. ft. and has a density of 1.57 lb. a cu. ft. It is made up in any size in convenient blanket form, having longitudinal seams spaced 6 in. apart. It can also be used in bulk form—though in this form, it is not so easy to handle. It is claimed further that refrigerator cars insulated with Dry Zero insulation have shown a dead-weight saving ranging from 1,000 to 3,000 lb. on each car.

Dry Zero is a processed vegetable fibre which is hollow in structure, but the ends of each fibre are closed forming a myriad of natural combined air cells. It possesses the peculiar characteristic of being naturally moisture repellent, and also has considerable natural resilience, an inherent quality of the fibre, which counteracts any tendency to settle in a wall. The effects of impact, vibration and torsion are negligible.

On account of its light weight, it can be applied to standard car construction in one course and in one piece extending from the door frame on one side to the door frame on the other side, at the same time effectively insulating the corner posts as well as the other frame members.

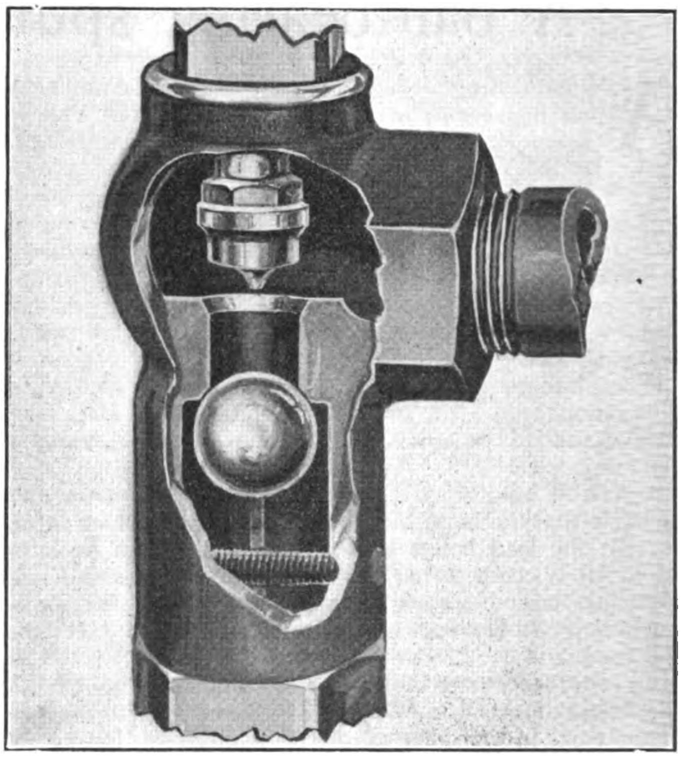
Automatic shut-off valve for oil lines

The breakage of an oil pipe usually leads to the loss of a considerable quantity of oil before the flow of oil through the break is stopped. The Johnston Manufacturing Company, Minneapolis, Minn., has developed an automatic shut-off valve, the action of which is analogous to that of a fuse in an electric circuit which shuts off the current in case of an excessive flow caused by a short circuit.

This feature is made possible by the action of a ball which rests in normal position in the lower part of the valve beneath the valve stem disk. With a normal flow of oil, the valve acts as a standard angle valve. When an excessive flow of oil occurs because of a broken pipe or any other cause, the ball is carried up against its seat as shown in the illustration, and quickly stops the flow of oil. The valve disk has an extension plunger which is a snug working fit in the oil passage below the valve seat. As soon as this plunger enters the passage, it forces down the oil between the plunger and the ball and releases the ball. The tip on the bottom of the plunger strikes the ball after the plunger has entered the oil passage and just before the valve disk reaches its seat so that the release of the ball is certain even after long service in very dirty oil may have caused wear.

It is said that no interference with the automatic closing of the valve is possible by partially opening the valve by hand, since the ball is free to rise and close the valve automatically before the plunger leaves the oil passage. There is no external part connected with the ball and its automatic operation cannot be affected by any external means. The valve must always be installed in a vertical position.

It is made in five different sizes from ½ in., increasing by ¼ in. increments to 1½ in., with a capacity in gallons per hour of 25, 100, 200, 350 and 800, respectively.

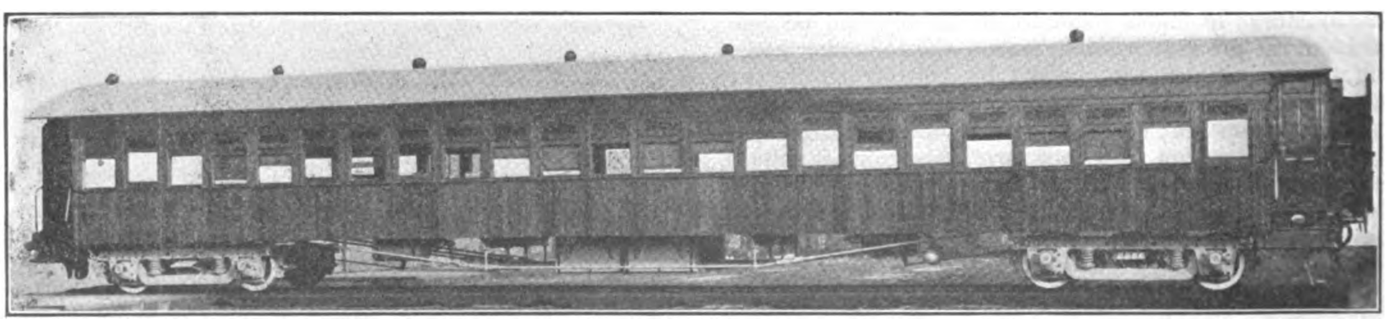


Valve closed by the automatic action of the ball to stop excessive flow of oil

Bearing metal adaptable to many purposes

Friction, wear and hot bearings have been the primary factors in retarding the speeding up of machinery. Two factors to be considered in reducing to a minimum these undersirable features are lubrication and bearings. Much attention has been given to the improvement of lubrication and little to the bearing material itself. It is contended that the ultimate source of bearing trouble lies in the material and not in the lubricant. J. E. Loudon & Co., Boston, Mass., conducted a series of experiments on bearing metals and finally developed a metal which is being marketed under the trade name of Mahanite.

An essential characteristic of a good bearing metal is its slow wearing quality. It is claimed for Mahanite that this characteristic has been obtained. Its lasting qualities make it an excellent bearing metal for high speed work. One of its properties is its cushioning effect which absorbs vibration. The metal is porous which provides it with ability to absorb oil, giving it a self-lubricating property. Mahanite may be obtained in the form of solid bars and solid or lined bushings. It may be used for machine and shafting bearing and car and locomotive journals. Grey iron is used for the sleeves of the lined bearings and bushings.



Passenger car built for the Central Argentine railway by the Gloucester Railway Carriage & Wagon Co., Ltd., London, Eng. Length over the buffers, 79 ft. 4 in.; height from rail, 13 ft. 3¾ in.; seating capaity, 138

General News

Edward Dahill, Jr., has been appointed chief engineer of the Freight Container Bureau of the American Railway Association, the new joint A. R. A. committee having decided that Colonel B. W. Dunn, chief inspector of the Bureau of Explosives, should devote his whole time to the explosives bureau. Colonel Dunn has had charge of the container bureau since its establishment. Headquarters, 30 Vesey street, New York City.

The Gulf, Mobile & Northern recently initiated a fuel saving contest for enginemen and firemen which has developed considerable enthusiasm, and promises to result in greatly increased interest in fuel conservation. It is expected that fuel saving records will be broken. The contest extends through the month of April and the winners will be sent at the expense of the company to the annual convention of the International Railway Fuel Association, at Chicago on May 26.

The Chicago Milwaukee & St. Paul during 1924 effected an excellent record in the conservation of fuel. In freight service the pounds of coal consumed per 1,000 gross ton-miles were reduced from 194.4 lb. in 1920 to 167.8 lb. in 1924. The consumption of coal per passenger car-mile in passenger service was reduced from 20.1 lb. in 1920 to 17.5 lb. in 1924. This saving in the use of coal amounted to 509,000 tons for the year, applied to the volume of business handled in 1924, and the saving in money, at the average price of coal in 1924, was $1,473,454.

The western roads have continued to sign agreements with the engineers and firemen on the basis of the Southern Pacific settlement, granting wage increases of approximately six per cent without important changes in working rules. A total of 46 western roads have now signed agreements. The latest roads include the Chicago, Milwaukee & St. Paul; the Atchison, Topeka & Santa Fe; the Duluth & Iron Range; the East St. Louis Junction; the Minneapolis & St. Louis; the Missouri-Kansas-Texas; the Northwestern Pacific; the Quincy, Omaha & Kansas City; the Texas & Pacific; the Union Railway of Memphis; the Oregon-Washington R. R. & Navigation Company; the Mississippi River & Bonne Terre; the Union Stock Yards of Omaha; the Chicago, Rock Island & Pacific; the Chicago, Rock Island & Gulf, and the Sioux City Terminal.

Locomotive Inspection Bureau's March report

The Bureau of Locomotive Inspection of the Interstate Commerce Commission in March inspected 6,676 locomotives, of which 3,007, or 45 per cent, were found defective, and 331 were ordered out of service, according to the commission's monthly report to the President on the condition of railroad equipment. The Bureau of Safety during the month inspected 110,475 freight cars, of which 3,696 were found defective, and 2,003 passenger cars, of which 26 were found defective. During March eleven cases, involving 14 violations of the safety appliance acts, were transmitted to various United States attorneys for prosecution.

Enola sets up a mile-stone

The shop of the Pennsylvania Railroad at Enola, Pa., opened on July 25, 1923, for the repair of the steel cars of the company, has lately completed work on the ten thousandth car, and the job was celebrated by having a photograph taken of J. W. Priest and his gang of 43 men, who did the work on this car. The total number of men employed in this shop at present is 833, of whom 419 own shares in the railroad company's stock. For the repair of steel cars there are three runways, on each of which there are three gangs of 43 men each; and two tricks are worked, thus employing 18 gangs in all. The daily output of this shop is from 37 to 40 cars. Repairing and rebuilding is done here for all parts of the Pennsylvania System.

Wage statistics for January

In January, 1925, the number of employees reported by Class I railroads was 1,728,333 a decrease of 8,366 or 0.5 per cent, as compared with the previous month, according to the Interstate Commerce Commission's monthly bulletin of wage statistics. The total compensation increased $3,011,216 or 1.3 per cent. Compared with the returns for January, 1924, the employment shows a decrease of 1.2 per cent and the total compensation an increase of 1.6 per cent. The most substantial change in straight time hourly earnings appears for the train and engine service employees, whose average straight time earnings per hour increased from 73.8 cents to 77.5 cents. For all employees reported on an hourly basis, the average straight time earnings per hour were 57.6 cents in January, 1924, and 58.8 cents in January, 1925.

Electric operation will be started on the Detroit & Ironton about June 1

First tests of the Detroit & Ironton locomotives will take place on a section of track just outside the River Rouge Ford plant at Detroit, Mich., about June 1. Foundations for trolley-support arches have been laid along three miles of this double-track line. Concrete parts for the trolley supports are being cast. Power for operating the road will be developed at 13,200 volts, 60-cycles, 3-phase alternating current. A frequency changer substation to be built near the power house will convert this energy to 22,000-volts, single-phase, 25-cycle alternating current power for use on

*Corrected figures.

Figures as to installations and retirements prepared by Car Service Division, A. R. A. Figures cover only those roads reporting to the Car Service Division. Figures of installations and retirements alike include equipment rebuilt to an extent sufficiently so that under the accounting rules it must be retired and entered in the equipment statement as new equipment.

the trolley. The track and trolley are expected to be in condition for tests about June 1.

Three of the four sections of the first locomotive have been practically completed. The main wiring on the first section has been completed and the control wire is being installed. The main wiring has also been partially completed on the second and third sections. Flexible armored cable is being used for all main circuit connections. This is a wiring feature which has probably never before been used in an electric locomotive. All of the main direct current leads are covered with steel armor, while the alternating current leads are covered with brass armor. It is expected that the locomotive will be completed and ready for tests some time during April.

New equipment for South Africa

The Times (London) Trade Supplement summarizes the report of the general manager of the South African Railways for the fiscal year ended March 31, 1924, in part, as follows:

A number of locally constructed rail-motor vehicles of the converted road-omnibus type have been introduced, and with the object of gaining practical experience of types of rail motor-coaches in use in other countries orders were placed for a 68 hp. Service car to seat 38 passengers and for a Sentinel-Cammell steam-coach to seat 40. Experiments have also been made with a tractor coach equipped with a 120 hp. producer-gas engine and electric transmission. The fuel used for gas production is the char removed from steam locomotive smoke-boxes. The tractor has been in use between Kimberley and Winters Rush, hauling a composite passenger coach, and the results of the experiment have warranted the ordering of a 500 hp. producer-gas tractor.

A number of cars have been converted to form a train to be used for purposes of agricultural demonstration. In addition to a coach and dining car for the technical and supervisory staff, the train contains 12 cars equipped for the demonstration of various forms of agricultural activity.

Twelve dining cars of the new "twin" type were being built in South Africa. They are 60 ft. long and operate in pairs, each pair comprising a restaurant car with 46 seats and another containing pantry, kitchen, and sleeping accommodation for the staff.

Maintenance of doors, door fixtures, etc., on freight car equipment

Circular No. D. V.-393 has recently been issued by the Mechanical Division of the A. R. A. calling attention to the lack of maintenance of side doors, end doors, roof doors and hatch covers, door fixtures, tracks, guides, brackets, stops and sealing devices on house car equipment.

This lack of maintenance has resulted in a large number of claims for damage to lading by the elements, the pilfering of lading occasioned by easy access to cars, as well as the resultant loss of doors and liability by accidents. In many cases doors found off the track have been rehung simply by forcing them into place without making necessary repairs to the loose or otherwise defective parts which permitted the door to become displaced. Complete repairs of a permanent and substantial character should be made to cars, either owned or foreign, when found with defective door fixtures or sealing devices. Under no conditions should cars having defective doors, fixtures or sealing devices, be loaded.

Attention is further directed to the necessity of car owners adopting standards for maintenance that will insure doors and hatch covers on house car equipment being of such design as will prevent their readily becoming defective or losing off in ordinary service.

It is requested, therefore, that car owners inaugurate an intensive campaign at all repair points, freight houses and loading stations, to the end that a decided improvement may be effected, in order to avoid necessity for the establishment of a rule which would allow refusal of such defective cars when offered in interchange under load.

Court News

Engineers qualified experts as to power of air pumps.—The West Virginia Supreme Court of Appeals holds that locomotive engineers with from 10 to 15 years' experience in operating engines were qualified to testify as to whether or not one air pump was sufficient to control a heavy train.—Lambert v. Virginia Ry. Co. (W. Va.), 122 S. E. 457.

Movement of engine without headlight violation of boiler inspection act.—The Kentucky Court of Appeals holds that the movement of a locomotive without a headlight was a violation of the Boiler Inspection Act and the proximate cause of the death of a brakeman thrown from a cut of cars as the result of a collision.—Callihan's Admr. v. C. & O. (Ky.) 263 S. W. 339.

Return of defective car not violation of law.—A terminal company receiving cars for transfer between other roads received a car with a defective running board, marked it for return as in bad order, and retained it until a string of cars for the company sending it had accumulated, when it was returned. The Circuit Court of Appeals, Sixth Circuit, holds that such retention and return were not a violation of the Safety Appliance Act.—U. S. v. Louisville & J., 1 Fed. (2nd) 646.

Safety appliance act provision as to grab-irons does not apply to top of tender.—Judgment was obtained in an action in the Georgia state courts by a baggageman injured while assisting in coaling the engine of his train, by being thrown from the tender while climbing down the ladder, by a sudden jerk of the train. The case was brought to the United States Supreme Court on certiorari. Negligence in operating the train was charged, and also omission to equip the locomotive with the appliances required by law, the top of the ladder not reaching over the top of the flange at the rear of the tender, so that a person climbing down the ladder had no handhold except the sheet-iron flange. This was alleged to be a violation of Sec. 2 of the Safety Appliance Act, which provides that: "All cars requiring secure ladders and secure running boards shall be equipped with such ladders and running boards, and all cars having ladders shall also be equipped with secure handholds or grab-irons on their roofs at the tops of such ladders."

The trial court charged the jury that the grab-iron provision

applied to a locomotive tender though it had no roof. Exception was taken.

The United States Supreme Court holds that the trial court erred in its charge on the effect of the statute, and the judgment of the Georgia Court of Appeals affirming judgment for the plaintiff was reversed and a new trial granted.

The Supreme Court said: "The word 'roofs' is the determining one. The Interstate Commerce Commission is empowered to designate the number, dimensions, location, and manner of application of the appliances provided for by Sec. 2. The commission's regulation as to ladders on tenders requires a suitable metal end or side ladder fastened with bolts or rivets. The omission to require a grab-iron is a practical construction by the commission. While the view of the commission is not conclusive with us, it is properly persuasive. We agree with it."—Davis v. Manry. Decided January 5, 1925. Opinion by Mr. Justice McKenna.

Meetings and Conventions

L. F. Loree to address Fuel Association convention

The International Railway Fuel Association has arranged an exceptional program for its seventeenth annual convention to be held at the Hotel Sherman, Chicago, May 26, 27, 28, 29. L. F. Loree, president of the Delaware & Hudson, J. D. Battle, traffic manager, National Coal Association, and President P. E. Bast, fuel engineer, Delaware & Hudson, are scheduled to make the opening addresses.

Wednesday, May 27, is known as "Operating Day" and the subjects to be discussed relate principally to the functions of the stores and operating departments. The program includes a paper by H. C. Pearce, director of purchases and stores, Chesapeake & Ohio; Mark Kuehn, chairman fuel committee, National Association of Purchasing Agents and G. M. Basford. Thursday, May 28, is to be known as "Mechanical Day" and the program includes papers by John Purcell, assistant to the vice-president, Atchison, Topeka & Santa Fe; and C. B. Smith, mechanical engineer, Boston & Maine. On the last day of the convention, J. W. Clark, chief fuel supervisor, Southern Pacific, is scheduled to read a paper on oil burning. The program is as follows:

TUESDAY, MAY 26

9:30 a.m.—(Daylight saving time). Opening addresses by J. D. Battle, traffic manager, National Coal Association. L. F. Loree, president, Delaware & Hudson. P. E. Bast (president), fuel engineer, Delaware & Hudson.
11:30 a.m.—Adjournment.
2:00 p.m.—Report of secretary-treasurer.
2:10 p.m.—Appointment of Auditing and other Special Committees.
2:20 p.m.—Unfinished business.
2:30 p.m.—New business.
2:40 p.m.—Report of Standing Committee on Fuel Stations.
3:30 p.m.—Report of Standing Committee on Fuel Accounting, Distribution and Statistics.
4:30 p.m.—Signals and the Saving of Fuel, B. J. Schwendt, superintendent of signals, New York Central Lines.
5:30 p.m.—Adjournment.

WEDNESDAY, MAY 27 (OPERATING DAY)

9:00 a.m.—How Can Fuel Purchases Affect Economy? H. C. Pearce, director of purchases and stores, Chesapeake & Ohio.
9:45 a.m.—Stocks, Consumption, and Production of Coal, Mark Kuehn, chairman, Fuel Committee, National Association of Purchasing Agents.
10:30 a.m.—Report of Standing Committee on Diesel Locomotives.
12:00 m. —Topical discussion. Effect on Fuel Consumption of Recent Developments in Operating Practice.
12:45 p.m.—Adjournment.
2:00 p.m.—Report of Standing Committee on Firing Practice (Oil section).
3:45 p.m.—Report of Standing Committee on Firing Practice (Coal section).
5:30 p.m.—Adjournment.

THURSDAY, MAY 28 (MECHANICAL DAY)

9:00 a.m.—How Can a Mechanical officer Affect Fuel Economy? John Purcell, assistant to vice-president, Atchison, Topeka & Santa Fe.
9:30 a.m.—Report of Standing Committee on Feedwater Heaters.
11:00 a.m.—Report of Standing Committee on Front Ends, Grates and Ash Pans.
12:00 m. —Topical discussion.
12:45 p.m.—Adjournment.
2:00 p.m.—Report of Standing Committee on Stationary Plants.
3:00 p.m.—Mechanical Means for Cleaning Locomotive Flues, C. B. Smith, mechanical engineer, Boston & Maine.
3:45 p.m.—Fundamental Fuel Factors, G. M. Basford.
4:45 p.m.—Report of Auditing and other special committees.
5:30 p.m.—Adjournment.

FRIDAY, MAY 29

9:00 a.m.—The Development of Oil Burning Practices on Locomotives, J. N. Clark, chief fuel supervisor, Southern Pacific Company.
10:00 a.m.—Report of Committee on Tanks.
10:15 a.m.—Report of Standing Committee on Constitution and By-Laws.
10:30 a.m.—Election of officers.
11:00 a.m.—Balloting for place of 1926 meeting.
11:30 a.m.—Convention adjournment.

The following list gives names of secretaries, dates of next or regular meetings and places of meeting of mechanical associations and railroad clubs.

AIR-BRAKE ASSOCIATION.—F. M. Nellis, Room 3014, 165 Broadway, New York City. Next meeting May 26-29, inclusive, Alexandria Hotel, Los Angeles, Cal.

AMERICAN RAILROAD MASTER TINNERS', COPPERSMITHS' AND PIPEFITTERS' ASSOCIATION.—C. Borcherdt, 202 North Hamlin ave., Chicago.

AMERICAN RAILWAY ASSOCIATION, DIVISION V.—MECHANICAL.—V. R. Hawthorne, 431 South Dearborn St., Chicago. Business meeting to be held in Chicago June 16, 17 and 18. No exhibit of railway supplies and machinery will be held.
DIVISION V.—EQUIPMENT PAINTING SECTION.—V. R. Hawthorne, Chicago. Next meeting September, 1925.
DIVISION VI.—PURCHASES AND STORES.—W. J. Farrell, 30 Vesey St., New York. Next meeting May 19, 20 and 21, at St. Louis, Mo.

AMERICAN RAILWAY TOOL FOREMEN'S ASSOCIATION.—G. G. Macina, 11402 Calumet Ave., Chicago. Annual convention August, 1925, Hotel Sherman, Chicago.

AMERICAN SOCIETY OF MECHANICAL ENGINEERS.—Calvin W. Rice, 29 W. Thirty-ninth St., New York. Railroad Division. A. F. Steubing, Bradford Corp., 25 West Forty-third street, New York. Spring meeting May 18 to 21, inclusive, Milwaukee, Wis.

AMERICAN SOCIETY FOR STEEL TREATING.—W. H. Eiseman, 4600 Prospect Ave., Cleveland, Ohio. Annual convention week of September 14, 1925, Cleveland, Ohio.

AMERICAN SOCIETY FOR TESTING MATERIALS.—C. L. Warwick, 1315 Spruce St., Philadelphia, Pa. Annual meeting, June 22-26, Chalfonte-Haddon Hall, Atlantic City, N. J..

ASSOCIATION OF RAILWAY ELECTRICAL ENGINEERS—Joseph A. Andreucetti, C. & N. W., Room 411, C. & N. W. Station, Chicago, Ill. Annual meeting October 20-24, Hotel Sherman, Chicago.

CANADIAN RAILWAY CLUB.—C. K. Crook, 129 Charron St., Montreal, Que. Regular meetings second Tuesday in each month, except June, July and August, at Windsor Hotel, Montreal, Que.

CAR FOREMEN'S ASSOCIATION OF CHICAGO.—Aaron Kline, 626 N. Pine Ave., Chicago, Ill. Meeting second Monday in month, except June, July and August, Great Northern Hotel, Chicago, Ill.

CAR FOREMEN'S ASSOCIATION OF ST. LOUIS.—R. E. Giger, 721 North 23rd street, E. St. Louis, Ill. Meetings, first Tuesday in month, except June, July and August, at the American Hotel Annex, St. Louis.

CENTRAL RAILWAY CLUB—H. D. Vought, 26 Cortlandt St., New York, N. Y. Regular meetings second Thursday each month, Hotel Statler, Buffalo, N. Y. Next regular meeting May 14. Paper on The New Locomotive will be read by W. H. Winterrowd, assistant to president, Lima Locomotive Works. Next interim meeting, June 11. Paper on Meeting Personnel will be presented by John G. Walber, vice-president in charge of personnel, New York Central. Young men's night.

CHIEF INTERCHANGE CAR INSPECTORS' AND CAR FOREMEN'S ASSOCIATION.—A. S. Sternberg, Belt Railway, Clearing Station, Chicago.

CINCINNATI RAILWAY CLUB.—W. C. Cooder, Union Central Building, Cincinnati, Ohio. Meetings second Tuesday, February, May, September and November. Next meeting May 12. No paper will be read, but a musical entertainment will be given by Doc. Howard's Cuvier entertainers. Dinner party and smoker.

CLEVELAND STEAM RAILWAY CLUB.—F. L. Frericks, 14416 Adler Ave., Cleveland, Ohio. Meeting first Monday each month at Hotel Cleveland, Public Square, Cleveland. Next meeting May 4. Paper on Train Resistance and Tonnage Rating will be read by F. E. Sellman, Master mechanic, Pennsylvania Lines.

INTERNATIONAL RAILROAD MASTER BLACKSMITHS' ASSOCIATION.—W. J. Mayer, Michigan Central, 2347 Clark Ave., Detroit, Mich. Next convention, Hotel Winton, Cleveland, Ohio, August 18, 19 and 20.

INTERNATIONAL RAILWAY FUEL ASSOCIATION.—J. B. Hutchinson, 6000 Michigan Ave., Chicago, Ill. Next annual convention May 26-29, Hotel Sherman, Chicago.

INTERNATIONAL RAILWAY GENERAL FOREMEN'S ASSOCIATION.—William Hall, 1061 W. Wabasha Ave., Winona, Minn. Annual convention September 8-11, Hotel Sherman, Chicago.

MASTER BOILER MAKERS' ASSOCIATION.—Harry D. Vought, 26 Cortlandt St., New York, N. Y. Next convention May 19-25, Hotel Sherman, Chicago.

NEW ENGLAND RAILROAD CLUB.—W. E. Cade, Jr., 683 Atlantic Ave., Boston, Mass. Regular meeting second Tuesday in month, except June, July, August and September. Copley-Plaza Hotel, Boston, Mass. Next meeting May 12. Annual banquet and entertainment.

NEW YORK RAILROAD CLUB.—H. D. Vought, 26 Cortlandt St., New York. Next meeting, Friday, May 15, 1925, at the Biltmore Hotel. Address by R. E. Woodruff, Erie Railroad, Buffalo, N. Y., on "Lubricating a railroad organization."

NIAGARA FRONTIER CAR MEN'S ASSOCIATION.—George A. J. Hochgreb, 623 Brisbane Building, Buffalo, N. Y. Regular meetings, January, March, May, September and October.

PACIFIC RAILWAY CLUB.—W. S. Wollner, 64 Pine St., San Francisco, Cal. Next meeting, Thursday, May 14, 1925.

RAILWAY CLUB OF GREENVILLE.—F. D. Castor, clerk, maintenance of way department, Bessemer & Lake Erie, Greenville, Pa. Meeting last Friday of each month, except June, July and August.

RAILWAY CLUB OF PITTSBURGH.—J. D. Conway, 515 Grandview Ave., Pittsburgh, Pa. Regular meeting fourth Thursday in month, except June, July and August. Fort Pitt Hotel, Pittsburgh, Pa.

ST. LOUIS RAILWAY CLUB.—B. W. Frauenthal, Union Station, St. Louis, Mo. Regular meetings second Friday in each month, except June, July and August. Next meeting May 8. Paper on Clay Products will be presented by J. C. Iselin, traffic manager, Blackman-Post. Moving picture showing development of clay industry.

SOUTHEASTERN CARMEN'S INTERCHANGE ASSOCIATION.—J. E. Rubley, Southern railway shops, Atlanta, Ga.

TRAVELING ENGINEERS' ASSOCIATION.—W. O. Thompson, 1177 East Ninety-eighth St., Cleveland, Ohio. Annual meeting September 15-18, 1925, Chicago.

WESTERN RAILWAY CLUB.—Bruce V. Crandall, 189 West Madison St., Chicago. Annual dinner May 23, Edgewater Beach Hotel, Chicago.

Supply Trade Notes

The Standard Stoker Company, Inc., has removed its New York City office from 5054 Grand Central Terminal to 350 Madison avenue.

The Midwest Forging Company, Chicago Heights, Ill., has moved its principal business office to 38 South Dearborn street, Chicago.

The Harnischfeger Corporation, Milwaukee, Wis., has appointed A. M. Lockett & Co., New Orleans, La., its agent in Louisiana and Mississippi.

Robert H. Blackall, 7 East Forty-second street, New York, has arranged for the rights to sell the Lawson pipe wrench in the United States.

A. H. Beale, president of the Lebanon Iron Company, Lebanon, Pa., has resigned to become president of the A. M. Byers Company, Pittsburgh, Pa.

The Whiting Corporation, Harvey, Ill., has opened a sales room at 997 Ellicott Square, Buffalo, N. Y., and has appointed W. R. Hans district manager.

The McGill Manufacturing Company, Valparaiso, Ind., has appointed the J. G. Pomeroy Company, San Francisco, Cal., its Pacific coast representative.

The Elvin Mechanical Stoker Company has removed its executive offices from 50 Church street to the third floor of 30 Church street, New York City.

E. H. Batchelder, Jr., Lytton building, Chicago, has been appointed western railroad representative of the varnish and enamel division of the Beaver Products Company.

The Kilby Car & Foundry Company, Anniston, Ala., has opened an office at 2038 Grand Central Terminal, New York, in charge of J. N. Brownrigg and Fred MacDonald.

The U. S. Light & Heat Corporation has removed its New York district office from the Grand Central Terminal to 161 West Sixty-fourth street, New York City.

Walter Bentley of the advertising department of the Railway Journal has been appointed sales manager of the Waugh Equipment Company, with headquarters in Chicago.

The Falls Hollow Staybolt Company, Cuyahoga Falls, Ohio, has opened a new office at 203 East Fifteenth street, New York, in charge of L. Wechsler, sales representative.

Alfred W. Lockwood has joined the sales organization of the Bridgeport Brass Company, Bridgeport, Conn., as a special representative, operating out of its New York office.

William H. Keller, Inc., has removed its office from 50 Church street, New York, to 50 Dey street, where a complete line of pneumatic tools and repair parts will be carried.

W. W. Glosser has been appointed general sales manager of the Verona Tool Works, Pittsburgh, Pa., and Frank B. Nimmo has been appointed assistant general sales manager.

The quick change speed sensitive drilling machine business of the Sipp Machine Company, Paterson, N. J., has recently been purchased by the Foote-Burt Company, Cleveland, Ohio.

The Gould Coupler Company and the Gould Storage Battery Company, Inc., have removed their offices from 30 East Forty-second street to 250 Park avenue, New York City.

J. C. Davis, of the sales department of the Ohio Injector Company, with headquarters at Wadsworth, Ohio, has been promoted to assistant sales manager, with the same headquarters.

Fred C. Schreiber, representative of the Stocker-Rumely-Wachs Company, has resigned to become sales representative of Manning, Maxwell & Moore, Inc., with headquarters in Chicago.

M. B. MacNeille, chief engineer of the hydraulic department of Fairbanks, Morse & Co., with headquarters in Three Rivers, Mich., has been promoted to manager of the pump division.

The Globe Steel Tube Company, Milwaukee, Wis., has opened a district sales office at 444 Frisco building, St. Louis, Mo., and has appointed E. C. Carroll manager of sales for that district.

The Ohio Locomotive Crane Company, Bucyrus, Ohio, has placed Arnold Walters, district sales manager, in charge of a newly opened district office at 647 Book building, Detroit, Mich.

The Whiting Corporation, Harvey, Ill., has removed its Chicago district sales office from 945 Monadnock block to 1502 Railway Exchange. R. S. Hammond is district sales manager.

The Kansas City Bolt & Nut Company will construct a one-story plant 90 ft. by 240 ft. in Kansas City, Mo., at an estimated cost of $23,000. A branch office has been opened at Tulsa, Okla.

The Elwell-Parker Electric Company, Cleveland, Ohio, has appointed J. P. Lyons, 612 Citizens and Southern Bank building, Atlanta, Ga., its district engineer for the territory contiguous to Atlanta.

At the recent annual meeting of the stockholders of the Yale & Towne Manufacturing Company, Stamford, Conn., the eight directors in office were unanimously continued as such, Vice-President Schuyler Merritt being elected chairman of the board and Gabriel S. Brown, a director to fill the vacancy caused by the death of Henry R. Towne. Addison Boren, assistant to the president and controller, was elected treasurer, succeeding J. H. Towne, who still retains the office of secretary. Mr. Towne's relinquishment of the treasurership was due to increasing encroachment on his time by other matters. Mr. Merritt, the newly elected chairman of the board, entered the Yale service in 1877 as an office assistant. In 1878 he was elected a director and at the same time secretary of the company. He served as treasurer from 1898 to 1902 and since then as a director. Educated for the law, he has always had charge of the company's legal affairs and also of its patent interests. During recent years he has given special attention to the business of the bank lock department. He is also chairman of the board of directors of the First-Stamford National Bank, and has represented the Fourth Congressional District of Connecticut in Congress since 1917. Mr. Boren, who has been elected treasurer, came to the service about seven years ago as manager of the Works Accounting Bureau. After completing his education he became associated with the Best Manufacturing Company of Pittsburgh, with whom he remained for 15 years. He then engaged in the public accountant business until his removal to Stamford to take up tasks with Yale & Towne. Mr. Boren served successively as chief accountant, controller, assistant to the president and finally treasurer. He is a director of the National Association of Cost Accountants and a certified public accountant of Connecticut.

Schuyler Merritt

W. H. East, assistant electrical engineer of the Chicago, Burlington & Quincy, with headquarters at Chicago, has resigned to become railway sales engineer of the Central Electric Company, Chicago.

Benjamin Nields, Jr., sales agent for the National Malleable & Steel Castings Company, Cleveland, Ohio, has removed his office from 30 Church street to 17 East Forty-second street, New York City.

The Harnischfeger Corporation, Milwaukee, Wis., has removed its Pittsburgh, Pa., sales office from the Fidelity building to 612 Farmers Bank Building, Fifth avenue and Wood street. A. J. Dreyer is district manager and M. B. Bradley is sales engineer at this office.

The Minwax Company, Inc., has removed its office from 18 East Forty-first street to 270 Madison avenue, New York City.

Its Chicago district office has been removed to 10 East Huron street, Chicago.

E. S. Jackman & Co., agents of the Firth-Sterling Steel Company, have removed from 333 Frankfort avenue, Cleveland, Ohio, to their new warehouse and office at 1424 East Twenty-fifth street, N. E. Cleveland.

Arthur E. Bendelari, who has been in charge of operations in Missouri and Oklahoma for the Eagle-Picher Lead Company, has been appointed vice-president and treasurer to succeed Thomas R. Brown, Jr., retired.

J. B. Murphy, district sales manager for the Minneapolis territory of J. D. Wallace & Co., manufacturers of woodworking machinery, has been promoted to assistant sales manager, with headquarters in Chicago.

The Truscon Steel Company, Youngstown, Ohio, will erect two warehouses in Buffalo, N. Y., on a piece of land 400 ft. by 150 ft., at Bailey avenue and William street. One will be erected at once and the other in the fall.

C. A. Ilgenfritz, assistant purchasing agent of the Youngstown Sheet & Tube Company, has been appointed purchasing agent of the United Alloy Steel Corporation, Canton, Ohio, to succeed George W. Starr, resigned.

Joseph M. Welles has been appointed resident representative of the Standard Coupler Company, New York. Mr. Welles will have his headquarters in the Peoples Gas building, Chicago. He succeeds W. Eckels, resigned.

W. Sharon Humes, sales representative of the Magnus Company, Inc., with headquarters in Chicago, has resigned to become sales representative of the Central Brake Shoe & Foundry Company, with headquarters in Chicago.

H. G. Von Nostrand of the sales department of the Illinois Steel Company, Chicago, and formerly manager of tie-plate sales of the Railroad Supply Company, Chicago, died on March 19 following an illness of six weeks.

The Master Tool Company, Cleveland, Ohio, reclaimers of pneumatic tools, has appointed M. W. Scott, eastern representative, with headquarters in Pittsburgh, Pa., and A. B. Stewart & Co., Chicago, western representative.

The Davis Equipment Company and M. E. Davis, dealers in railroad and construction equipment have removed their offices from 50 Church street to 8 West Fortieth street, New York City.

Matt J. Herold, formerly in charge of sales in the East Central division of the Wood-Imes Manufacturing Company, has resigned to become general sales manager of the United States Electrical Tool Company, Cincinnati, Ohio.

S. G. Down, vice-president of the Westinghouse Air Brake Company, Wilmerding, Pa., has been elected also a member of the board of directors, filling a vacancy on the board created by the death of Morris Rosenwald.

G. W. Brogan, Inc., Towson, Md., is now acting as merchandising counsel and handling the advertising of the Bonney Forge & Tool Works, Allentown, Pa., manufacturers of drop forged wrenches and of the chrome vanadium wrench.

Paul T. Farrell of the purchasing department of the Youngstown Sheet & Tube Company, Youngstown, Ohio, has been promoted to assistant purchasing agent to succeed C. A. Ilgenfritz, resigned to accept a position with another company.

The Mid-West Forging Company, Chicago, is enlarging its works at Chicago Heights, Ill., by the addition of a steel building 50 by 120 ft. for manufacturing purposes, a steel building 40 by 70 ft. for steel storage and a warehouse 40 by 120 ft.

A building used for the storage of pattern and flash lumber at the Berwick, Pa., plant of the American Car & Foundry Company was totally destroyed by fire on February 27, entailing a loss of from $400,000 to $500,000. The loss will not delay production.

William C. Wolfe has been appointed district sales manager, welded and weldless division of the American Chain Company, Inc., Bridgeport, Conn. Mr. Wolfe's headquarters are at 208 South La Salle street, Chicago. He succeeds George C. Isbester, resigned.

The Houston Car Wheel & Machine Company, Houston, Tex., is preparing plans for extensions, including a one-story building 75 ft. by 200 ft., the installation of an electric furnace, electric traveling cranes, heavy duty machine tools and auxiliary equipment.

The Railway Car Forging Company, Chicago, has been incorporated to manufacture iron and steel forgings, pressed steel parts and other metal products for car equipment. The company has taken over the Chicago Heights, Ill., plant of the Illinois Car & Manufacturing Company.

The Firth-Sterling Steel Company, E. S. Jackman & Co., agents, has moved its Los Angeles, Cal., office from 336 East Third street to larger quarters at 2154 Santa Fe avenue, Los Angeles. William Ely Nelson, who has been with the company almost 25 years, is Pacific coast representative.

The G. A. Gray Company is constructing a new shop and office building at Evanston (Cincinnati), Ohio. The shop is to be a steel frame building, 420 ft. by 210 ft., with walls of steel sash and glass. The office will be a two-story brick building, located at the eastern end of the shop.

Howard Longstreth, secretary of the Lebanon Iron Company, Lebanon, Pa., has been elected president to succeed A. H. Beale, who has resigned to accept service with another company. H. W. Pratt has been appointed secretary-treasurer and J. J. McDermott has been appointed assistant treasurer.

The Morton Manufacturing Company, Chicago, has appointed the Crowe-Matthews Company, 212 Douglas building, Seattle, Wash., and 1177 Dock street, Tacoma, Wash., its exclusive and direct representative covering the sale of Acme line of railway appliances in the northwestern section of the United States.

The Walworth Manufacturing Company, Boston, Mass., recently formed an engineering products division to co-operate with the engineering production and sales departments of the company. John M. Olmsted has been appointed general manager of the division, with headquarters in Chicago and Fred W. Duemler, assistant manager at New York.

Lyle Marshall, former manager of the service department of the Industrial Works, Bay City, Mich., and later connected with the Chicago office, has been promoted to district sales manager in the newly opened office at 619 Dixie Terminal building, Cincinnati, Ohio. James E. Shearer, assistant sales manager, Bay City, Mich., has been transferred to New York.

Andrew C. Duncan, 2835 Washington Boulevard, St. Louis, Mo., has been appointed district engineer for the Elwell-Parker Electric Company, Cleveland, Ohio, for the territory contiguous to St. Louis. George C. Hays has been appointed district engineer of the territory contiguous to Indianapolis, Ind. Mr. Hays' headquarters are 225 Indiana Terminal Warehouse building, Indianapolis.

The Bird-Archer Company, New York, is now conducting its Canadian business entirely from a general office at 300 McGill building, Montreal, Que. Previously the Canadian business has been conducted from the head offices at New York; the Canadian factory and laboratory will be located at Cobourg, Ont. Hugh C. Harragin is in charge of the administration of the Canadian business with head offices at Montreal.

The Electric Storage Battery Company, Philadelphia, Pa., has bought land as a site for a factory branch to be built in Boston, Mass., on Ashford street, near Babcock. The new building will cover about 35,000 sq. ft., and will consist of a two-story office fronting on Ashford street, with a one-story manufacturing establishment in the rear. It will be of modern daylight construction and the equipment will be modern in every respect.

Harry B. Gilmore, for the past 17 years manager of the distributing organization of the Western Electric Company, at Boston, Mass., has been elected secretary of the company. A few months ago he was made assistant secretary and was transferred to New York. He succeeds as secretary George C. Pratt who in the future will devote his entire time to his duties as general attorney. Donald S. Pratt was elected an assistant secretary to Mr. Gilmore.

C. M. Robertson, vice-president in charge of Chicago sales of the Consolidated Machine Tool Company, has resigned to become sales engineer of the Orton & Steinbrenner Company. From 1901

to 1908 he was superintendent of the Colburn Machine Tool Company, Cleveland, and from the latter date until 1918 he was manager of the Chicago territory of the Essley Machine Tool Company. From 1918 until his recent promotion he was vice-president in charge of the Chicago sales of the Consolidated Machine Tool Company.

The Linde Air Products Company, New York, manufacturer and distributor of oxygen for welding and cutting, has opened the following new district sales offices: In the First National Soo Line building, Minneapolis, Minn., C. E. Donegan, district sales manager; Lincoln Life building, Birmingham, Ala., W. A. K. Popp, district sales manager, and in the Exchange National Bank building, Tulsa, Okla., G. D. Grubb, district sales manager. J. W. Foster, senior salesman in the Pittsburgh Linde district, has been appointed district sales manager at Baltimore, Md.

The Gold Car Heating & Lighting Company, New York, will be temporarily represented in the Chicago territory by F. O. Bailey, manager of sales, and A. D. Stuyer with address the same as heretofore. W. G. Willcoxson is no longer connected with the company. W. H. Ivers, who has again become associated with the company, will be located at St. Louis, Mo., and will represent the territory formerly represented by W. J. Roehl. Tom Moore has been appointed representative in charge of the southern territory, with headquarters in the Royster building, Norfolk, Va. Mr. Moore was formerly purchasing agent of the Virginian Railway.

Farrand P. Hall has been appointed district sales manager of the Carborundum Company in charge of the sales organization and branch warehouse at Cleveland, Ohio, succeeding John MacArthur, who has been assigned to special sales service work at Niagara Falls, N. Y. Mr. Hall joined the Carborundum sales force in 1914 as a salesman, covering the territory in and about Montreal and the Maritime provinces. From 1916 to 1922 he was engaged in the retail hardware business, returning to the Carborundum Company in 1922. Mr. MacArthur has been a member of the sales force since 1909. He was appointed district sales manager at Cleveland in January, 1919.

O'Neill Ryan, Jr., has been appointed advertising manager of the Celotex Company, Chicago, to succeed M. F. Harris, resigned. W. L. Bryson, formerly district manager of the Beaver Products Company, Kansas City, Mo., has been appointed manager of the St. Louis division, with headquarters at St. Louis, Mo. The Celotex Company has granted a license for the manufacture of its product in Australia to a new company which is now being organized by H. C. Armstrong, Sydney, Australia, in conjunction with Crawford Vaughan, ex-premier of South Australia. This company will erect a mill at a cost of approximately $650,000 which will have a yearly capacity of 30,000,000 ft.

R. P. Townsend has been appointed eastern assistant manager of the railroad department of Johns-Manville, Inc., with headquarters at New York. Mr. Townsend entered the service of the New York Central in November, 1906, after having graduated from Walworth Institute. He resigned in July, 1917, to become purchasing agent and later assistant to vice-president of the Liberty Steel Products Company, which later changed its name to the American Railway Appliances Company. Mr. Townsend resigned from that company in March, 1924, to enter the railroad department of the Murphy Varnish Company, which position he held until his new connection with Johns-Manville, Inc.

The Oneida Manufacturing Company, Green Bay, Wis., has been acquired by the Railway Motors Corporation, Railway Exchange building, Chicago, which has been incorporated under the laws of Delaware with a capital of $1,000,000. Officers of the new company will be, president, L. W. Melcher, president and general manager of the Oneida Manufacturing Company; R. E. Frame, treasurer of the Central Brake Shoe & Foundry Company, Chicago; A. C. Deverall, formerly general superintendent of motive power of the great Northern; A. A. Aggerbeck, Chicago; J. H. Taylor, president of the McCartney National Bank, Green Bay, Wis. The Green Bay plant will be used to manufacture power units. Other plants will be established in various districts.

Ralph C. Davison, engineer of the American Abrasive Metals Company, New York, died of pneumonia on April 15 at his home in Plainfield, N. J., at the age of 50. Mr. Davison was educated at Stevens Institute. He became associated with the American Abrasive Metals Company in January, 1918, and previously had served for about ten years with the American Mason Safety Tread Company, New York, in a selling and engineering capacity and as a director. He had also been connected with the Concrete Association of America, and at one time was an associate editor of the Railroad Gazette. Mr. Davison was a member of the American Society of Mechanical Engineers, the American Society of Safety Engineers and the New York Railroad Club.

The extensive patent litigation which has been going on since 1911 between The Safety Car Heating & Lighting Company and the U. S. Light & Heat Corporation, and its predecessor, The United States Light & Heating Company, recently resulted in a judgment against the U. S. Light & Heat Corporation for over $500,000. The parties have agreed to settle this judgment by the sale to The Safety Car Heating & Lighting Company by the U. S. Light & Heat Corporation of all of its patents, machinery, equipment and inventory used in, or connected with car lighting. This sale does not include USL arc welders or the USL batteries. U. S. Light & Heat Corporation will therefore continue to manufacture and sell arc welders and a complete line of batteries, including train lighting batteries. The Safety Car Heating & Lighting Company will be in position to furnish USL type car lighting devices, repairs and replacements.

Charles R. Long, Jr. buys interests of Harry Vissering

Charles R. Long, Jr., president of the Charles R. Long, Jr., Company, manufacturers of railway and industrial paints, Louisville, Ky., vice-president of Harry Vissering & Company, manufacturers of railway supplies and equipment, and vice-president of the Okadee Company, manufacturers of locomotive specialties, Chicago, and also vice-president of the Viloco Machine Company, manufacturing machinists and engineers, Benton Harbor, Mich., has purchased the entire interest of Harry Vissering in the above companies and Mr. Vissering has retired from all of these companies. Mr. Long was born in Louisville, Ky., and after graduating from high school in 1888 entered business as secretary and treasurer of the Stratler Bros. Tobacco Company, Louisville, Ky., which position he held from 1890 to 1896. In the latter year he organized the Charles R. Long, Jr., Company to manufacture railway paints. In 1909 he also became one of the organizers of Harry Vissering & Company. In 1913 he was one of the founders of the Okadee Company and later became one of the incorporators of the Viloco Machine Company. In the reorganization of the Viloco Machine Company, Mr. Long, vice-president, has been elected president, with headquarters at Louisville, Ky. In the reorganization of the Okadee Company, S. W. Russell, formerly secretary and treasurer of the Charles R. Long, Jr., Company, with headquarters at Louisville, Ky., has been appointed vice-president; J. S. Lemley, formerly mechanical expert, has been promoted to vice-president, with headquarters in the newly opened office in the Railway Exchange building, St. Louis, Mo., and W. H. Heckman, formerly mechanical engineer, has been promoted to vice-president. In the reorganization of Harry Vissering & Company, G. S. Turner, formerly vice-president, has been promoted to president. A. G. Hollingshead, president of the Okadee Company, and S. W. Russell have been appointed vice-presidents and W. H. Heckman, mechanical engineer, and J. S. Lemley, mechanical expert, have been promoted to vice-presidents. In the reorganization of the Charles R. Long, Jr., Company, A. G. Hollingshead, president of the Okadee Company, will be vice-president, and S. W. Russell, secretary and treasurer, has been promoted to vice-president.

Charles R. Long, Jr.

Personal Mention

General

James King, superintendent of shops of the Pacific Fruit Express at Colton, Cal., has been transferred to Los Angeles, Cal., succeeding L. E. Martmill.

C. L. Buckingham has been appointed engineer of tests of the Missouri-Kansas-Texas, with headquarters at Parsons, Kansas, succeeding N. J. Boughton, who has been transferred.

W. F. Flynn, superintendent of motive power of the Michigan Central, has been transferred in a similar capacity to the New York Central, Lines East, with headquarters at New York.

J. Archie Jones has been appointed general air brake supervisor of the Delaware & Hudson, succeeding H. A. Flynn, resigned to enter the service of the New York Air Brake Company.

H. W. Faus, special engineer on the staff of the chief engineer of motive power and rolling stock of the New York Central Railroad, has been appointed engineer of materials and equipment tests, with headquarters at New York.

C. A. Garber, master mechanic of the Illinois Central, with headquarters at Memphis, Tenn., has been appointed mechanical superintendent of the Missouri Pacific, with headquarters at St. Louis, Mo., succeeding W. C. Smith.

F. G. Grimshaw, general superintendent of motive power of the Southwestern region of the Pennsylvania, with headquarters at St. Louis, Mo., has been promoted to works manager at Altoona, Pa., succeeding P. F. Smith, Jr., who has been granted a leave of absence from active duty owing to ill health. Mr. Grimshaw was born on November 26, 1878, at Paterson, N. J. He attended Cornell University, and entered railway service on January 9, 1902, as a special apprentice in the Pennsylvania's shops at Altoona, Pa. From March to May, 1905, he was motive power inspector at Altoona. He then became a yard clerk on the Pittsburgh division and in May, 1906, was promoted to assistant yardmaster. From August of the same year to June, 1907, he was assistant master mechanic of the Monongahela division. He then became master mechanic of the West Jersey & Seashore and served in that capacity until September, 1912, when he was appointed assistant engineer of motive power of the Western Pennsylvania division. In November, 1914, he became assistant engineer of electrical equipment of the Philadelphia Terminal division. He was appointed superintendent of motive power of the New Jersey division in July, 1917, and in May, 1918, was appointed assistant to the general manager at Philadelphia. In March, 1920, he became superintendent of the Eastern division and served in that capacity for a year, when he was appointed superintendent of motive power of the Eastern Ohio division at Pittsburgh, Pa. In June, 1924, he became general superintendent of motive power of the Southwestern region.

F. G. Grimshaw

C. W. Buffington has been appointed district boiler inspector of the Eastern General division of the Chesapeake & Ohio, with jurisdiction over all points east of Huntington, W. Va., including the Huntington shops. Mr. Buffington's headquarters are at Clifton Forge, Va.

J. F. Jennings has been appointed superintendent of motive power of the Michigan Central, succeeding W. H. Flynn.

F. P. Neesley, division master mechanic of the Michigan Central at Jackson, Mich., has been appointed assistant superintendent of motive power, succeeding J. F. Jennings.

Merle R. Reed, master mechanic of the Pennsylvania at Logansport, Ind., has been appointed assistant general superintendent of motive power of the Northwestern region with headquarters at Chicago. Mr. Reed was born on June 26, 1883, at Newton, Ill. He attended Rose Polytechnic Institute from which he was graduated in June, 1905. Previous to this time he had served during the summer of 1904 as a laborer in the Terre Haute shops of the Pittsburgh, Cincinnati, Chicago & St. Louis, a subsidiary of the Pennsylvania. After his graduation he returned to the Terre Haute shops as a signal repairman. A few months later he resigned to become a special apprentice on the Union Pacific at Omaha, Neb. He returned to the Panhandle in September of the following year as a draftsman in the Terre Haute shops. In June, 1907, he was promoted to assistant foreman and in February, 1909, became chief draftsman. In April, 1917, he was transferred to the Northwest System of the Pennsylvania, Lines West, as a general car inspector, and was promoted to superintendent of car repairs on the Pennsylvania, Lines West, in September, 1918. He was appointed master mechanic of the Eastern division in August, 1919, and when the administration of the Pennsylvania was reorganized in March, 1920, he was transferred to the Logansport division as master mechanic.

M. R. Reed

Master Mechanics and Road Foremen

W. B. Porter, assistant engineer of motive power of the Eastern region of the Pennsylvania, has been appointed master mechanic at Logansport, Ind.

W. F. Lauer, general foreman of the shops of the Illinois Central at Memphis, Tenn., has been promoted to master mechanic, with the same headquarters. Mr. Lauer was born on December 31, 1877, at Galion, Ohio. He attended the public and high schools at that place and on December 1, 1893, entered the employ of the Erie as a machinist apprentice at Galion. In December, 1897, he became a machinist on the Big Four at Bellfontaine, Ohio; in May, 1898, a machinist on the Lake Shore at Collinswood, Ohio; in January, 1899, tool foreman of the Erie at Galion; in January, 1904, machine shop foreman at Cleveland, Ohio; in January, 1908, general foreman of the Chicago & Erie branch of the Erie at Huntington, Ind., and in February, 1912, general foreman of the Illinois Central at Memphis.

W. F. Lauer

E. H. Carlson has been appointed acting master mechanic of the Montana division of the Northern Pacific, with headquarters at Livingston, Mont., succeeding R. P. Blake, who has been temporarily assigned to other duties.

C. L. GIBSON has been appointed master mechanic of the Stockton division of the Southern Pacific, with headquarters at Tracy, Cal., succeeding H. H. Carrick.

GEORGE H. LITTLEMORE, formerly an engineman on the Idaho division of the Northern Pacific, has been appointed road foreman of engines of the Montana division.

C. W. ADAMS, superintendent of shops of the Michigan Central at Jackson, has been appointed division master mechanic at Jackson, Mich., succeeding F. P. Neesley.

Shop and Enginehouse

G. W. DUNNING has been promoted to general foreman of the Southern, with headquarters at Columbia, S. C.

N. L. VAUGHN, roundhouse foreman of the Missouri Pacific at Lexa, Ark., has been transferred to Little Rock, Ark.

GEORGE M. GAGE has been promoted to enginehouse foreman of the Buffalo, Rochester & Pittsburgh, at East Salamanca, N. Y.

L. N. MCCARL, night foreman of the Honey Pot enginehouse of the Pennsylvania, has been promoted to day enginehouse foreman.

J. A. LASCH has been appointed roundhouse foreman of the Missouri Pacific, with headquarters at St. Louis, Mo., succeeding J. B. Crahan.

FRANK FOUSE, whose appointment as shop superintendent of the Lehigh Valley at Packerton, Pa., was announced in the March issue of the *Railway Mechanical Engineer*, was born at Martinsburg, Pa. He attended the Juniata College and in 1896 entered the employ of the Pennsylvania railroad. Mr. Fouse has since been in constant railway service with several leading railroads. His experience included seven years abroad, during which time he became master car builder of the London shops of the Grand Trunk railway. Prior to his entering the employ of the Lehigh Valley, he had been transferred as master car builder to the shops of the Grand Trunk at Montreal.

Frank Fouse

THEO. ROBERSON, foreman of the Waldo avenue enginehouse of the Pennsylvania, has been transferred as enginehouse foreman to Meadows, N. J.

P. A. SCHUBERT, gang foreman of the Northumberland enginehouse of the Pennsylvania, has been transferred to Wilkes-Barre, Pa., succeeding T. J. Parks.

T. J. PARKS, gang foreman of the Pennsylvania at Wilkes-Barre, Pa., has been appointed night foreman of the Honey Pot enginehouse, succeeding L. N. McCarl.

G. W. McElrea, assistant foreman of the Waldo avenue enginehouse of the Pennsylvania, has been promoted to enginehouse foreman, succeeding Theo. Roberson.

J. B. CRAHAN, roundhouse foreman of the Missouri Pacific at St. Louis, Mo., has been appointed general foreman locomotive shops, with the same headquarters.

G. G. DAVIS, superintendent of shops of the Cleveland, Cincinnati, Chicago & St. Louis, with headquarters at Beech Grove, Ind., has retired from active service.

C. J. BALFOUR, gang foreman of the enginehouse of the Pennsylvania, at Meadows, N. J., has been promoted to assistant enginehouse foreman, succeeding W. H. Oyer.

W. H. OYER, assistant enginehouse foreman of the Pennsylvania at Meadows, N. J., has been promoted to assistant foreman of the Waldo avenue enginehouse, succeeding G. W. McElrea.

H. H. CARRICK, master mechanic on the Southern Pacific, with headquarters at Tracy, Cal., has been promoted to superintendent of shops at Los Angeles, Cal., succeeding W. A. Rogers, deceased.

H. D. CARPENTER, motive power inspector of the Panhandle division of the Pennsylvania System, has been appointed enginehouse foreman of the Ohio River & Western, with headquarters at Zanesville, Ohio.

W. R. BENSON, superintendent of shops of the Michigan Central at St. Thomas, Ont., has been appointed superintendent of shops at Jackson, Mich., succeeding C. W. Adams. Mr. Benson was born in 1889 at St. Thomas, and was educated in the public and high schools of that city. In 1906 he entered the employ of the Michigan Central as a machinist apprentice, serving in this capacity for four years. He then worked in several manufacturing plants at Detroit, Mich., and for the Canadian Pacific at Toronto, Havelock, MacTier and London, Ont. Re-entering the employ of the Michigan Central at St. Thomas in July, 1913, he served consecutively as piecework inspector, general piecework inspector, erecting shop foreman, general roundhouse foreman, assistant general foreman, general foreman and superintendent of shops.

Purchasing and Stores

W. F. SANFORD has been appointed district storekeeper of the Chicago & North Western with headquarters at Green Bay, Wis., succeeding W. F. Redman, promoted.

E. H. LEHMAN, general storekeeper of the Ohio Central lines of the New York Central, has been appointed assistant general storekeeper, with headquarters at Columbus, Ohio.

J. C. MACDONALD has been appointed district storekeeper of the Southern district of the Chicago, Milwaukee & St. Paul, with headquarters at Dubuque, Iowa, succeeding G. T. Richards.

J. P. MURPHY, general storekeeper of the New York Central, lines west, with headquarters at Collinwood, Ohio, has been given jurisdiction also over the Ohio Central lines, with the same headquarters.

E. J. LEONARD, division storekeeper of the Chicago & North Western at Clinton, Iowa, has been transferred to the Iowa division, with headquarters at Boone, Iowa, succeeding F. H. Fick, promoted.

G. T. RICHARDS, district storekeeper of the Southern district of the Chicago, Milwaukee & St. Paul, has been transferred to the Northern district, with headquarters at Minneapolis, succeeding J. T. Kelly.

W. B. HALL, general storekeeper of the Denver & Rio Grande Western, with headquarters at Denver, Colo., has been promoted to general purchasing agent, with the same headquarters, a newly created position.

J. T. KELLY, district storekeeper of the Northern district of the Chicago, Milwaukee & St. Paul, with headquarters at Minneapolis, Minn., has been appointed chief stockman, with headquarters at Milwaukee, Wis., succeeding H. L. BRILLINGER, deceased.

Obituary

WILLIAM A. ROGERS, superintendent of the general shops of the Southern Pacific at Los Angeles, Cal., died on March 18. Mr. Rogers was born on December 25, 1874, at Brantford, Canada, and in 1887 entered the employ of the Grand Trunk, now the Canadian National, as a machinist apprentice. Upon completion of his apprenticeship, he traveled extensively, visiting various parts of the United States, Canada and Mexico. About 1893 he joined the construction forces of the New Orleans & North Eastern railroad. The following year he became master mechanic, handling much of the material used for the extension of the line across Louisana and Mississippi. About 1895 he was air brake and compressor mechanic of the Southern Pacific at Wadsworth, Nev.; about 1897 or 1898, machine foreman of the Oregon Short Line at Pocatello, Idaho, and in 1898 employed by the Prescott & Eastern railroad at Prescott, Ariz. In 1905 he entered the employ of the Los Angeles & Salt Lake, now the Union Pacific, serving consecutively as machinist; general foreman at Los Angeles, Cal., and master mechanic at Las Vegas, N. M. In September, 1914, he became general foreman of the Los Angeles shops of the Southern Pacific; and in October, 1917, superintendent of shops.

Entered at the Post Office at New York, N. Y., as mail matter of the second class.

Request for change of address should reach the New York office two weeks before the date of the issue with which it is to go into effect. It is difficult and often impossible to supply back numbers to replace those undelivered through failure to send advance notice. In sending us change of address, be sure to send us your old address as well as the new one.

Subscriptions, including the eight daily editions of the Railway Age published in June, in connection with the annual convention of the American Railway Association, Mechanical Division, payable in advance and postage free: United States, Canada and Mexico, $3.00 a year; foreign countries, not including daily editions of the Railway Age, $4.00. Foreign subscription may be paid through our London office, 34 Victoria Street, S. W. 1, in £ s. d. Single copy 35 cents.

The *Railway Mechanical Engineer* is a member of the Associated Business Papers (A. B. P.) and the Audit Bureau of Circulation (A. B. C.).

Railway Mechanical Engineer

Vol. 99 — June, 1925 — No. 6

Training in the art of leadership

The article or study on "Training foremen in leadership" in this issue, is based upon observations of the editorial staff of the *Railway Mechanical Engineer* and replies to a letter which was sent to the heads of the mechanical departments of the more important railroads in the United States and Canada. So much interest has been shown in this problem of helping the foremen and supervisors to perfect themselves in the art of leadership, that an attempt was made to round up the practices looking toward this end on all of the railroads. The study cannot be said to be complete, for it is apparent that not all of the officers who replied to our letter fully covered all of the things that they are doing to inspire and help the foremen to develop their leadership ability. It is surprising, however, to note the many different things that are being done. Other important developments are being tried out on some roads which are still in a more or less experimental state and which we are not permitted to divulge at this time. The big thing is that the railroad managements are awakening to the importance of this question and that the foremen themselves appreciate the situation and are keen to take advantage of anything that will help them to get better results.

The *Railway Mechanical Engineer* is always glad to hear from its readers, but we would particularly appreciate any suggestions from you concerning constructive steps which are being taken on this problem, which are not mentioned in the article or are not fully covered by it. We should like to know also, for instance, what particular thing has been most helpful to you in securing a better understanding of how best to direct and lead the men in your charge. Have you found some book or method or principle or agency particularly helpful? If so, tell us about it.

How much is a machine tool worth?

As the reader turns over the pages of the section devoted to new machine tools and devices he will find many machines and tools that will increase shop output. The question is, however, how do we determine their real worth? We can arrive at a certain figure by considering the quantity and quality of metal in the machine or we can estimate the cost to the manufacturer to build it. This method will, in principle, be somewhat akin to a story which was told recently by the master mechanic of a large shop on one railroad in the East.

Once upon a time, as all good fairy tales begin, there was an employer who paid his men according to their weight; in other words, the heavier a man weighed the higher the wage. Evidently the work was of such a nature that size and brute strength were the chief assets. As the business expanded the employer hired another assistant. The salaries of the two men were fixed according to their weights. It so happened that the small man was quite keen in working out clever schemes and kinks for improving production, while the larger man relied solely upon brute strength. The employer was forced to change the basis of wage payment.

There are many machine tool users who are inclined to estimate the worth of a machine from the standpoint of so much iron and steel or by what it cost the manufacturer to build it. But a mass of iron and steel cannot be made into a machine without first being organized in the mind of the designer.

The equipment produced today by the machine tool builders is the result of a process of evolution through an endless variety of mechanical apparatus designed to meet the needs of the time. It is the product of many years of experience, research and experiment. Brains has been the most important factor in the development of the modern machine tool, and it is constantly becoming better and more efficient. From the standpoint of the user the worth of a machine depends upon how much better and cheaper it can produce its product than other machine tools used for the same class of work.

The foreman's job

It has been said that the greatest undeveloped asset on a railroad is the human element. Two factors are necessary to release this great possibility—a broad and wise policy on the part of the management in dealing with its employees, and a capable, well-trained body of foremen and supervisors who can interpret the management to the men and lead them in a wise and tactful way, so that they may be developed to the limit of their capabilities. Morale is all-important in any organization. Experts who have been planning in recent years to bring the morale in the army to the highest possible standard have adopted as a slogan. "The army builds men." The meaning or intent of this is that each man is critically analyzed and studied, and is assigned to that class of work for which he is best suited and so directed that he will make the best possible use of the disposition and talents with which he is endowed. It is just as important to do this in an industrial or railroad organization as it is to do it in the army. No two men are alike. They differ widely in their likes and dislikes and in their individual characteristics. They will be happier and will give better service if they are used on that work for which they are best fitted by nature and if they are encouraged and trained so that the best use may be made of their peculiar characteristics.

This is no small task. It means that the foreman must be a keen student of human nature and must study how to deal tactfully and wisely with the most complicated and

sensitive of mechanisms—the human being. Some foremen and supervisors are succeeding in doing this in a big way. The author of the first prize article in the *Railway Mechanical Engineer* contest on the "Opportunities and possibilities of the Foreman," which appears elsewhere in this issue, is an outstanding example. We regret that we cannot use his real name, but his article more or less clearly reflects his personality and methods. It is worthy of the most careful thought and study, particularly if it is read in conjunction with the article on "Training foremen in leadership," which also appears in this number.

Incidentally, the prize article offers much in the way of suggestion for discussion topics at foremen's meetings and staff meetings. Do you agree with "Bill Brown?" Have you gone him one better in some respects? Can his suggestions be applied to your conditions? Has he overlooked or understated important principles? The *Railway Mechanical Engineer* will also be glad to have your reactions.

Terminal maintenance of passenger cars

The terminal maintenance of passenger equipment is one of the big problems of the car department, particularly at those terminals which handle a large volume of suburban traffic. A survey of the methods of handling a large number of units of equipment at terminals indicates that proper facilities and organization are woefully lacking. The location of the storage tracks, adequate facilities for making repairs, the right kind of organization for handling repairs, and the proper analysis of the terminal operating conditions are factors that must be given careful consideration in order to handle passenger equipment economically and with dispatch.

At the modern locomotive terminal the trackage is so arranged so as to reduce to a minimum the amount and the distance of the movements to get locomotives in and out of the terminal. Such is not generally the case with passenger cars at terminals. The storage tracks are usually a considerable distance from the terminal, which results in high shifting costs owing to the time and distance required to move equipment. This cannot be remedied over night but should be kept in mind when planning future terminal layouts. The operating conditions at a locomotive terminal are carefully analyzed so that the locomotives are quickly serviced and ready for their runs without any unnecessary delays. The operations at a passenger terminal afford the mechanical officers an unusual opportunity to make a graphic analysis of the arrival and departure of equipment so that each unit can be properly maintained without withdrawing it from service. In other words, the cars should be withdrawn from service after the morning peak traffic load, repaired during the day and put back in service to handle the evening rush hour traffic. The practice will reduce to a minimum the number of cars required to handle the traffic and will increase the car miles between shoppings.

In order to repair the cars between the morning and evening rush hours, the proper repair facilities must be provided convenient to the terminal. Proper facilities should also be provided for cleaning the cars and repairing trucks and wheels. A modern drop pit should be placed as convenient as possible to a wheel lathe. The usual practice is to have a large number of extra wheels on hand ready to replace worn ones; the removed wheels are then loaded on cars and sent to the nearest wheel lathe for repairs. This practice is expensive—a considerable amount of capital is tied up in extra wheels, to say nothing of the expense involved in transporting them to and from the repair shop. The location of a drop pit and a wheel lathe at the terminal will eliminate this expensive operation.

In the final analysis, the principal object of the plan of terminal operation outlined above is to increase the length of time between the shopping of cars, and in doing so, keep the number of cars going to the repair shops to a minimum.

The importance of knowing detail costs

Under the present system of accounting usually from 30 to 40 days elapse after the close of each month before the master mechanic knows the cost on his division per locomotive mile for repairs, lubrication, enginehouse expense, fuel, etc.—that is, if he waits for the various reports to be forwarded to him from the accounting department. From the standpoint of efficient shop management such figures are of comparatively little value for about the only way a master mechanic can ascertain whether his shop costs are increasing or decreasing is by personal investigation and inspection. Unless he has the results of a similar investigation to refer to, made at the time of the last report, an investigation made 30 or 40 days after the time to which the figures refer will avail little. The only way by which the master mechanic can have his cost figures when he needs and can use them is by getting them himself.

Cost finding is a complex matter at best and as railroad shops grow to greater proportions, this complexity will increase in like ratio. The methods and approximations which may be adequate for a small shop, cannot be relied upon when the plant becomes so large that personal observation by the master mechanic or shop superintendent is insufficient. In many railroad shops, where so-called cost systems have been installed, the cost system is considered satisfactory if it simply shows the cost of performing a certain class of repairs. But the modern conception of a cost finding system is much more exacting. Such a system should show costs in such a form that deductions may be drawn as to the reasons for them and the possibilities of reducing them.

A system of this kind would undoubtedly require a considerable increase in the office force of the master mechanic, but a cost-keeping system that simply records costs for the purpose of knowing the expenditures made, say for a given class of repairs, has accomplished only a small part of its mission. Efficient shop management requires a knowledge of the activity of each department so that the master mechanic or shop superintendent can take proper steps when necessary to apply remedial measures.

It is not only true of the railroads, but of other industries as well, that the art of cost finding is still in a crude and undeveloped stage, so far at least as individual detail costs are concerned. That there is a growing appreciation of the importance of cost finding among mechanical department officers is evidenced by the extensive installation of shop scheduling systems in which repair costs are taken into account and the recent studies made by various roads as to the utilization of money appropriated for repair work. A recent example of where the money expended for repair work has been made the fundamental factor of the shop administration is at the Finley shops of the Southern Railway, Birmingham, Ala. A description of the locomotive unit was published in the March issue of the *Railway Mechanical Engineer* and the car shops are described elsewhere in this issue. Both shops are under the same administration and real progress has been made during the short period they have been in operation, by proper control of labor and material expenditures.

The system at the Finley shops, however, as well as in

the majority of other shops throughout this country where cost systems are in operation, does not deal with the finding of the detail costs. The knowledge of what it costs per locomotive mile for repairs, enginehouse expense, etc., will possibly arouse the master mechanic to action if his costs are too high in comparison with those of other divisions. But figures showing only general or summarized costs are of little practical benefit to the master mechanic or shop superintendent if he wants to know where the money is being spent to the least advantage. He must have available more detail data.

Planning for the future

Complaint is frequently voiced against the treatment received by mechanical department budgets at the hands of the executives responsible for capital expenditures. To some extent the lack of sympathy with the plans of the mechanical department for improving its facilities is the result of the position of the mechanical department in the railroad organization because it is primarily a spending and not an earning department. Locomotives and cars are the tools of the railroad by which it produces the ton-miles and passenger-miles from which the revenue of the road is derived. The value of these facilities and of improvements in them which will increase the ratio of revenue-producing capacity to the cost of their operation is much less difficult of appreciation by the executive than is the value of machine tools, ash and inspection pit facilities or modern drop pit, boiler washing and material-handling facilities which in the mind of the executive are not primarily connected with the production of transportation. The details of their operation are incomprehensible to the average executive and he is not interested in them.

It is a question, however, whether the executive is entirely responsible for the viewpoint with which he approaches the consideration of requests for appropriations to provide these facilities or to replace those which have outlived their usefulness with modern units capable of reducing maintenance costs and increasing equipment capacity by keeping it in service for a larger percentage of the time. Is not the mechanical officer himself in a measure responsible for this situation?

Many mechanical department budgets present to the executive a long list of details, each machine tool or other facility representing in effect a separate project with its own explanation and justification which goes into details of shop operation in which the executive is not interested and to which he cannot give the necessary attention to arrive at a thorough comprehension of the possibilities or of how each detail dovetails into the complete equipment maintenance structure. The entire budget is thus open to attack piecemeal. On the other hand, a grade revision program is presented as a whole and a bridge here or a signal there are details which must be accepted if the project as a whole is accepted.

Is not the mechanical department suffering in a measure from a lack of a comprehensive survey of its needs and possibilities? Is there not an opportunity for a complete survey of the situation as a whole on each road and the formulation of a program of improvements which not only meets the immediate requirements but looks ahead to the ultimate development of completely co-ordinated facilities to form a plant from which the maximum equipment serviceability may be obtained from a minimum expenditure per equipment unit? Such a program, it is true, will call for the expenditure of millions of capital instead of thousands, but it will present a comprehensive and comprehensible picture to the executive. The results can be measured in more serviceable locomotive-hours and in decreased cost of locomotive and car maintenance per unit of service, which means far more to the executive than, for instance, a saving of a few minutes or even a few hours in machining a crank pin or valve chamber bushing by the installation of a new turret lathe or a new boring mill.

The results of a complete program of rehabilitation, carefully worked out to facilitate the extension of locomotive runs, for instance, which the operating department may have in mind, have a direct appeal to the executive which will at least lead to sympathetic consideration and meet with less opposition than would an unco-ordinated list of tools and other facilities. A project requiring the expenditure of ten million dollars, carefully spread over a period of say ten years, resulting in improved equipment utilization and decreased costs which could be measured in terms of their effect on the operating ratio would probably be less difficult to put over than a one hundred thousand dollar project for ten or fifteen new machine tools, each of which would amply justify itself, but the results of all of which together could hardly be found in the operating ratio. The mechanical officer of vision and enterprise has a big opportunity at least to put himself and his department in a position to command the attention and respect of his executive, and in some cases even of his board of directors.

What Our Readers Think

Supply salesmen should read this letter

[The writer of the following letter asked that his identity be concealed]

To the Editor:

There is, I believe, no one in charge of a railroad shop more interested in the supply salesmen and their wares than the writer, who thinks he has learned more of the progress of inventions and what improvements are being made in the interest of shop production from these men than perhaps from any other source, except it be from the advertising and other pages of the mechanical journals.

In view of this belief, his office door is always open to them and he is never too busy to discuss with them the goods they wish to call attention to. As a class, they are above the ordinary man in specialized knowledge and whoever thinks he knows more than these men, has probably overlooked something that would be to his own advantage and material interests. All of which is merely mentioned to show his attitude towards mechanical salesmen as a class. However, the following interview took place recently in his office and is submitted in the hope that it will reach the attention of the class of men he is so partial to and that it will be of benefit to them:

"Good morning, Sir. Are you Mr. B———, superintendent of these shops?"

"Yes sir."

"Well I am representing the ——— Tap Company. We make the finest line of taps made. Our stay bolt taps are a specialty with us. They have become standardized on the X.Y.Z. railroad, after severe competitive tests. I have also conducted tests on the A. B. C. and on the P. D. Q. railways with excellent success and have proved our taps to be better than our competitors'."

"Well, that is quite interesting. How do you mean they proved themselves to be better? Were yours high speed steel and the other fellows' carbon?"

"No sir. They were all carbon steel taps but we tapped more holes than the other fellows."

"How many holes did you tap before they failed?"

"Well, I did not keep tab on the number of holes tapped but ours did the most holes."

"Don't you think it it would have been valuable data to have the number of holes each tapped?"

"Well, it might be."

"What was the thickness of the boiler plate you were tapping?"

"Oh! The usual kind of fire box plate. I did not measure the thickness. But it was the same thickness for all the taps tested."

"What revolutions per minute were the taps used at?"

"Why, as fast as the motors would run."

"You do not know the r. p. m. then, at all?"

"No, I did not think that was necessary."

"What make of air motors did you use? Perhaps we can find out the r. p. m. from that information if you have the air pressure used."

"I do not know the air pressure but one motor was a Little Giant, I think they call it. I do not know the make of the others."

"Well, were they all the same make?"

"I am not sure of that."

"What lubricant did you use on the test?"

"Well, I do know that, it was a heavy oil."

"What kind of oil?"

"A very heavy dark colored oil they put on with a paint brush."

"But you have no idea just what oil it was?"

"No sir. I did not think that made any difference."

"In your traveling around with these stay bolt taps, what lubricant do you find the most used when tapping stay bolt holes?"

"I never took any particular notice of them."

"You say your taps beat the other makes in number of holes tapped. Just what do you attribute it to, that they proved able to tap the greatest number of holes before failing?"

"Well our factory uses the greatest care in selection of steel and they have a special method of tempering them."

"Are the threads of your taps ground or cut in the lathe?"

"I don't know just how they are threaded. But I do know they grind them after they are threaded."

"What make of taps were those you tested yours against?"

"Well, we salesmen do not make a practice of naming our competitors' goods when talking to prospective customers."

"But you did get the names of them, did you?"

"Oh, yes!"

"Well let me tell you a few things without intentionally hurting your feelings at all. I must say you have yet much to learn before you become a successful salesman. You were, according to the ethics of your business correct, I suppose, in not mentioning the names of your competitors' goods to me. At least, I believe that is what the sales managers teach, although I do not know exactly why. That much you appear to have learned thoroughly. But how much more welcome you would be in here were you able to give me more particulars of your test. To tell me that the speed was, say, 250 r. p. m., through Luken's or Otis' or some other brand of ⅜-in. fire box steel. That paraffine oil was first used but that the taps all appeared to get rather hot and that white lead was tried with good results. That the best one tapped 2,180 holes and the next one 2,000 and the other one 1,860. That the reason you believe your tap to be the best was because your company was continually making tests in the factory. That one tap out of each batch, picked at random had to go through so many holes at such a speed before the others were sent out. That you had spent considerable time in the factory watching the process of manufacture and the expert care exercised to get them the correct size and temper. To explain the Brinell testing of them, stating that while ground taps may last somewhat longer and would cut a more accurate sized hole and are an excellent tap where interchangability is necessary, still for boiler work, the taps threaded in the lathes are quite practicable enough and cost much less.

"That there appears to be a great variance of opinion as to which is the best lubricant to use but from your own personal observation, leaving out the cost of it, a mixture of white lead and linseed oil in certain proportions gave the greatest number of well threaded holes per tap. That the r. p. m. varies all the way from 100 to 275 in different localities. That in some places where they practice electric welding for closing up the old holes of the fireboxes no make of tap will successfully stand up, where owing to high voltage or other causes, the hole has been made almost as hard as the tap itself. Now I am sure you will take this advice from an old salesman in the spirit it is given. Take this pass out to the boiler shop and ask the foreman for all the information on taps and tapping he can give you. I will call him on the phone and tell him to look out for you. Good-bye and good luck to you. Well, thanks, I'll take one, I don't smoke myself but will give it to my chief clerk. Call again some day."

SHOP SUPERINTENDENT

Wear of cross-compound compressor cylinders

MILWAUKEE, Wis.

TO THE EDITOR:

In the April, 1925, *Railway Mechanical Engineer,* page 200, there was an inquiry from R. J. K. for an explanation as to why the air cylinders of the 8½-in. cross-compound air compressor do not have the greatest wear at the same points on the cylinder walls as the 9½-in. and 11-in. compressors.

While it is possibly true that under certain conditions the wear of the high-pressure air cylinder of the cross-compound compressor will be different from that of the 9½-in. or 11-in. compressors, the low pressure air cylinder will be found to wear exactly the same as those of the other compressors; that is, the least wear of the cylinder wall will be found at the center of the piston stroke.

The excessive wear near the ends of the cylinder is caused by the packing rings being pressed harder against the cylinder wall as the compression of the air increases toward the end of the piston stroke. The cylinder walls of all air compressors should wear more at the ends than in the center on account of the increased friction of the rings. The cylinder wall of the high-pressure cylinder of the cross-compound compressor will also wear in this manner if the compressor is properly balanced, but it should be borne in mind that it cannot be properly balanced for all main reservoir pressures. For illustration, if properly balanced when operating with 200 lb. of steam against 100 lb. main reservoir pressure, it would be out of balance when operating against 130 lb. main reservoir pressure for the reason that the high-pressure steam piston, with 200 lb. steam pressure, can only compress the air in the low-presure air cylinder to approximately 40 lb., all further increase of pressure being accomplished by the low-pressure steam, high-pressure air piston. When the cross-compound compressor is operating against low main reservoir pressure, the low-pressure steam, high-pressure air piston will complete its stroke to the end of the cylinder, but when the main reservoir pressure is high, this piston stops a greater or lesser distance from the end of its stroke.

The low-pressure piston is a floating piston and is in no way connected to the valve mechanism. When this compressor is in a service which requires high main reservoir pressure, such as passenger service where 110 lb. brake pipe and 130 lb. main reservoir pressures are standard, there will be very little wear of the cylinder wall at the end close to the counterbore. The greatest wear, however, will not be in the center as stated by R. J. K., but a certain distance back of the counterbore. In other words, this cylinder will wear in the same manner as those of the other compressors within the zone of its piston stroke. When calipering this cylinder it will be found that the smallest diameter is near the counterbore, the next larger diameter at the center and the largest diameter a short distance from the counterbore.

The low-pressure steam, high-pressure air piston stops before completing its full stroke because of the by-pass grooves which are placed in both ends of the low-pressure steam cylinder. There are three by-pass grooves machined in each end of the low-pressure steam cylinder wall, each groove is 2 in. long, ⅝ in. wide and 3/16 in. deep. When the piston, operating against high main reservoir pressure, uncovers these grooves, the steam escapes and the piston stops, with the result as before stated.

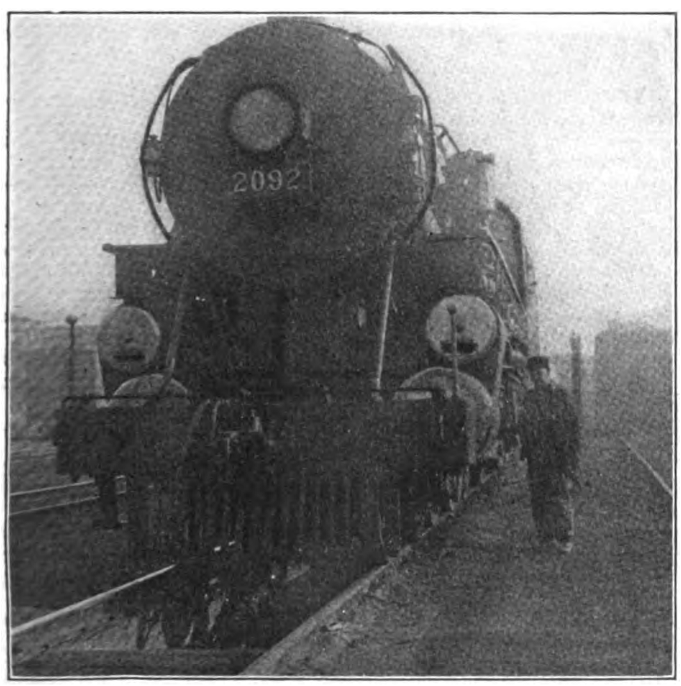
JAMES ELDER,
General air brake supervisor, Chicago, Milwaukee & St. Paul.

Lehigh Valley engine terminal at Sayre, Pa.—The system locomotive shops can be seen in the background

Assignment of locomotives for enginehouse repairs

Re-organized forces and co-operation increase efficiency of Lehigh Valley engine terminals

ENGINE terminal running repair practice has always been considered an entirely different problem from locomotive shop work, owing to the necessity of taking into consideration the unexpected element of emergency situations. A terminal which can anticipate the unexpected and be in a position to provide power for emergency requirements at times of peak traffic without disrupting the despatching schedule is indeed unusual. And yet, this apparently can be attained by departing, in some respects from usual engine terminal practice and intelligently applying a successful feature of modern back shop practice; namely, specialized gangs and assigned work. While the following article deals entirely with the application of this principle at the Sayre, Pa., engine terminal, the same operations are standard at all other terminal enginehouses on the Lehigh Valley.



Inbound inspection pit—Note the nickel plated head casings on the passenger locomotive

The Sayre engine terminal is one of the most important on the Lehigh Valley. The operations at this terminal present a most interesting example of the value of thoroughly analyzing operating conditions and then inaugurating practices to improve them which constitute a radical departure from established precedent. This terminal is located at approximately the mid-point between Buffalo, N. Y., and New York City and despatches power for slow and fast freight, passenger, milk and yard service. During the twelve months period ending March 31, 1925, this terminal despatched an average of 3,580 locomotives per month for all classes of service, an average of 118 for each 24-hr. day. The maximum number of locomotives despatched during any one month in that period was 4,013 during October, 1924, an average of 130 per day.

Slow freight power is despatched for runs to Manchester, N. Y., on the west and Coxton, Pa., on the east. Power for milk and fast freight service is despatched from Sayre to Lehighton eastbound, a distance of 152 miles; for main line passenger and fast freight service from Sayre to Buffalo, N. Y., westbound, a distance of 176 miles, and for passenger service from Sayre to Easton eastbound, a distance of 194 miles. Sayre is the home repair terminal for most of the power despatched. Most of the locomotives are used on turn-around runs, only inspection and light running repairs being made

during the lay-over at the outlying terminals. For example, in main line passenger service one locomotive running on a through passenger train from Sayre to Buffalo is handled on consecutive days by three crews, each of which in turn makes a turn-around run from Sayre to Buffalo and return, a distance of 352 miles in 24 hr.; between Sayre and Easton, locomotives handled in the same way make 388 miles in 24 hr. Passenger locomotives on these runs will average from 10,000 to 12,000 miles per month.

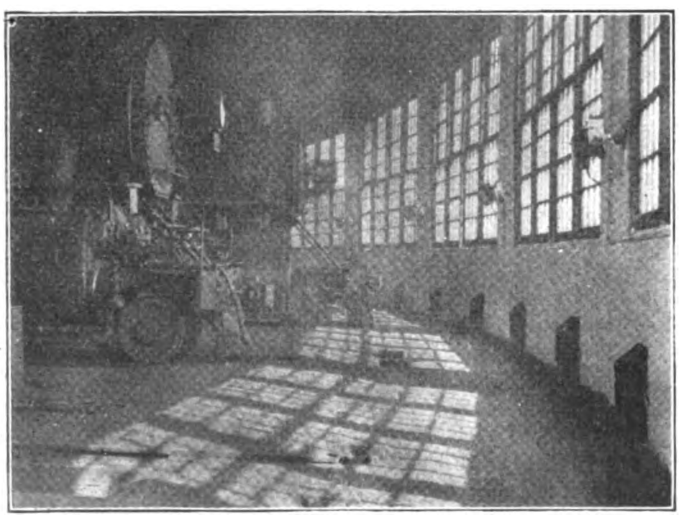
For some time past the Lehigh Valley, particularly on the Seneca division, has made a practice of complete assignment of power to road crews in all classes of service and has found that this method of handling locomotives has distinct advantages over the practice of pooling power. All regularly assigned engine crews have assigned locomotives and an extra board is maintained to cover jobs created by regular men laying off, and extra trains, such as special or work trains. If an extra job is boarded for five or more consecutive days, it becomes a regularly assigned job with an assigned locomotive.

The Sayre engine terminal consists of a 40-stall brick enginehouse and an annex shop with 10 repair tracks served by a transfer table. Owing to the fact that the annex shop is of comparatively old construction, it has not been possible to provide overhead crane facilities without the necessity of making expensive building alterations. Therefore, in order to handle the heavy modern power adequately a 200-ton Whiting locomotive hoist was installed. The annex machine shop is equipped with machine tools as follows:

2 Vertical boring mills.	1 Slotter.
1 Horizontal boring mill.	2 Shapers.
3 Drill presses.	1 Hydraulic press.
1 Turret lathe.	3 Emery grinders.
2 Planers.	1 Steam hammer.
1 Wheel lathe.	1 Power hack saw.
11 Engine lathes.	

Re-organized plan of operation

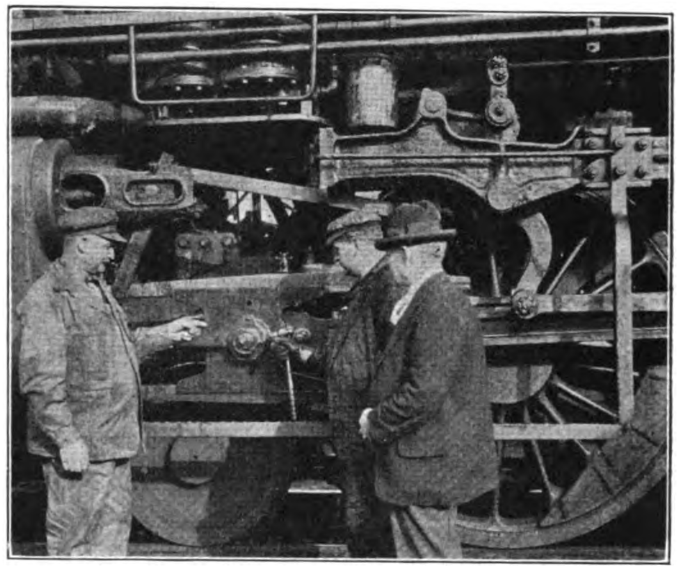
The realization of certain advantages gained from assigned power raised the question in the minds of mechanical department officers as to why these advantages might not apply in a different way to the methods of handling repair work at the engine terminal. As a consequence, after a careful study of conditions, a complete re-organization of forces was made at the Sayre engine terminal in the early part of 1924 and a new system of handling running repairs, which is described in this article, was put into effect about April 1, 1924.



Flood lighting in the enginehouse facilitates night work

In general, the controlling factors of the re-organization of the terminal forces are as follows:

1—The regular assignment of all locomotives and engine crews.
2—The assignment of locomotives to regular enginehouse mechanics for maintenance.
3—A definite assigned list of serviceable locomotives:
(a)—Locomotives assigned to regular crews.
(b)—Locomotives assigned extra to replace regular locomotives withdrawn for repairs or to handle emergency business. Under this classification there are eight serviceable locomotives assigned at all times, four for the eastbound board and four for the westbound board.

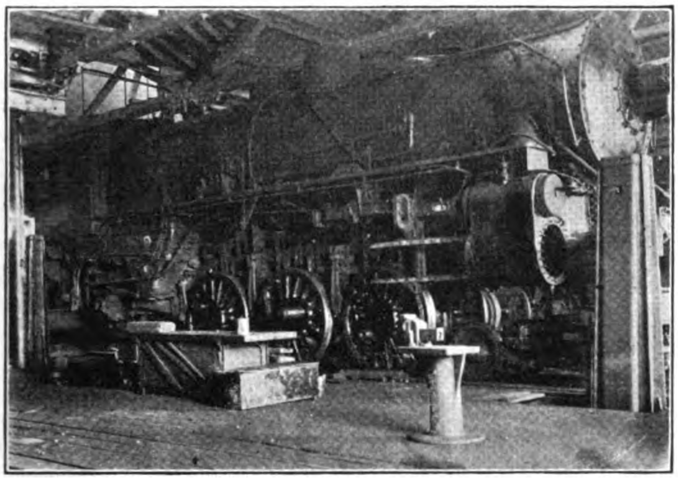


Co-operation between road and shop men has raised the maintenance standard

4—Enginehouse forces handle and despatch only serviceable power.
5—Enginehouse forces handle no heavy work and there is no despatching of locomotives on anticipated repairs.
6—The complete separation of enginehouse forces into two groups:
(a)—Forces to handle despatched serviceable power.
(b)—Forces to handle heavy repairs and to maintain and provide serviceable locomotives for regular assignment.
7—Division of stalls in the enginehouse with specified pits and repair forces for certain classes of power:
(a)—Stalls Nos. 1 to 20, inclusive, for freight repair forces handling serviceable heavy power.
(b)—Stalls Nos. 21 to 32, inclusive, for heavy repair forces, handling all washouts and locomotives withdrawn from service for general maintenance. In order to facilitate the handling of heavy repair work, pits Nos. 21 to 32 were selected because of their close proximity to the annex machine shop and enginehouse storeroom.
(c)—Stalls Nos. 33 to 46, inclusive, are assigned to passenger and light power forces, handling passenger, light freight and yard locomotives.
8—The inauguration of regular meetings of the engine terminal supervisory forces on the following schedules:
(a)—Daily meetings held at 8:00 a. m. to discuss the handling of schedule work, despatching of power, emergencies, detentions and discipline.
(b)—Weekly meetings to discuss the scheduled withdrawal of locomotives for the following week, defining the work to be done, this work being determined by special inspection; the scheduling of washouts, and general discussions.
(c)—Monthly meeting for the discussion of work scheduled for the following month, at which time all heavy work is determined for the enginehouse heavy repair forces, including locomotives to be shopped in the annex and locomotives to be sent to the system shop, which is located at Sayre. The division road foremen of engines attend these regular monthly meetings in order to discuss with the master mechanic and engine terminal supervisors the work which should be done on locomotives as discovered by them on the road.

In many modern engine terminals the tendency has been in recent years to have specialized gangs look after

certain well-defined classes of repair work. This is in line with the common practice of classifying and specializing repair work in locomotive shops. The important difference in the organization methods described here lies in the fact that there are not only specialized gangs in the engine terminals, but that to each gang is assigned



Wheeling a heavy Pacific type locomotive on the 200-ton hoist in the annex

a definite number of individual locomotives for the maintenance of which they are solely responsible.

Enginehouse organization

The general enginehouse foreman who reports directly to the master mechanic has under him two general foremen, one responsible for all repair work in the enginehouse, and the other in charge of the annex shop. In addition to these two general foremen, the boilermaker foreman and the labor foreman report directly to the general enginehouse foreman.

Reporting directly to the general foreman in charge of the enginehouse proper are four gang foremen in charge of the following work:

1—All heavy repair work on locomotives out of service, which are being handled in stalls Nos. 21 to 32.

2—All running repair work on serviceable passenger power, which are being handled in stalls Nos. 33 to 46.

3—All running repair work on serviceable freight power, in stalls Nos. 1 to 20.

4—Specialty foreman in charge of gangs assigned to air brake work, booster maintenance, stoker maintenance, flange oilers and drifting valves, lubricators and superheater damper cylinders, all pipe work on live and dead power, repairs to air reverse gears on live and dead power, all cab valve work, setting safety valves and boiler inspection certificates, and electric headlight maintenance.

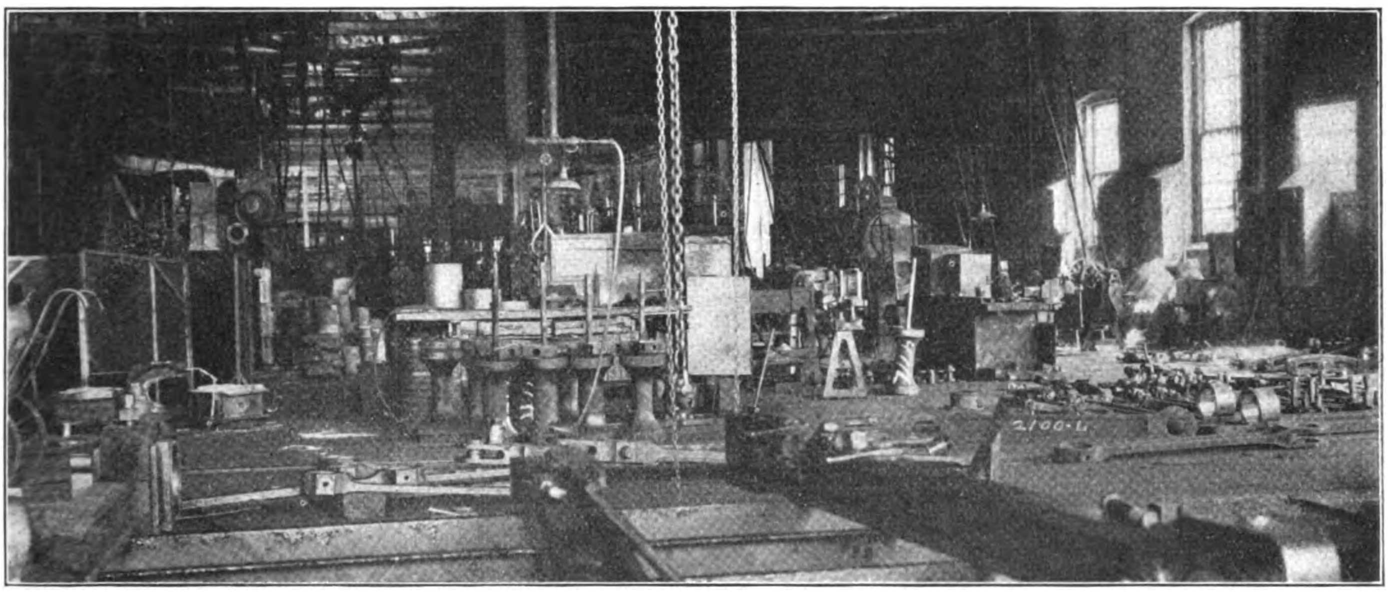
Every effort is made to increase the time locomotives are available for service and this system has made it possible to effect an appreciable reduction in the time required to repair a locomotive. Likewise, a very close check is kept on the matter of terminal delays.

Terminal inspection and maintenance records

When a locomotive comes into the terminal after a run it passes over an inspection pit on the inbound track. This pit is 160 ft. long and is provided with electric lights to facilitate the inspection of inaccessible parts of the running gear at night. The inbound inspector makes a report on the same blank form as that used by the engineman, and copies of this report are furnished, together with the engineman's report, directly to the gang to which that particular locomotive is assigned. While all foremen receive copies of work reports for locomotives which are maintained by the gangs under their supervision the fact that each gang knows exactly what work is expected of it on certain assigned locomotives relieves the foreman of the necessity of assigning work slips.

As previously mentioned, the gangs handling the running repairs on live serviceable power in the enginehouse work only on serviceable power, for as soon as a locomotive is scheduled for repairs sufficiently heavy to require its withdrawal from service, it is immediately transferred to the heavy work section of the house or to the annex shop. In this way repair work is concentrated, there being no dead engines in the two sections of the house assigned to serviceable power. All washouts are handled in the heavy work section, and the washouts are so scheduled that they are made on week-days only, any locomotives on which the washout date falls on Sunday are scheduled to be washed before that day.

The value of complete maintenance and running repair records is appreciated and regular reports are distributed among the supervisory forces such as those covering the daily, weekly and monthly meetings. One report par-



View at one end of annex shop

ticularly which seems to be worthy of special mention is a set of two records which are kept on driving box grease consumption. One of these is a daily record showing that an inspection has been made of each driving box on each locomotive, and if it has been necessary to apply grease, a record of the amount of grease is entered in the column of the report showing the particular driving box to which the amount of grease was applied. This daily report is filled out for all locomotives despatched during the 24-hr. period. The second form provides a monthly record of grease consumption for each individual locomotive, the information for which is transferred from the daily report. Both reports show the mileage made by the locomotive. These records have enabled the master mechanic to keep in very close touch with the hot journal situation, as it can readily be seen that if the report indicates that any particular driving box on a certain locomotive is requiring more than a normal amount of grease, it is an indication that attention is required. In this way it is practically always possible to anticipate "hot journal" trouble and remove the cause before it becomes serious.

Scheduling heavy repairs

A scheduling system for the annex repair shop has been installed which is remarkably simple in operation and requires very little work on the part of the supervisory forces to keep it posted. The forms used in connection with this schedule system are shown in Figs. 1 and 2. When a locomotive is placed in the annex shop for repairs, the work to be done on it is determined by a special inspection and a special work report is furnished to the general foreman in charge of the annex. The form shown in Fig. 1 shows the various items of work to be performed by the different departments on each consecutive day while the locomotive is in the shop. The general foreman of the annex shop indicates on this form each morning whether or not all work which is scheduled for that particular date has been done. For example, the form shown in Fig. 1 is filled out and it

Driving Box Grease Consumption -- Individual Engine Record
Sayre Enginehouse

Eng. No. 2092 Month of March 1925

Date	Box R-1	Box R-2	Box R-3	Box R-4	Box L-1	Box L-2	Box L-3	Box L-4	Total Mileage
1	OK	OK	1 lb.		OK	OK	OK		390
2									
3									
30									
31									

These records show the history of driving box conditions on each locomotive during the month

will be noted that locomotive No. 462 which was put in the shop on March 12, 1925, for Class 5 repairs, was scheduled out on March 29, 1925. By referring to the form shown in Fig. 2, it will be noticed that a cross has been marked under the twelfth day of the month which indicates that this engine entered the shop on that day. As previously stated, in the daily foremen's meeting, the schedule form shown in Fig. 1 is checked up each day, and providing all work which has been scheduled to be done on a certain locomotive has been completed on schedule time, a cross mark is entered on the progress form for that day. If any of the items on the schedule

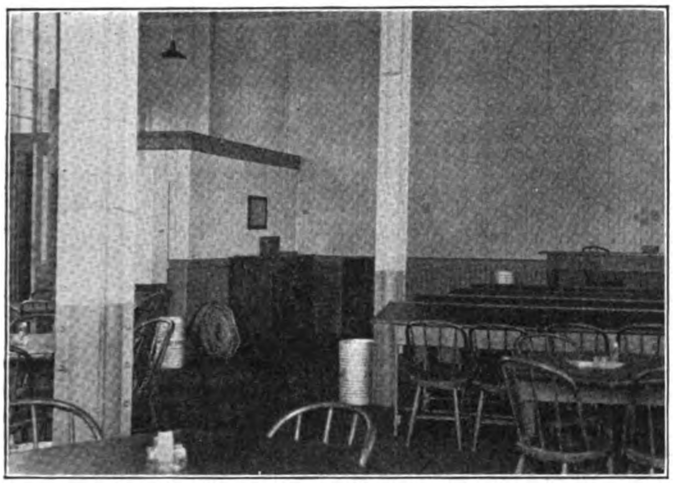
Fig. 1—Form for indicating work to be performed by different departments on each day while locomotive is in the shop

form have not been completed on time the space for that particular date on the progress record is left blank.

It can be readily seen that if all work on all locomotives has been completed to date, there will be a cross in the daily column on the progress record for all locomotives remaining in the shop. By referring to Fig. 2, this can be seen under the column headed March 26. The first four lines of the progress record under the date of March 26 are blank because of the fact that these locomotives have previously left the shop on the dates indicated by the circles.

If for any reason the work on any particular locomotive is not up to schedule, the blank space opposite the number of that locomotive and under the current date on the progress report will constitute a break in the continuity of the vertical lines of crosses. Wherever a blank space appears on a progressive record for any day, it is a warning to the master mechanic that the work on that particular locomotive is behind schedule and he can immediately have an investigation to determine the cause.



The foremen's training classroom

Increased efficiency obtained

The inauguration of this plan of maintenance has resulted in increased efficiency in many ways. The feature of assigning locomotives to definite gangs has not only relieved the supervisors of a great amount of detail work, but it has served to definitely fix responsibility for all work. The average running repair gang working on serviceable freight and passenger power does not have more than seven to ten assigned locomotives to maintain, and, because of the fact that they are working on the same locomotives day after day, they are able to keep in close touch with the work required. Also, the road crews have come to know the men in the enginehouse who maintain the locomotives they handle and in this way a spirit of co-operation has been brought about which is being reflected in a higher standard of maintenance.

A concerted effort has been made to effect a reduction in terminal detentions. To this end a bulletin board was posted in the enginehouse on which every terminal detention is marked up, showing the engine number, the actual number of minutes delayed, the cause of delay and the *man responsible*. This practice has had its effect and, inasmuch as the terminal detention record may be considered a fair indicator of the over-all efficiency of the enginehouse organization, it is interesting to note the consistent reduction in terminal detentions, as shown by Table I, over a period of 15 months, and particularly since the present system went into effect in April, 1924.

Table I—Locomotives despatched and terminal detention at Sayre by months

	Locomotives despatched	Terminal detention hr.	Terminal detention min.	No. min. delay per 100 locos. despatched
January, 1924	3,740	15	45	25.2
February, 1924	3,509	11	50	20.2
March, 1924	3,611	29	38	49.4
April, 1924	3,387	25	35	47.0
May, 1924	3,696	10	15	17.1
June, 1924	3,322	13	0	23.5
July, 1924	3,337	6	45	12.2
August, 1924	3,537	9	35	16.3
September, 1924	3,644	6	30	10.7
October, 1924	4,013	9	47	14.7
November, 1924	3,737	8	33	19.1
December, 1924	3,471	6	5	10.5
January, 1925	3,283	6	50	12.5
February, 1925	3,246	8	38	15.9
March, 1925	3,308	3	50	6.9

Likewise, a marked improvement is evident in the matter of locomotive failures on the road. The average number of failures per month during the first six months of 1924 was 23 and the average number of locomotive-miles per failure was 18,788. During the last six months of 1924 the average number of failures per month had dropped to seven and the mileage per failure had increased to 56,181. In October, 1924, there were only six failures and the mileage was 69,624. These figures are averages for all classes of service. Incidentally, the reduction in the number of locomotive road failures has had a beneficial effect on the average car mileage per day.

Employee relations

Practically no effort has been spared on the part of the Lehigh Valley to improve the morale of all the employees. At the Sayre terminal, which is located adjacent to the large system shops, many novel features have been inaugurated to promote cordial relations. An assembly hall has been provided in which social functions take place and in connection with the assembly hall a cafeteria has been established for the convenience of the men. A man has been assigned from the organization at Sayre terminal who devotes his entire time to personnel work among the enginehouse employees.

The enginehouse mechanics are all employed on a

Fig. 2—Form for recording the progress of locomotives through the shop

day-work basis and a service record is kept for each man. With the system of assigned repairs in effect, it is a comparatively easy matter to know the individual is performing his duties, and these records are carefully checked up periodically with the idea of properly rewarding meritorious service or administering discipline, should the occasion demand.

Another feature of the personnel work is the recent establishment of a foremen's training class. The entire supervisory force of the enginehouse and annex, consisting of 25 men, has enrolled in the correspondence engineering extension department of the Pennsylvania State College and are pursuing studies bearing on the important factors of employee relations and the principles of shop organization. A special room has been set aside for the use of the foremen's training class and it is gradually being equipped with all facilities required in a classroom of this description, including many charts and drawings used for instruction purposes as well as a library of important technical books and periodicals. The foremen's training class meets at least once a week and all are carrying on their studies in the extension course at the same rate of progress, class instruction rather than individual study constituting the program.

Conclusion

A study of operating conditions at the Sayre terminal after the organization had been in effect for a period of about 12 months disclosed the fact that it had been possible to effect a reduction of terminal operating expenses and at the same time increase the output. The assignment of locomotives and crews has made it possible to increase the number of turn-around runs, and locomotives are assigned as nearly as possible to trains for which they are particularly suited. It has also been possible to effect a decrease in road supervision and engine crew expense due to improved operation and maintenance. As a means of direct comparison, considering the first two months of 1925 and the same two months of 1924, the records show a reduction of 30 per cent in man-hours, 63 per cent in overtime, 27 per cent in payroll and 40 per cent in materials used. A reduction in force of approximately 110 men has been made possible by the re-organization. It might be added that most of these men have been absorbed by transfer to other departments or other points on the road and have not been released from service. For the above-mentioned period there has been an average total reduction of approximately 30 per cent in all the terminal operating expenses chargeable to the locomotive department.

One of the outstanding facts in connection with this terminal operation is that conditions are such that it is possible to keep ahead of the work at all times. As previously mentioned, eight locomotives are maintained ready for emergency service so that it is not necessary to despatch power on anticipated repairs.

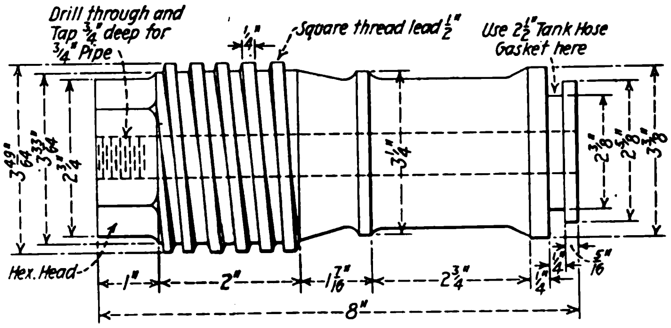
In considering the results of this operation, the fact must not be overlooked that the Lehigh Valley has made remarkable progress in establishing a spirit of co-operation among its employees. The new scheme of enginehouse organization did not meet with instant favor. After over a year of actual operation, however, it has demonstrated distinct advantages not only to the company but to the men, who are keenly enthusiastic over its possibilities.

Nozzle for testing feed-water heaters

By A. T. E.

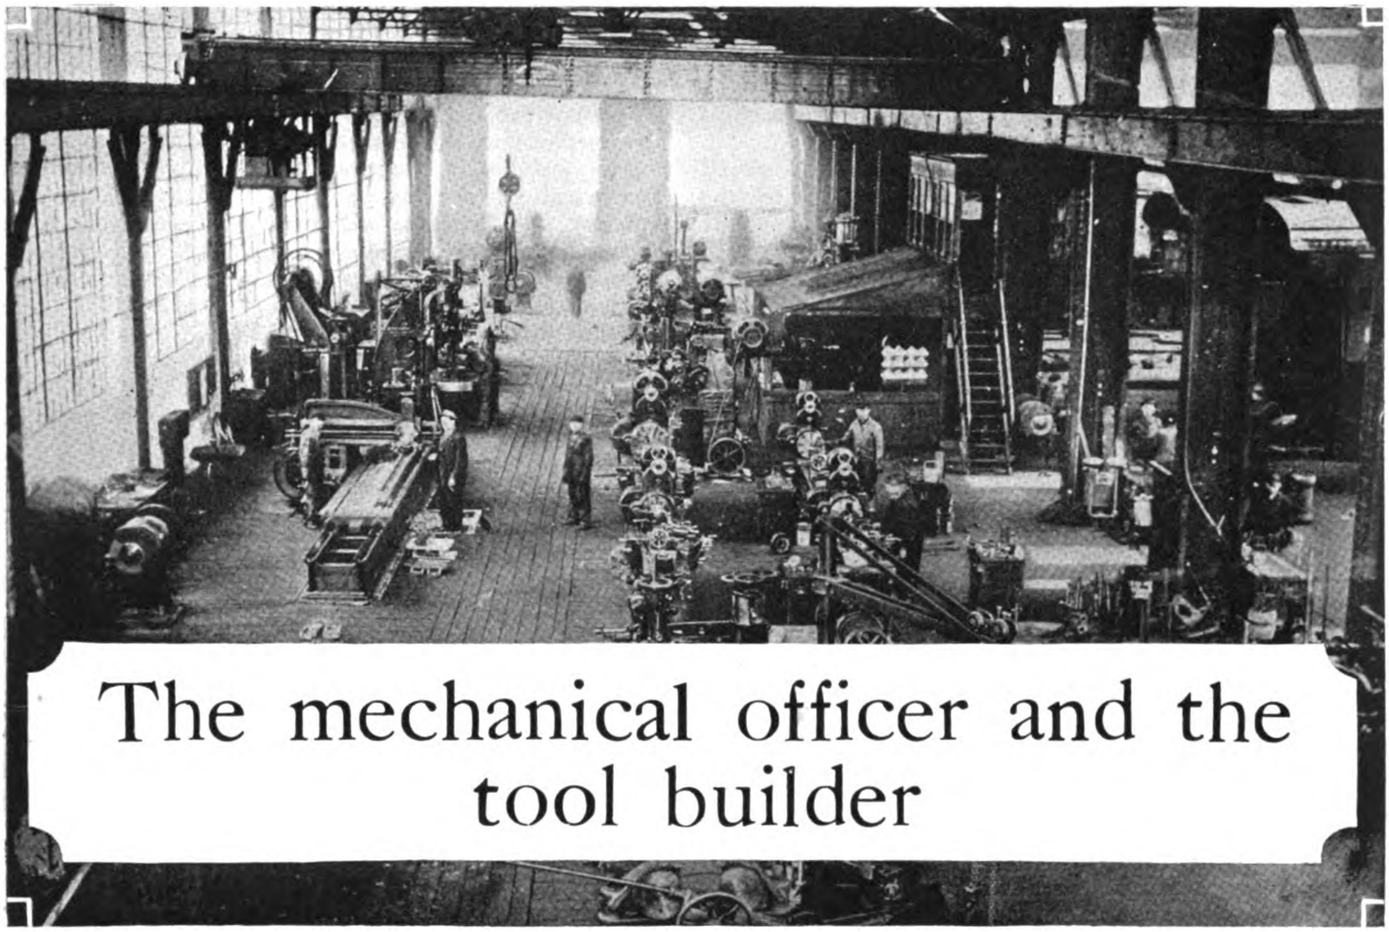
THE device shown in the sketch is used in testing locomotive feed-water heaters equipped with "Y" connections in the branch pipe for the purpose of washing out the feed-water heater. It has been the practice in recent years to equip feed-water heaters with these "Y" connections, particularly in territories having bad water. The fitting shown in the sketch may be used on either the condensate line where it returns to the tank, or on the feed-water pump supply pipe.

It is the usual practice to test the feed-water heater at the time of the monthly inspection of the locomotive. This is done by closing the locomotive boiler check stop valve and opening the condensate valve. Water is pumped into the feed-water heater under pressure through a tapped hole in the end of the heater, which is plugged when not in use, or through a tapped hole located just above the flanged connection to the branch pipe. Water coming out of the condensate valve at the front of the tank or under the cab, indicates a leak in the heater tubes. This procedure is also followed in cases where the heater has the condensate pipe returning to the feed-water pump supply line. In testing this type of equipment the locomotive tank valve is closed tight. Water from the condensate valve might indicate that there is a leak in the feed-water heater tubes or that water is passing by the feed-water pump valves and back through the supply pipe. However, if the fitting shown in the sketch is screwed into the connection of the branch pipe leading to the heater, water from the condensate valve will show that the leak is due to a bad feed-water heater tube.



Nozzle for testing feed-water heaters of the closed type

In cases where the equipment has the condensate pipe returning to the supply pipe of the feed-water pump, with no "Y" connection in the branch pipe, the heater can be tested by blanking the branch pipe leading to the pump or breaking a joint of the condensate pipe between the heater and the supply pipe.



The mechanical officer and the tool builder

Some possibilities for co-operation as seen from the viewpoint of the machine tool industry

By E. F. DuBrul
General Manager, National Machine Tool Builders Association, Cincinnati, Ohio

ALL business is necessarily a matter of co-operation. In small scale, localized business co-operation is between individual producers and users. As the business of the world expands, co-operation extends as between larger and larger economic units, and between greater and greater numbers of units. In time, numbers of independently acting units are gathered into various sorts of associations for the purpose of securing better co-operation. Through such associations the common problems of whole industries are co-operatively studied and solved. Such problems are not solely the internal problems of the industry, but also those that require attention in the mass because of contacts with other industries and interests.

Without such organizations to present the broad industry problem, whole industries suffer waste because their natural co-laborers are not informed of the possibilities of better co-operation. The railroads themselves have been conspicuous sufferers at the hands of the public because of failure to organize along broad lines of industry co-operation. Through co-operation between industry organizations the common problems of diverse industries are studied and solved to bring about still closer co-operation, and thereby to make still more effective the use of the man power of the world.

Through its association, the machine tool industry is continuously collecting, classifying, studying and distributing information and seeking to promote group co-operation with industries using machine tools. Some of the information coming to the association deals with conditions met in selling machine tools to railroads. Some of these conditions could well be modified, to the great benefit of the railroads themselves. The following remarks are not universally applicable to all roads, of course. But they do reflect conditions that are common enough to be of interest to the readers of *Railway Mechanical Engineer.*

Buying machine tool value, not price

Too many railroads buy machine tools on price as the main factor. Where definite specifications can be made, and goods checked against them, then price is a heavy factor. The lower price, all other conditions being equal, should command the business. But, in buying a machine tool one buys an individualized product. No two manufacturers build tools that are identical in structure. To decide sensibly as between two similar machines many things must be taken into consideration before one can really say that Tool *A* at its price is preferable to Tool *B* at its price. This determination is an engineering function. If a purchasing policy is established to the neglect of this engineering function, railroad's shop efficiency suffers to an extent that is of essential interest to the public that pays the bill.

It is to the common interest of the roads, the public and

the machine tool industry that railroad purchases of machine tools be made on the engineering basis, and not on the mere basis of price. Therefore, it is the duty of mechanical department officers, in co-operation with the organized machine tool industry, to devise scientific engineering methods of purchasing.

Some roads may have a really scientific basis of scoring or otherwise weighing the various factors on which the relative merits of similar machines are finally judged. If so, it would be to the benefit of all railroads to have such methods studied and standardized. If there are such definite methods of scoring they are in force on very few railroads. In most cases where the mechanical department has the actual power of decision, the decision is made by "general impression" rather than by definite scoring. The mechanical men "like" such and such a machine more than they do another similar one, but they seldom put the reasons for their likes and dislikes down on paper. In other words, they do not definitely analyze and "score" the machines one against the other. Naturally, when the purchasing or financial authorities want to know why they are asked to pay more for one machine than is asked for another, the mechanical officer is at a loss for an answer, if he has not gone at the matter in a cold blooded, engineering way.

I know it is not going to be easy to devise any scoring system. But I also know that unless and until it is devised, any road's mechanical department will buy on impressions rather than on classified facts that can be defended when the price looks too big to the purchasing department. It seems to me to be up to the railway mechanical department officers to devise good methods of applying engineering methods to railroad buying of machine tools and to call the organized machine tool industry's engineers into consultation on the problem.

Internal consultations and explanations

Reports frequently reach us that subordinates in railroad shops have asked for certain tools, but that the superior officers have given them something else—without explanation as to why the subordinate's request was not complied with. Now, while there are probably good reasons for the change, I submit that it is not good management to leave the subordinate in ignorance of those reasons. To be given something other than the tool he had recommended, without being told why his recommendation was not approved, is sure to cause him to lose interest and initiative, and to become a "buck-passer."

Use the machine tool builders' service

Many mechanical officers seem to lack appreciation of the value of the consulting service that many machine tool builders gladly place at the disposal of their customers. If they do not use this service, their shop management is less efficient than it should be.

Some mechanical officers seem to think that such offers of service are merely schemes for "putting something over" on the mechanical department. Now, any man with that idea is certainly not of the engineering type; he is not open minded to learn all the facts that will help him in running his own job. There is much criticism of the efficiency of railroad shops and much of this criticism is justified. It will harm any mechanical officer and his road if he closes his ears to this general criticism. To close his doors to able men who are desirous of helping him, is itself to say the least, a confession of incompetence. Machine tool engineers can show the shop supervisors many a good way of reducing costs of repairs by better tooling or handling of machine tools now in their shops. The only thing "put over" in such cases, is something to the direct benefit of the men served, because it makes them better railway men.

If the machine tool builder is willing to study a given job, and present definite data as to production and cost, any competent engineer can then determine whether the new methods would be profitable or not. There can be nothing sinister or suspicious in desiring to submit data from which a determination can be made as to a probable economy. On the other hand, there is something suspicious in a refusal to permit such submittal. It is perfectly natural to ask, "Why should a man refuse to consider such data unless he is trying to cover up something?" Is he so incompetent that he cannot judge of the facts such data might show? Or is he opposed to the presentation of facts for fear that they might damage him in the eyes of his superiors? Or are there other sinister reasons for his opposition?

The mechanical officer should, like Cæsar's wife, be above suspicion of any such reasons and therefore he cannot afford to reject service of great value, offered to him by machine tool builders. Nor should he neglect to use such data when received.

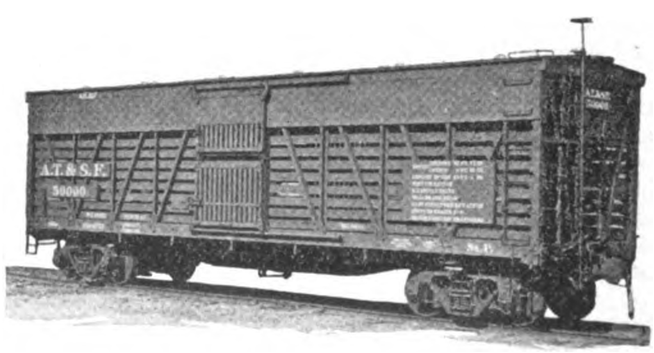
In offering such service the machine tool builder realizes that his own profit must come in making tools that are profit making investments for their users. He has to sell the profitableness of the tool to a competent buyer as the first step in selling the tool. Unless he can demonstrate "Profit" he cannot sell the tool. When he does demonstrate "Profit," the buyer purchases the tool merely as an incidental means for securing the "Profit." The competent builder and seller of machine tools is prepared to demonstrate "Profit" in a scientific impersonal engineering report wherever he can find "Profit" to exist for the user. Any mechanical officer who asks for this demonstration has done full duty by himself, his profession, his company and the public.

A duty to the public

The railroad business is one charged with a peculiar public interest, as we all know. That public interest demands that railway operation and management shall be efficient in every department so that the public shall pay the lowest rates for service consistent with the principle of a fair return on the railroads' property value. So it is the duty of the railway mechanical departments to use all available means to reduce the costs of maintaining the equipment entrusted to their care. The two things herein suggested will play some part in this reduction of maintenance costs. They are:

1. Devise and use definite scientific, engineering methods in purchasing machine tools.

2. Make free use of the production engineering service offered by machine tool builders to improve shop methods.



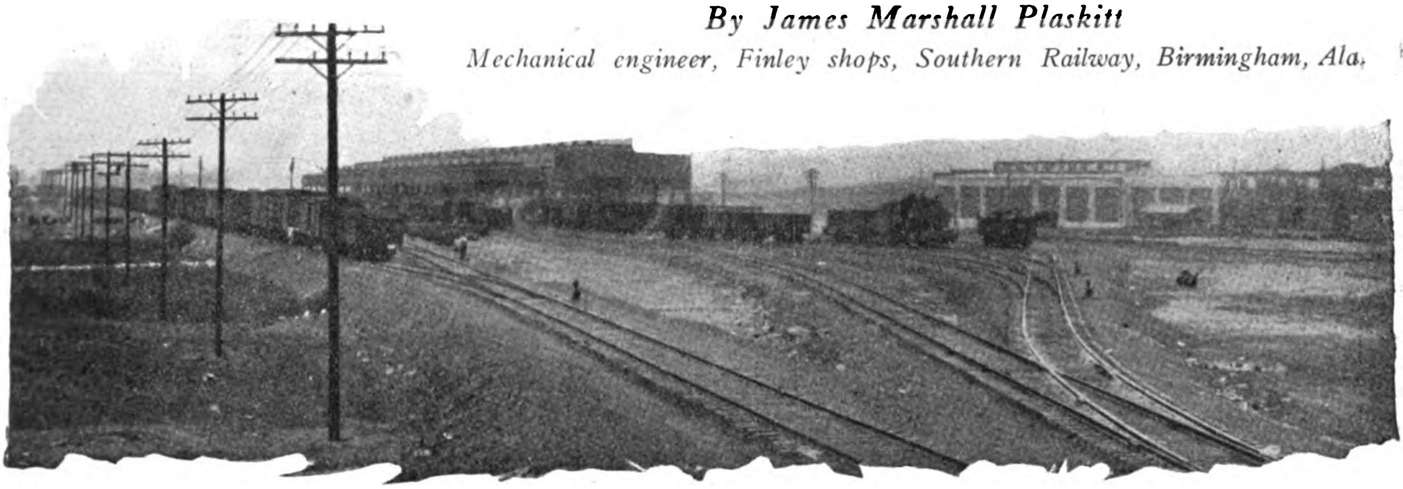
40-Ton, steel-frame, single-deck stock and coke car built by the Standard Steel Car Company

A modern freight car repair shop

Southern completes plant at Finley—New equipment helps to increase production.

By James Marshall Plaskitt

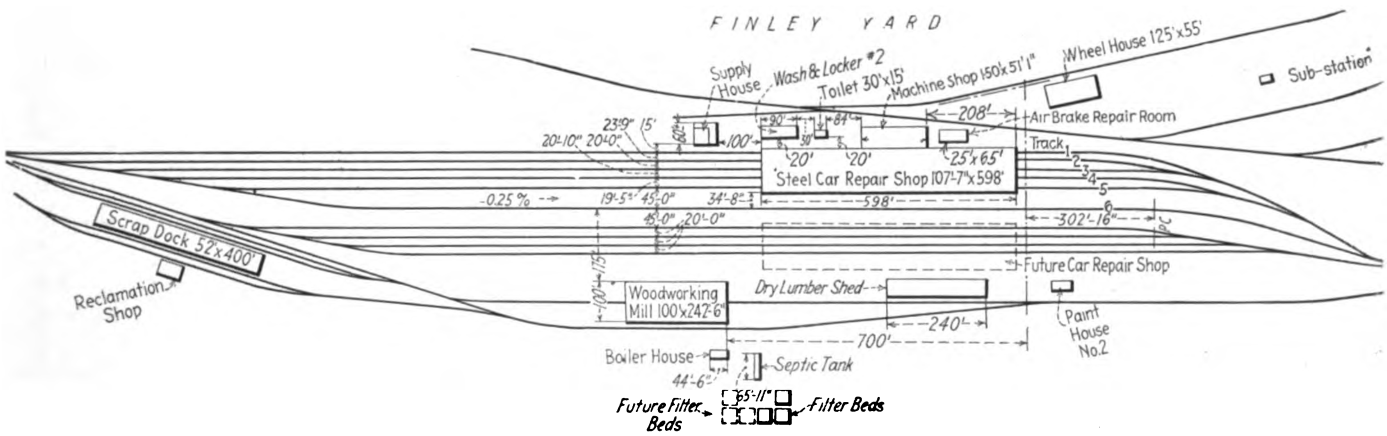
Mechanical engineer, Finley shops, Southern Railway, Birmingham, Ala.



On December 1, 1924, the freight car repair shops of the Southern Railway System were moved from Avondale, near Birmingham, Ala., to the new Finley shops at North Birmingham. The installation at Finley consists of both a car and locomotive repair shop, and also a 25-stall enginehouse which has been in operation for a number of years. The entire plant, the locomotive unit of which was described in the March, 1925, issue of the *Railway Mechanical Engineer,* is under the direct supervision of the master mechanic, to whom the general foreman of car repairs reports.

Practically the same scheme of administration as used for the locomotive shops is used in the management of the car shops. The master mechanic presides over joint meetings of the foremen in the car and locomotive departments. At these meetings policies to be established that affect the plant as a whole are outlined and discussed, errors and misunderstandings relative to handling the work are corrected and various suggestions for improving production are talked over. Weekly meetings are also held by the general foreman of car repairs with all the car department supervisors at which the program of performing the work is discussed, constructive suggestions and criticisms are received and the work is outlined for the coming week.

Daily progress reports are sent to the master mechanic each morning by the general foreman of car repairs. These reports contain a summary of the progress of the previous day's work in the entire Birmingham territory and they show the bad order cars awaiting repairs at all stations, the bad order cars repaired the previous day, cars painted the previous day, cars recommended for retirement or reconstruction, and the total number of men engaged in repairing cars. Similar figures are also compiled for foreign cars and included in the totals. In addition, the master mechanic keeps in personal touch with the progress of the work through frequent daily inspections.



Layout of the car repair tracks and buildings

The various department heads and their assistants are held rigidly responsible for the work under their supervision. The frequent staff meetings serve to clear up matters of doubt and also acquaint the foremen with the various developments in their particular fields.

It is evident, from what has been accomplished during the short period of time these shops have been in operation, that it was a wise step to abolish the use of antiquated

equipment in favor of more modern types, even though it required a large capital expenditure. A large repair point in the Birmingham territory is necessary for the Southern Railway System. Approximately 3,000 freight cars are handled in its terminals daily and this territory embodies one of the largest interchange points in the South. Interchange is made with the Birmingham Belt, the Atlanta, Birmingham & Atlantic, the St. Louis-San Francisco, the Birmingham Southern, the Central of Georgia, the Seaboard Air Line, the Illinois Central and the Louisville & Nashville.

Design and location of buildings facilitates production

The Finley shops occupy a tract of about 100 acres, the locomotive and car repair units being separated by sufficient ground to permit expansion should future requirements demand it. Referring to the cross-section drawing, the car repair shop is an open type shed built of structural steel and rests on a concrete foundation. It is 598 ft. long by 107 ft. 7 in. wide and is built with three bays containing five longitudinal tracks. Track No. 1 is served by two overhead electric cranes of 15-ton capacity. Tracks No. 2 and No. 3 are served by cranes of the same type but of 20-ton capacity. These three tracks are used for heavy overhauling or general repair work while tracks No. 4 and No. 5 are used for finishing, such as completing the carpenter and light metal work on box cars. Permanent scaffolding, secured to the roof girders as shown in one of the illustrations, is located along tracks No. 4 and No. 5. It is hung so that the floor of the scaffolding is located at a height about half way up the side of the average box car body.

Table I—Machinery installed in the fabricating shop

No. of machines	Description
3	Acme double-head bolt cutters
1	36-in. Niles-Bement-Pond vertical drill press
1	5-ft. Dresses Machine Tool Co. radial drill
1	8-in. by 48-in. grindstone
1	Single head pipe threading machine
1	Cleveland Punch & Shear Works punch
1	Cleveland Punch & Shear Works shear
1	10-in. Southern railway pneumatic flanging clamp
1	500-lb. Bradley hammer
1	Buffalo Forge Co. blower
1	Southern railway pneumatic coupler yoke riveter
1	8-ft. Southern railway open forge
1	60-in. Southern railway open fire

Referring to the layout drawing of the car shops, it will be noted that the machine shop is a part of the car repair shop building, conveniently located midway along the No. 1 track side. It is 158 ft. long by 51 ft. wide and opens directly into the car repair shed. This arrangement permits efficient handling of material from the machine shop to tracks No. 1, No. 2 and No. 3, where the general repair work on all-steel cars is performed. Considerable attention has been given to providing suitable and adequate machine tools, a list of which is shown in Table I.

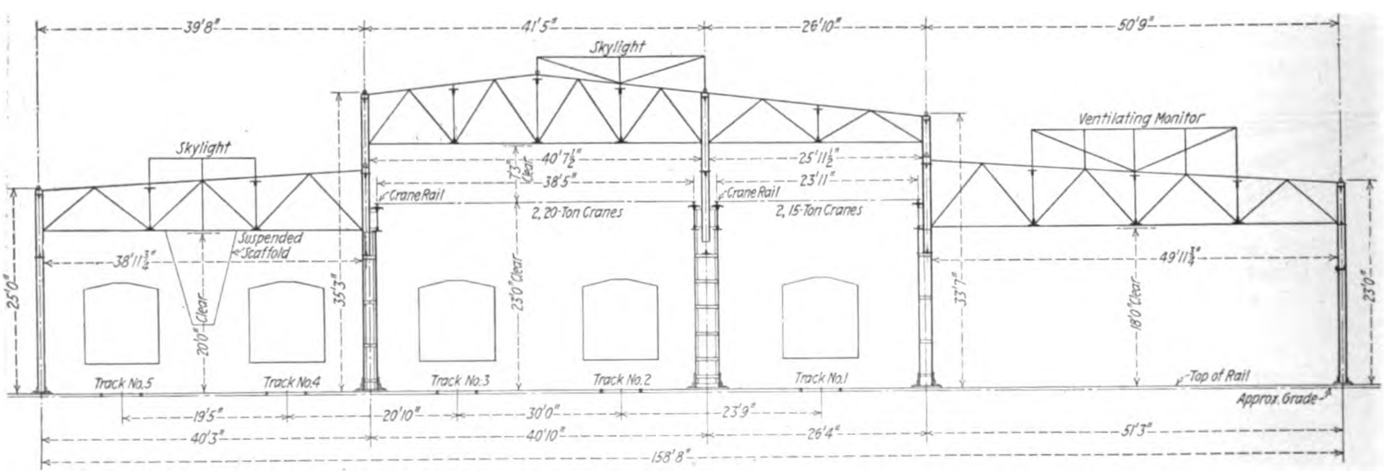
The entire building, including the machine shop, is well lighted. Steel sash skylights in the roof of the car repair shed and standard steel sash windows in the walls, provide excellent lighting conditions during the day. Pyle-National 1,000-watt flood lights are placed at the ends of the car repair shop, as shown in one of the illustrations, to provide light for the yard tracks in both directions leading away from the shed. Drop lights are placed at regular intervals within the building. These lights afford sufficient light for a full force at times when the work demands a night shift. Air manifolds and electric drops to serve the pneumatic and electric tools are located at the columns.

Permanent scaffolds on tracks No. 4 and No. 5

Wheel shop is well equipped

The wheel shop is of brick and concrete construction, 125 ft. long by 55 ft. 10 in. wide and is located northeast of the steel car repair shop. The floor is made of creosoted wooden blocks laid on a concrete base. The building is heated by a system of individual units which utilizes the exhaust steam from the power plant. Unit heaters are placed along the walls and along the interior lines of columns of the various shop buildings.

This shop is well equipped with machine tools, as shown in Table II, for the efficient handling of wheels and axles. The track located to the north of the building is used for

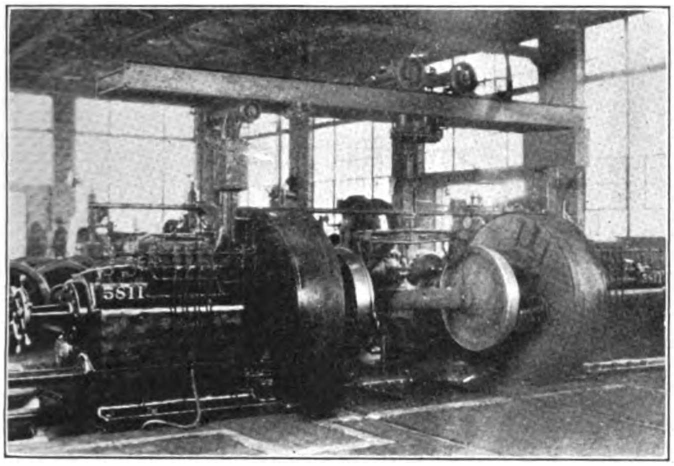


Cross section of the car repair shed

the transportation of wheels to the repair tracks. This track also serves the main and auxiliary storehouses.

The wood working mill

The wood working mill is a large, modern, steel frame and brick concrete structure, measuring 100 ft. by 242 ft. The floor is of wood block laid on concrete and is free from columns, steel trusses of 100 ft. span being used for the roof structure. The side and end walls are almost entirely of steel sash which, in addition to a large monitor has insured ample natural light. A track has been laid along the longitudinal center line with connections at each end to the car repair yard tracks. Some of the wood working equipment was transferred from the old shop at Avondale; however, a large part of the machines are new. A list of the machine tools installed in the wood mill is shown in Table III.



Turning steel wheels in the wheel shop

The arrangement of machine tools and equipment in the wood mill has been carefully planned so as to avoid any back-tracking or re-handling as material is routed through the shop. It is possible to handle all lumber from the dock at one end and route it directly through the mill to the opposite end for delivery to the lumber shed, which is shown in an illustration on page 340.

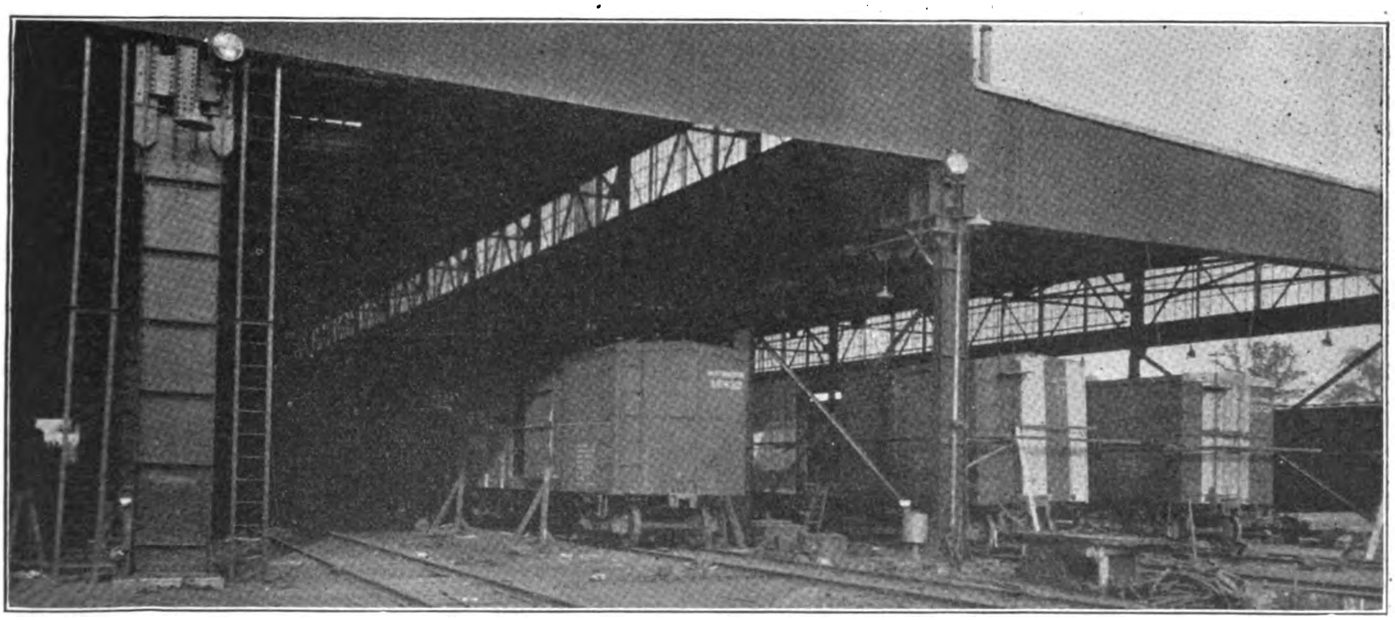
In the manufacture of side sills, the lumber is passed through an opening in the end wall of the mill from the dock directly to the four-side timber dresser or planer. It is next routed to the cut-off saw, layout benches, and thence to the two-spindle boring machine, where it is bored. Upon completion of this operation, it is routed to the tenoning machine, after which it is loaded and sent to the car repair shop. Practically the same route is followed in the case of end sills, except they are sent to the gainer after leaving the layout benches and from there to the combination hollow spindle mortiser.

Table II—Machine tools installed in the wheel shop

No. of machines	Description
1	48-in. Putnam boring mill
1	48-in. Niles-Bement-Pond car wheel boring mill
1	26-in. by 14-ft. Niles-Bement-Pond axle lathe
1	Safety Emery Wheel Co. emery wheel grinder, motor drive
1	300-ton Niles-Bement-Pond car wheel press
1	52-in. Niles-Bement-Pond heavy duty coach wheel lathe
1	200-ton Niles-Bement-Pond wheel press

Side doors are assembled at the east end of the mill where a steel-top table is located. The machines used in this work are arranged in close proximity to the table on which the doors are assembled and the nails are automatically clinched on the steel top as they are driven. The bottom iron structure or side door bottom guide, made from scrap flues in the blacksmith shop, are also applied here. Bearings 1¾ in. thick are left on the side door bottom guide strips by the blacksmith shop. These bearings function as wedges for the car door so that a tight fit is insured when the door is closed. The utilization of scrap flues for this purpose is a considerable saving.

A conveying system for removing shavings is now being installed. It is to be so arranged that it will collect the shavings at the various machines as fast as they accumulate. All shavings and wood waste material are used for fuel at the auxiliary power house which is located at the southeastern end of the wood mill, as shown in the layout drawing of the car repair tracks and buildings.



Exterior view of the car repair shed showing the location of the flood lights—Track No. 5 at the extreme right

The dry lumber shed is located east of the wood working mill as shown in the layout drawing of the car repair tracks and buildings. It is of heavy timber construction, boarded at the ends and measures 41 ft. by 241 ft., thus

providing ample storage space. Its location makes it readily accessible for the delivery of material to the wood mill or the car repair shop as well as for the reception of lumber shipments.

Storage and delivery of material

The main storehouse and office building is located adjacent to the locomotive unit. One end of this building, which was described in the March, 1925, *Railway Mechanical Engineer*, is devoted to the offices of the master mechanic, division storekeeper and the other to the store room. The administration of the stores department for both the car and locomotive departments is handled from this office. A sub-storehouse or supply house is located northwest of the car repair shop. This building was formerly used at the Finley enginehouse and was moved to its present location when the new car shops were constructed. It is of frame construction. The system used for storing material is similar to the one used in the main storehouse. Casting docks are provided west of the building and delivery of the material from the sub-storehouse and casting yard to the car repair shop is handled by means of Ford tractors and trailers. The same system of delivery is used for handling lumber from the dry lumber shed to the wood working mill as well as for the delivery of all material to the crews working in the car repair shop. Special attention is given to the handling of supplies to see that they operate efficiently and that material is always at hand when needed.

Table III—Machine tools installed in the wood mill

No. of machines	Description
1	Berry & Orton band saw
1	Atlantic Works swinging cut-off saw
1	Atlantic filing and setting bench

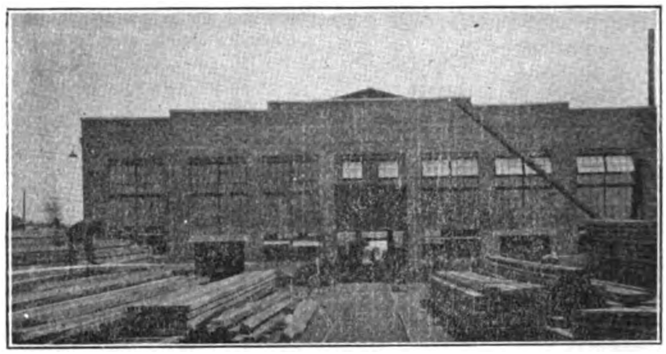
1	Singer sewing machine for upholstery work
1	No. 10 S. A. Woods Machine Co. large planer

Complete facilities are provided for painting

The paint shop is located immediately east of the dry lumber shed and alongside of the same track. The building is of brick and concrete construction and contains two rooms separated by fireproof doors. One room contains the tanks for paint mixing oils and paint storage, while the other room is used for stencil racks, car painting records and a screen drying rack, and is equipped with work benches and easels for sign painting and special jobs. As shown in one of the illustrations, the stencil racks consist of several panels or doors hinged at the back which may be swung open or closed as desired. An entire set of stencils for each class of freight cars is hung on a side of each of the panels. The idea is much the same as the picture files seen in many art galleries and the racks provide a unique and convenient method for keeping the stencils filed. A blackboard record is kept of the individual cars that are painted and stencilled so that all work may be credited properly to the material and labor charges.



View of the lumber docks and the west end of the wood mill

This paint shop is operated as an auxiliary to the main paint shop which is located in the locomotive unit. Practically all of the painting is performed mechanically, the cars being switched from the outgoing tracks of the car repair shop to the tracks east of the car repair shop. After the work of painting and stenciling has been completed, the cars are weighed, inspected and switched out at the west end of the car repair yard to be placed in service.

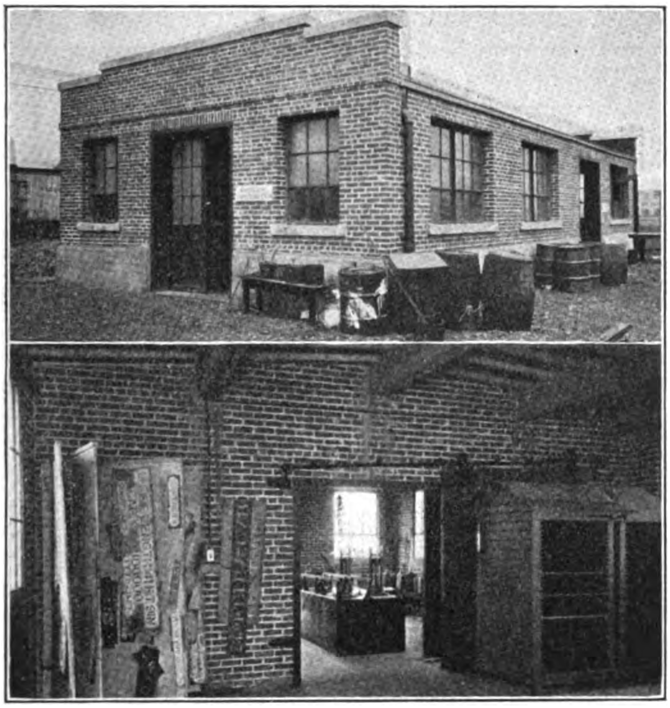
Method of handling repairs through the shop—Steel underframe box cars

At the present time the management has appropriated funds for the application of 80 steel underframes per month to box cars at the Finley shops. These appropriations are based on a certain fixed amount inclusive of labor and material for each car and the shop is not permitted to exceed a certain specified amount for the performance

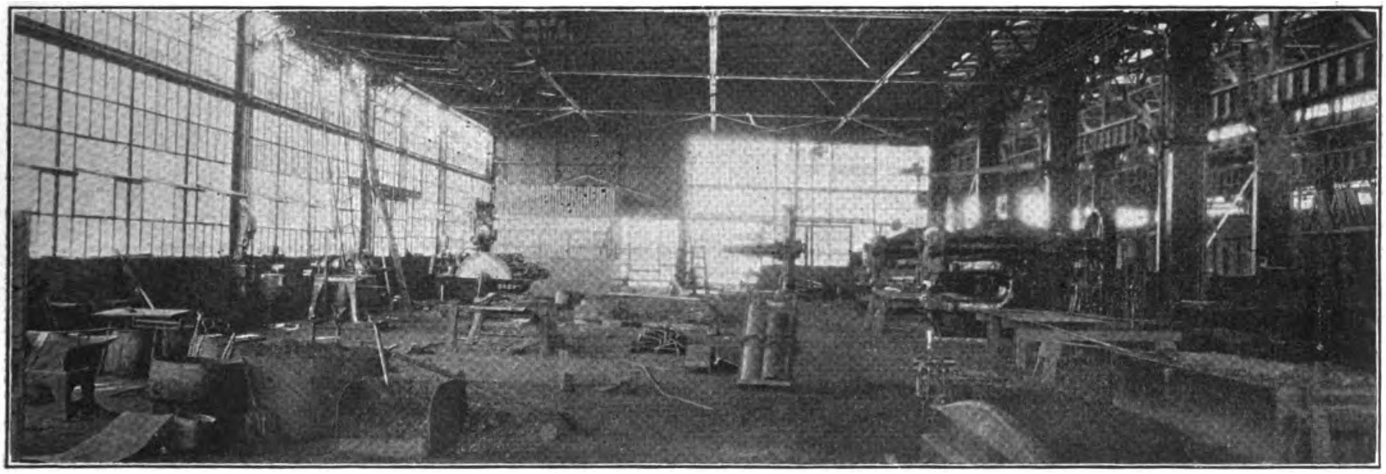
of this work. In addition to the work of installing steel underframes, there is a considerable amount of heavy repair work to perform on steel and other freight cars, such as the conversion of beer and ice cars to box cars and the overhauling of coaches.

Light and running repairs are handled on the five tracks



Above—Exterior view of the paint shop; Below—Interior view of the work room showing the stencil racks at the left

adjacent to the car repair shop. They have a combined capacity of approximately 200 cars. In addition, the repair tracks west of the car repair shop, having a capacity of 100 cars, can also be used for this work. The light repair tracks are usually "worked out" once a day. Provisions have been made for performing a certain



Interior view of the steel fabricating shop

amount of light repair work in the Finley yards and at the Thirty-Sixth street yards at Birmingham and also at 10 car repair points located at various stations throughout the Birmingham territory. Reports are forwarded by the car repair men at the various repair points throughout this territory to the office of the general foreman of car repairs at Finley. His office is located near the wood working mill and three billing repair clerks are employed to check the records and complete the billing repair cards for foreign lines in accordance with the American Railway Association interchange rules.

Applying steel underframes

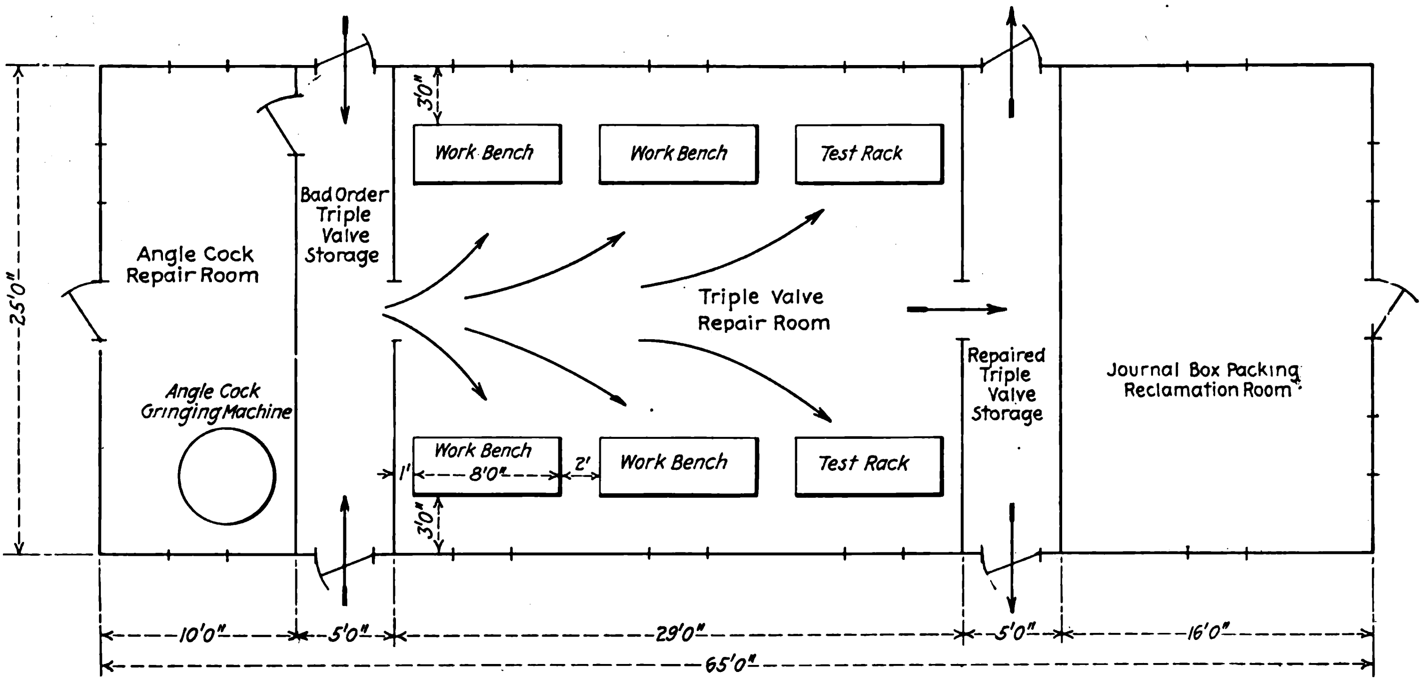
Bad ordered cars suitable for the application of steel underframes are switched to the car department as required. All work is performed with a view to restoring 100 per cent mileage to the cars. For this reason, it is necessary to make all of the required body repairs, repairs to the safety appliances, air brakes, foundation brake gear, trucks, etc., before the car leaves the shop. The work of stripping the decayed or otherwise defective material is performed as far as possible on the stripping tracks outside of the car repair shop. The amount of work necessary varies according to the actual condition of the car. After stripping, cuts of 12 cars are placed on tracks No. 2 or No. 3 or both, as deemed advisable. It is the usual practice to assign two men from the body and truck crews respectively to each car.

One of the illustrations shows the various operations performed on an individual box car receiving a steel underframe. This work is usually handled in the following manner. The body is lifted clear of the trucks by means of two 20-ton overhead cranes, each of which is provided with a steel cable sling. The trucks are then run forward just clear of the body and are spaced at the correct distance to receive the steel underframe. The car body is then lowered on two trestles and the body crew releases the cranes and proceeds with the work of repair. As soon as the cranes are released from the body, they are used to lift the steel underframe from storage and carry it to position over the trucks. The underframe is then lowered and placed on the trucks, the center pins are applied and secured. The next operation is applying the nailing sills to the steel underframe. As soon as this work is completed, the car body is then lifted clear of the trestles, moved forward and lowered in position on the steel underframe. Mention should be made of the fact that the underframe is not applied to the trucks until the truck crew has completed the work of repairs on the trucks.

After the body has been lowered in position on the steel underframe, it is fitted with down rods and secured to the underframe. When the entire truck is fitted with underframes, it is shifted to track No. 4 or No. 5, the crews following through for the finishing work, and the body repairs are then completed. The sequence of operations for body repairs is shown on page 339.

All repair work is performed as far as possible in the car repair shop. As soon as a cut of cars has been com-

pleted, they are switched to one of the paint tracks at the east end of the shed adjacent to the paint shop. Here the cars are given two coats of paint by the mechanical process and are then moved to track No. 6, where the cars are stenciled. After a thorough inspection, the cut is marked O.K. for service and is then switched to the Finley transportation yard where the cars are weighed and placed in service. In the case of heavy repairs, where steel underframes are not applied, the operations are practically the same as far as the routing and methods of crane service are concerned. On account of having the service of the two overhead cranes for tracks No. 2 and No. 3, it was found impossible to install a permanent scaffolding, as was done for the finishing tracks No. 4 and No. 5. However, temporary scaffolds are erected and nailed to the car bodies. The loss of time in preparing this temporary arrangement does not materially decrease the efficiency of the work on these tracks. It is believed that this decrease will be eliminated by the utilization of sling scaffolding.



Floor plan of the air brake repair room—The arrows show the routing of the work through the shop

Heavy repairs to all-steel cars

Steel cars requiring general overhauling are placed on track No. 1 in the car repair shop. Little, if any, stripping is done before the cars are switched into the shed, as in the case of wooden freight cars, because of the ease with which the cranes can assist in this work. The various operations used in making repairs to steel cars may be summerized as follows: After the cars are switched to track No. 1, the stripping is accomplished with the assistance of the two cranes. Damaged and corroded parts are removed by the acetylene cutting torch when necessary. Steel parts, such as truck sides, bolsters, draft gears, brake beams and hangers are reclaimed by welding or are sent to the machine shop bay nearby for renewal or repairs as may be deemed necessary. All air

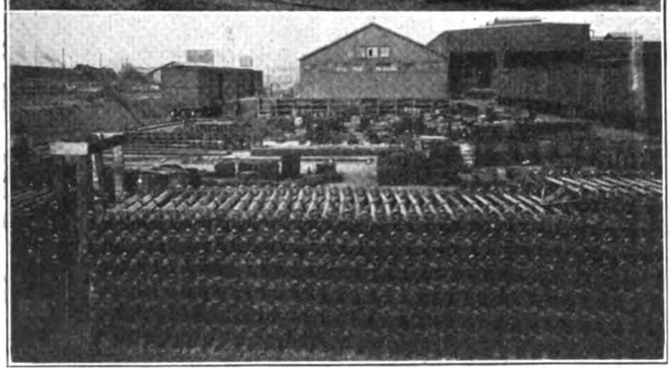
brake and piping work, including that of box and other freight cars, is classified and performed strictly in accordance with A. R. A. requirements. Truck repairs are performed by special gangs. A body gang usually consists of two car repair men and helpers, who remove or apply all the necessary steel to the body. After the work of repair has been completed, the cars are then switched in cuts to the paint tracks. The work of painting, stenciling and weighing is performed in practically the same manner as for the box cars.

System for handling air brake repairs for the car shop

A feature of the car repair work at Finley is the air brake repair department which is located north of the car repair shop adjacent to the machine shop. The building is constructed entirely of scrap beams, sills, siding and planking that has been removed from old cars. The cost of construction was, therefore, quite low. The windows were taken from an old coach. Referring to the floor plan of the air brake room, the building is 25 ft. wide by 65 ft. long. It is divided into three rooms, the first of which is used for the reclamation and grinding of angle cocks. The center room, which is the largest, is used as the triple valve repair and test room. The third room is used for the reclamation of journal box packing and is not connected with the air brake department.

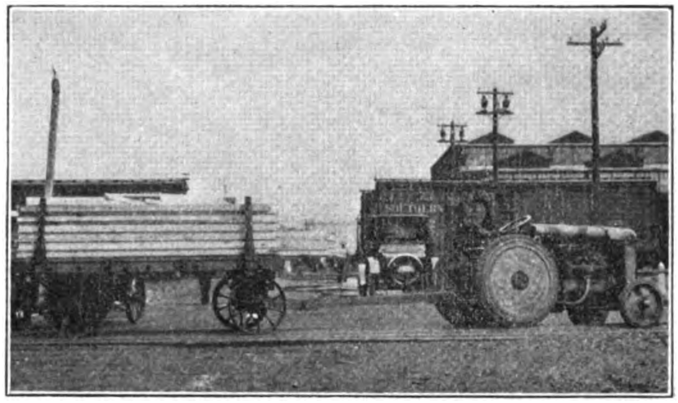
The triple valve repair and test room contains four work benches and two test racks. Bad order triple valves are brought into the room and placed on a storage rack which is located along the wall next to the angle cock repair room. The routing of the triple valves through the repair room is shown by the arrows. Upon completion of the



Above—The dry lumber shed—Below—The casting docks west of the sub-storehouse

work of repairing and testing, the triple valves are placed in a second storage rack at the opposite end of the room, from which valves can be removed as needed. The work benches are of steel, manufactured in the boiler shop, and are of a construction similar to those used in the air brake department of the locomotive unit. The angle cock repair room has two entrances, one of which leads into the triple valve repair room and the other is an outside entrance located at the end of the building. Bad order angle cocks may be routed through the same entrance as that used for bad order triple valves, and directly into the air brake repair room. Repaired angle cocks are routed through the outside entrance without any interference with the work. A multiple angle cock grinding machine is used for grinding angle cocks, located as shown in the floor plan.

Considerable attention is paid to the work of air brake repairs. The general air brake foreman presides over meetings of the staff, at which information and instruction relative to air brake maintenance is given. The proper methods to be employed as well as the recording of the various operations of the Rules of Interchange are discussed at these meetings. Weekly classes of instruction are also held in order to better acquaint the men with the correct methods employed in the repair and maintenance of air brakes.



Material is handled by trailers and Ford tractors

The journal box packing reclamation room is equipped entirely with shop-built machines and vats for the work of reclamation. It has a concrete floor and is provided with suitable connections for steam which is used in the process of reclamation.

Excellent comfort facilities are provided for the workmen

A wash and locker room is located in a separate building of brick and concrete construction, convenient to the car repair shop. The locker room is arranged with double rows of high steel lockers and ample space is provided at the opposite end where washing facilities for the men have been installed. A convenient feature of the lockers is that they have been built high enough to hang suits or overcoats in them without having to be folded. A separate building for the toilets is located approximately midway between the wash and locker building and the machine shop.

Adequate facilities have also been provided for protection against fire. A number of hose reel carts have been placed in small buildings of wooden construction located in a convenient position to the fire plugs. A sign placed over the door of each hose house gives instructions as to the location of the fire as indicated by the number of blasts of the fire whistle. Supplementary to the fire fighting equipment is an excellent departmental organization. Weekly fire drills are held at unexpected periods and at one of these tests recently conducted three streams were turned on the tank shop of the locomotive unit in 1 min. 30 sec. after the alarm had been given.

Administration

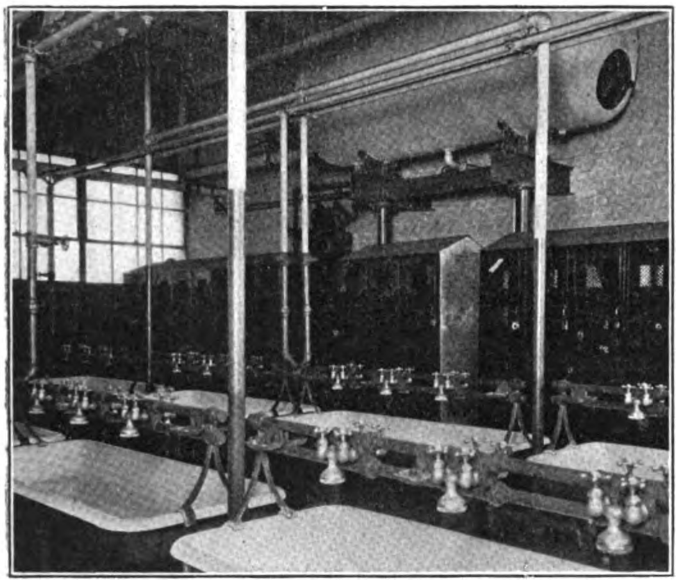
It is a policy of the administration to keep a close watch on expenditures. The system in vogue is based on the amount expended for labor and material for all repair work performed. In issuing authority for addition and

betterment work, such as the application of steel underframes or the conversion of cars from one type to another, a separate appropriation is assigned and an accurate record is kept of the labor and material expended on each individual car. All requisitions for material must show the station at which the work is being done, the number of the car and to what appropriation the amount expended should be charged. In addition to this material record, a labor record is kept by charging the workman's time against each individual car. Credit is allowed for all material scrapped and deductions are made for all scrap and second-hand material.

All the general work is charged to foreign and system car accounts as required by maintenance of equipment department instructions. A careful check is kept in the master mechanic's office as to the progress and cost of repairs from these sources. By means of this check the possibility of exceeding the appropriation is practically eliminated.

Co-operation between the men and supervisory forces has been an important factor

As stated in a preceding paragraph the results that have already been obtained during the short period of operation



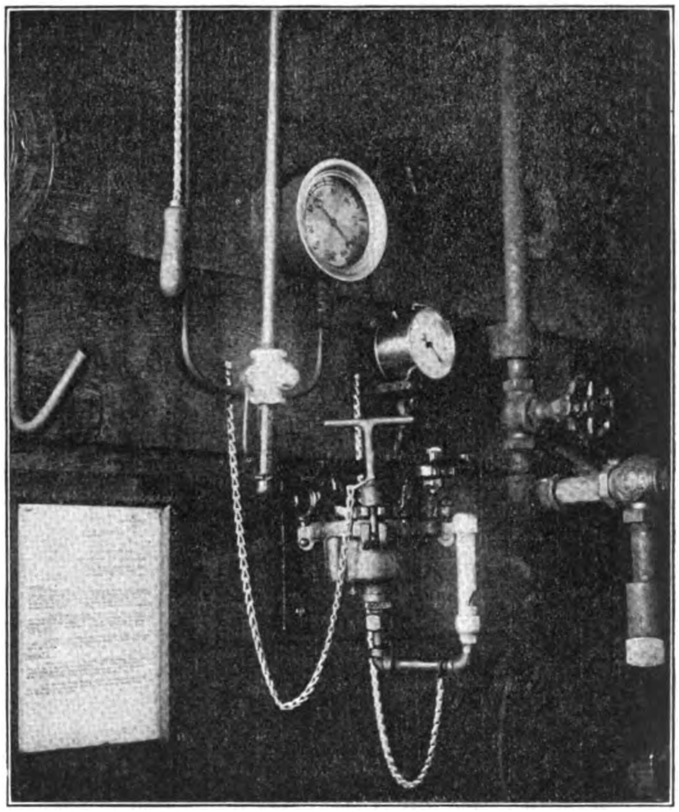
Interior of the wash and locker room—The lockers can accommodate overcoats or suits without folding

of the Finley car shops show a considerable decrease in the cost of production over that of the old shops at Avondale. No small share of the credit can be given to the spirit of co-operation and interest that has been shown by the men and the supervisory forces in bringing about the record that has already been achieved. C. E. Keever, master mechanic of the Finley shops, has created an excellent spirit of co-operation and progressiveness in both the car and locomotive departments. The shops were laid out under the general direction of H. W. Miller, vice-president, the engineering details being handled by B. Herman, chief engineer. The machine tool and mechanical department details were planned under the direction of R. L. Ettenger, mechanical assistant to the vice-president. The development of the plans and construction for the car shops as well as the locomotive shops, described on page 165 of the March issue of the *Railway Mechanical Engineer* were carried forward by Dwight P. Robinson & Co., Inc., New York.

A convenient whistle valve test rack

By Frank Bentley

THE accompanying illustration shows a conveniently arranged whistle valve test rack. Above the rack, but not shown in the illustration, is the drum for the air volume, out of one end of which leads the pipe carrying the necessary car discharge valve with the restricted orifice. The chain to the discharge valve, which is shown at the left, is pulleyed so that the handle attached to it may be pulled while watching the timing clock to the right. The testing whistle and the wrench for removing the diaphragm case under examination are never lost or misplaced as they are kept at the rack by small chains fastened to the wall. For the convenience of the operator the instructions for testing are framed and secured to the wall



Compact, permanent arrangement for testing whistle valves

to the left. The gage for observing the pressure is directly above the valve cap bracket and cap which are permanent parts of the rack equipment.

One hour, twenty-four minutes was the time required recently by H. W. Lehr's crew, at the Thirty-second street repair shop of the Pennsylvania Railroad, at Pittsburgh, Pa., to take out the 12 wheels of a dining car and put other wheels in their places. This was in an emergency when a diner which had started on a special run from Philadelphia to San Francisco had its wheels flattened, because of an emergency application of the brakes, at a point east of Pittsburgh. Mr. Lehr's crew consisted of A. C. Hussong, A. Dawidowicz, J. Bruszak, J. Pavlovic, M. Dvorabic, J. Koss, J. Starkowitz, F. Pasko, P. Sikora, C. Belancey, P. Starkowitz, R. Cillo, J. Stacherski, J. Lujic, J. Majkut, L. M. Bauer, J. Kozak, G. W. Euler, F. C. Johnson, J. Grosiak, A. Teofilak and S. Pluto. The train waited for the car.

Milling machines in railway shops

Classes of work for which they are fitted, cutters of proper design and lubrication are important considerations

By Leroy R. Gurley

SEVERAL articles appeared in the *Railway Mechanical Engineer* in 1917 and 1918, dealing with the subject of milling machines in railroad shops. Without exception the introductory paragraphs of these articles lamented the fact that the railroads were backward in more generally applying milling processes to certain classes of work. The articles were enthusiastic over the possibilities of the economies effected by machining certain classes of work on milling machines which then were usually done on the planer, shaper or slotter.

On investigation of present day milling machine practice in railroad shops over that of eight years ago, it has been found that the railroads have appreciated its possibilities and are applying its principles to the work for which it is suited. Within the past eight years, various sizes of horizontal and vertical millers have been placed on the market for handling large pieces of work such as rod and link motion work. This work was formerly done on the planer or slotter. However, this does not mean that the milling machine is always more effective than the planer or slotter, because for many operations these machines are better adapted. When single parts are to be machined, the time required to set up and perform the operation on a planer is less than when setting up the work on a milling machine and getting milling cutters of the required shape and size to perform the work. For the quantity production of many duplicate parts, however, the milling machine cannot be equalled.

Types of milling machines used in railroad shops

The milling machine was originally developed for manufacturing the small, irregular shaped parts used in the construction of fire arms and the milling process is still employed very extensively in the production of similar work, especially when the parts must be interchangeable. Milling machines are used for a great variety of operations and many types have been designed for finishing specific classes of work to the best advantage. They are widely used at the present time in the railway shops for milling many large castings or forgings which were formerly finished exclusively by planing; in fact, it is sometimes difficult to determine whether certain parts should be planed or milled to secure the best results.

The four principal types of milling machines used in the railway shops are the plain, universal, horizontal and vertical. The names used distinguish different classes of milling machines and indicate some additional feature that is characteristic or they may relate to the nature of the work for which the machine is intended.

Plain milling machine.—This type has a horizontal cutter spindle and is of the column and knee construction, which means that there is a vertical column, and a knee which is fitted to guiding ways on the face of the column, to provide vertical adjustments for the work table. Plain milling machines are commonly used for milling operations which can be performed by feeding the work in a straight line either vertically or in a horizontal plane, although in modern practice there are many exceptions to this rule. In the last few years, a number of improvements have been made in the plain milling machine that have added to its adaptability for railroad work and the two more important of these are greater power to drive the cutters to the limit and quicker methods for changing speeds and feed so that either can be readily adjusted for any particular part to be machined. These two improvements are especially valuable in railroad work, because a long run on one job cannot be expected.

Universal milling machine.—A universal type of milling machine is so named because it is adapted to a very wide range of milling operations. Its construction is similar to that of a plain milling machine although a universal type has certain attachments which plain machines do not ordinarily have, that make it possible to mill a large variety of work. This type has a knee which can be moved vertically on the column and a table with both cross and longitudinal movements. There is a difference, however, in the method of mounting the table on the knee. The table of a plain machine is carried by a saddle which is free to move laterally but does not permit the swiveling of the table. The swiveling base of the saddle of the universal machine makes it possible to do work such as helical milling which can not be done on a plain machine unless a spiral milling attachment were used that provides an angular attachment for the cutter. Practically all machines of this type are equipped with auxiliary appliances such as the dividing or indexing head, vertical milling attachments, etc. The universal milling machine is usually found in the tool room of the railroad shops.

Horizontal milling machine.—Any milling machine equipped with a horizontal spindle may be classified as a horizontal type but this name is generally applied to designs which have a horizontal work table, like that of a planer, and a horizontal cutter spindle. There are exceptions, however, to this classification. When a machine has a horizontal work table and bed, but is equipped with vertical spindles, it is termed by some manufacturers "a vertical spindle, horizontal machine." When the horizontal design of the planer type has a single spindle carried by a column at one side of the work table, it is sometimes known as the open side type or as a single spindle side head type. A machine designed in this way is also called a rotary planer, especially intended for milling plain surfaces or for slabing operations by using a large inserted tooth cutter head. This type of machine is generally used for heavy milling operations such as milling and fluting main and side rods.

Vertical milling machines.—When an end mill is driven directly by inserting it in a spindle of the plain type, it is difficult to mill some surfaces, especially if much hand manipulation is required, because the mill operates on the rear side of the work where it cannot readily be seen when one is in the required position for controlling the machine; moreover, it is frequently necessary to clamp the work against an angle plate to locate it in a vertical position or at right angles to the end mill when the latter is driven by a horizontal spindle to overcome these objectionable features. Special vertical milling machines have been designated. These machines are usually designated as

adjustable rotary milling machines and are especially adaptable in the railroad shop for such work as rod ending, strap profile milling and milling out side rods.

Milling processes

Some of the more general milling operations are classified either in accordance with the type of milling cutter used or the name given. A certain operation may indicate the method of presenting the cutter to the work. For instance, there are operations known as face milling, angular milling, form milling, etc. Some milling operations are associated with a special type of machine, whereas others merely indicate the type of cutter used or a certain method of milling. The following definitions are believed

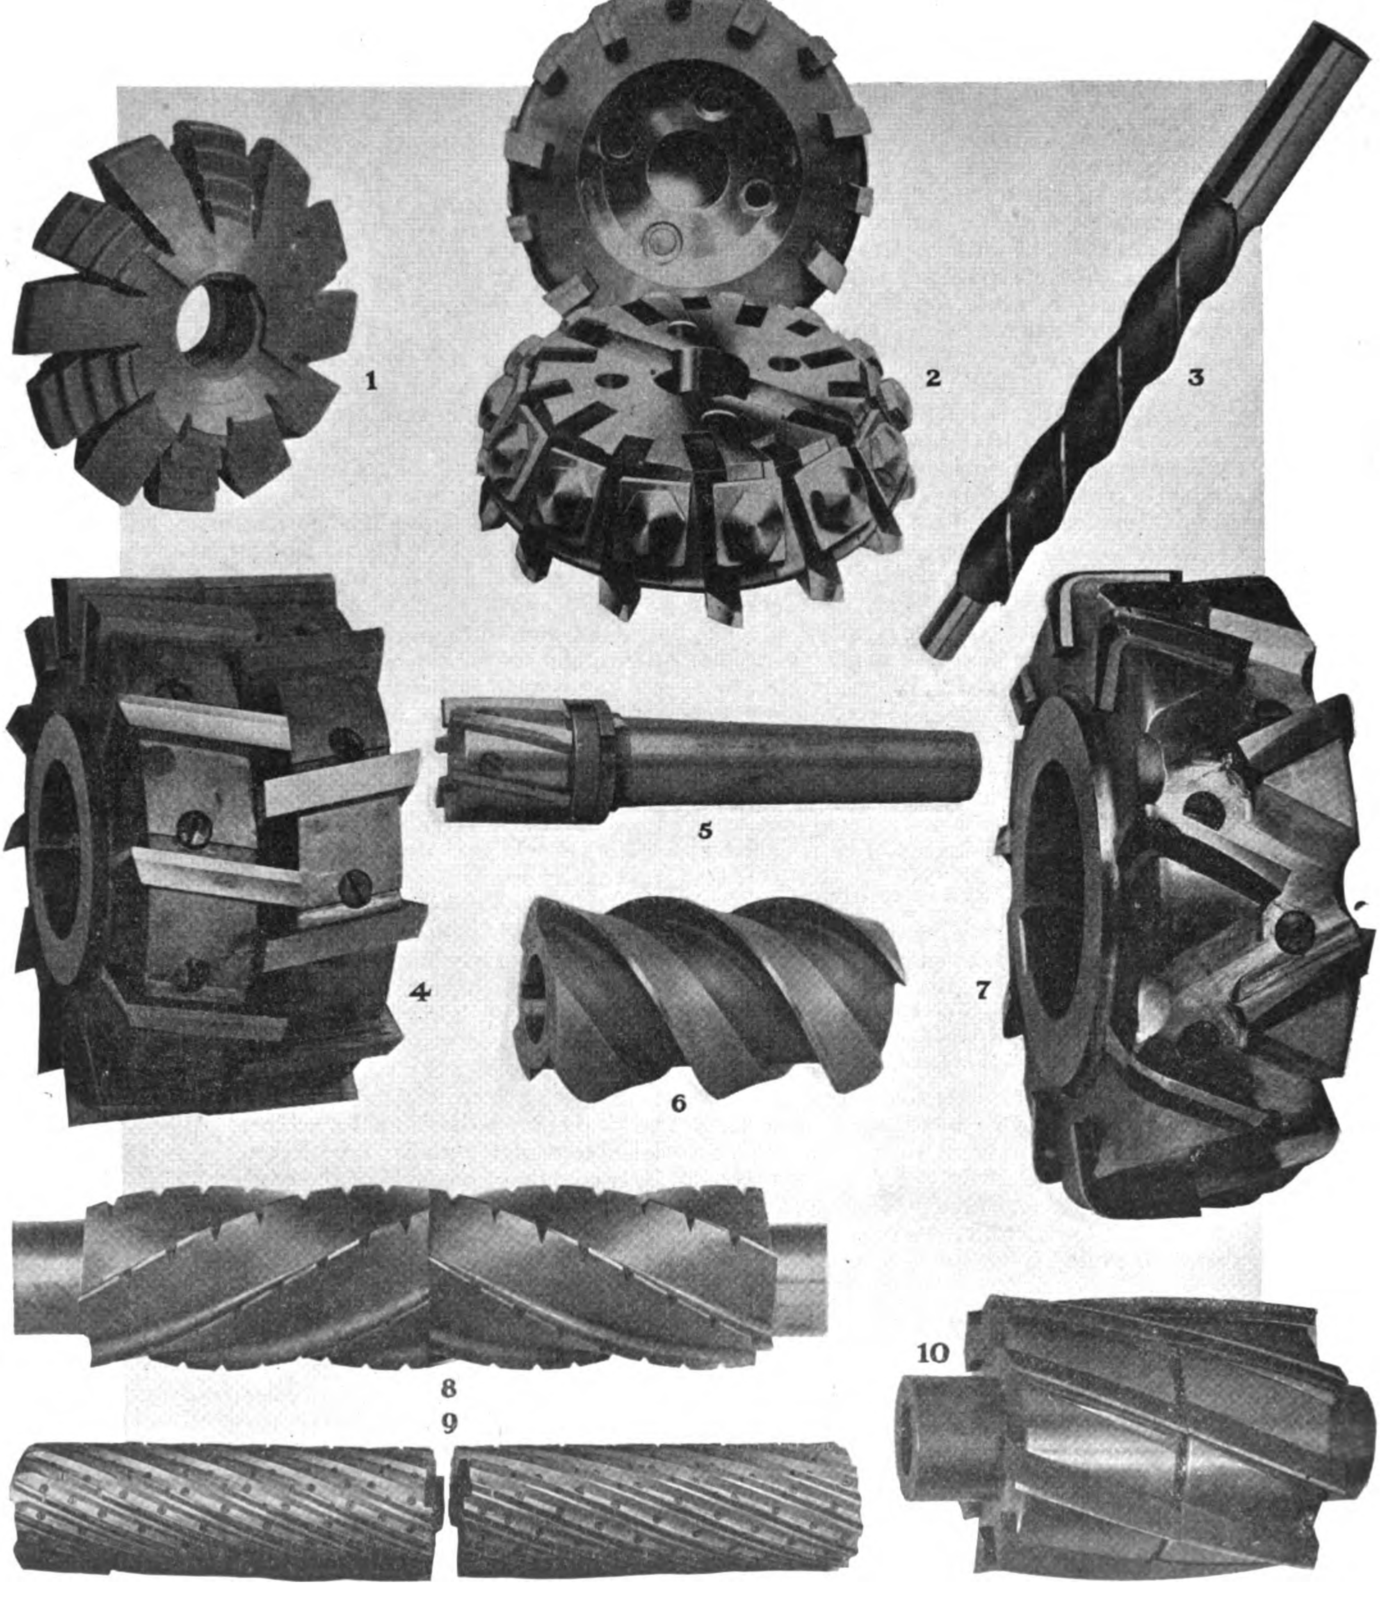

Fig. 12—Cutters used on milling machines in railroad shops

(1) Large cutter for milling involute gear teeth; (2) Inserted tooth face miller for heavy work; (3) Helical cutter for milling rods; (4) Inserted tooth interlocked cutters for milling shoes and wedges; (5) Spiral inserted tooth end mill; (6) Helical mill of the hole or arbor type; (7) Inserted tooth cutter for channeling main rods; (8) A pair of plain, niched tooth cutters mounted on an arbor; (9) Inserted tooth slab cutters for milling driving rods; (10) Inserted tooth cutters

to conform to general practice, although in some cases there is no generally accepted agreement regarding the use of these terms.

Face milling, as the term is generally used, means the production of a plane surface by the teeth of a milling cutter which operate in a plane at right angles to the axis of the cutter.

Gang milling means that surfaces in different planes are milled simultaneously by a combination or gang of two or more cutters.

End milling is a term usually applied to milling operations requiring an end-mill, as, for example, the cutting of slots, facing narrow surfaces, etc.

Straddle milling is an operation requiring the use of two side milling cutters which are spaced on the arbor a definite distance apart, in order to finish two or more parallel surfaces simultaneously.

Angular milling relates to the machining of surfaces which are at an angle neither perpendicular to nor parallel with the axis of the milling cutter, the teeth of the cutter being inclined the required amount.

Form milling is a method of producing a surface which may either be curved or of irregular shape, by using a formed cutter the teeth or the cutting edges of which conform to the shape required.

Slab milling is a term which is generally understood to mean the machining of comparatively broad flat surfaces, either by means of a cylindrical cutter or a face-mill.

These milling operations are the ones more commonly used on milling machines in the railroad shop. Profiling and routing are operations which are used in the railroad shops only in rare instances.

Milling cutters

To secure the most economical utilization of milling machines, it is imperative that properly designed cutters be used for each milling process. There are many shapes and sizes of cutters, a group of which are shown in Fig. 12, but they may all be classified under a few principal types.

The improvements in milling cutters adapted for railway practice and other work have been remarkable in the last few years and have contributed greatly to the present success of milling. The cutters of a few years ago had teeth spaced from 1/4 to 3/8 in. and many are in use today, the faces of the teeth being cut radial from the center. The teeth were generally all straight or only slightly spiral and, except on form cutters or gear cutters, they were rarely ground on the cutting face. It was generally thought that it was necessary to have fine teeth in order to obtain smooth surfaces, but it has been found that the slight irregularities in the finished surface are revolution marks and have no relation to the number of teeth in the cutter. For instance, it has been found that if feeding 1/16 in. per revolution of the cutter, the irregularities or slight depressions in the surface are 1/16 in. apart; if the feed is 1/8 in. feed, then the depressions are 1/8 in. apart, etc.

The cutters now largely employed for flat surface milling have teeth spaced from 1 in. to 1 1/4 in. and cut a spiral of about 25 deg. The face of the tooth is undercut or given a rake of from 7 to 10 deg., the cutting face and the top of the teeth being ground after hardening. All sharp corners at the bottom of the tooth are avoided. These are essential features of a cutter of maximum strength to cut and remove metal quickly with the least consumption of power, and at the same time to produce a satisfactory finish.

The plain milling cutter is cylindrical in shape, with teeth either straight or spiral. The teeth are generally niched at intervals along the cutting edge to break up the chips. The maximum diameter of these cutters is about 4 1/2 in., above which the inserted tooth type are used.

The side milling cutter, also known as a straddle cutter, because a cutter of this type is frequently used in pairs for straddle milling, are cutters commonly used in railroad practice. This type is provided with teeth on both sides as well as on the periphery of the cylindrical surface. Side milling cutters are used for cutting grooves or slots, as well as for many other operations. They are often used in conjunction with other forms of cutters for milling special shapes in a single operation.

Inserted-teeth milling cutters are widely used in railroad shops. The advantages claimed for this type of cutter are that considerable can be saved in its construction by making the body from machine steel and that the teeth can be readily renewed in case of breakage, which cannot be done with the solid type. The objections to this type of cutter are the difficulty of obtaining sufficient spiral, lack of chip space and liability of breaking the teeth. The latter objection is generally overcome by making the teeth amply large.

End-mills are used in railroad shops for cutting ports in valve chamber bushings and similar work. They are provided with teeth both on the cylindrical surface and on the plain end surface; this permits them to cut in an endwise as well as in a sidewise direction.

Face mills, in railway work, are useful for milling driving box cellars and a number of castings used on the locomotive and tender. They work equally well if made solid or with the inserted teeth. Since, in face milling,

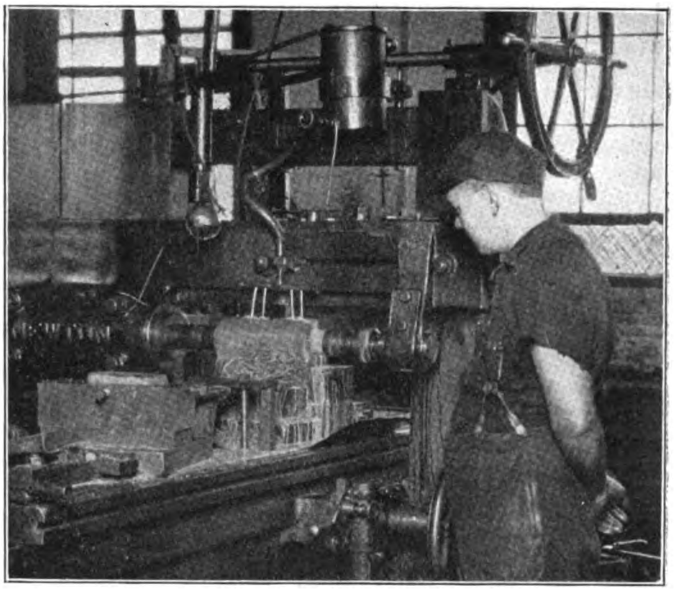

Fig. 13—Milling a link bracket on a horizontal miller with the cutters completely covered with the lubricant

practically all of the cutting is done by the periphery of the cutter, the teeth should have the same degree of rake and angle as the slab mill for rapid cutting.

The helical type of cutter is one which was especially designed for the railroad shop. The shank type is primarily intended for internal finishing, either working from a drilled hole or working in from the end of the piece. The steep spiral with which these cutters are designed gives them a shearing action that enables the cut to be taken easily while maintaining a good finish. At the same time, the undercut teeth contribute to the free cutting action, and require less power for driving. These cutters are generally used in the railway shops on vertical or horizontal millers for cutting out of the solid the back

and front ends of main rods. Fig. 12 shows a group of various types of milling cutters used for different classes of work in the railroad shops.

Grinding cutters

The use of properly ground cutters is especially essential in order to obtain the maximum output of milling machines, and unless this is attended to, high rates of speeds and feeds cannot be expected. Considering for the present the outside of the tooth, it is very necessary that it be ground to give the correct amount of back clearance. Too sharp an angle will cause the cutter to chatter, hook in and produce rough surfaces. Too little clearance will cause the cutter to drag and prevent proper cutting. Many cutters have been condemned on account of too sharp teeth or angle, where a slight removal of the keen edge either by grinding or wear would have remedied the trouble. No hard and fast rule can be given governing the amount of clearance, as different metals will require different degrees. For steel such as used largely in locomotive construction, a back clearance of about three degrees appears to be satisfactory for a 4½-in. cutter. It is a good plan occasionally to measure this back clearance, which can readily be done by a bevel protractor. The data obtained will be available for grinding future cutters. Sheet steel gages made to the proper angle for testing cutters after being ground will be a great help. When a happy medium has been arrived at for grinding the back angle, it will be found that cutters as they come from the grinding machine will start off at once to full capacity without the nursing often necessary with improperly ground cutters. Some of the cutter grinding machines are arranged so that the amount of back clearance can be adjusted.

To grind the front rake of a tooth or the undercut surface is somewhat difficult on the average universal grinding machine, but it can be performed in a fairly satisfactory manner by setting the grinding spindle at right angles to the groove in the cutter and using a cup grinding

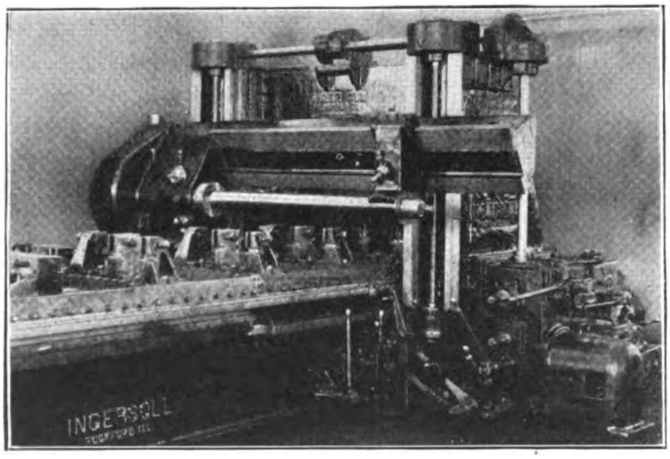

Fig. 14—Fixture for holding almost every style of locomotive driving rod

wheel. The cutter must be passed back and forth holding its face against the wheel. Some of the latter grinding machines are equipped with spiral grinding attachment that will grind this surface nearly perfect. Even with the hand method, however, the results obtained in the way of longer life between grindings, fully justify the additional expense of this one grinding. The grinding of the face of a tooth may be likened to the grinding of the top face of a lathe tool. Who would think of making use of a lathe tool that had not been ground on the face after hardening? A smooth surface is absolutely necessary to prevent the chip dragging on the lathe tool or the cutter tooth face. The question as to how often a cutter should be ground may be answered by observing the chips. When these show a discoloration in spite of a liberal supply of compound it usually indicates that the cutter teeth are either dull or broken.

Lubrication of cutters

One of the greatest factors for efficiency in milling is the proper lubrication of the cutters. Without some good means of cooling, it is impossible to approach the maximum amount of work possible with any design of cutters, because the limit of speed is reached when the cutter burns. It has been demonstrated that the nature of the lubricant is of minor importance so long as a sufficient quantity is provided. The newer milling machines are equipped with a system of lubrication that floods the cutters, which is very effective. Fig 13 shows a link bracket being milled on a horizontal miller with the cutter completely covered with the lubricant.

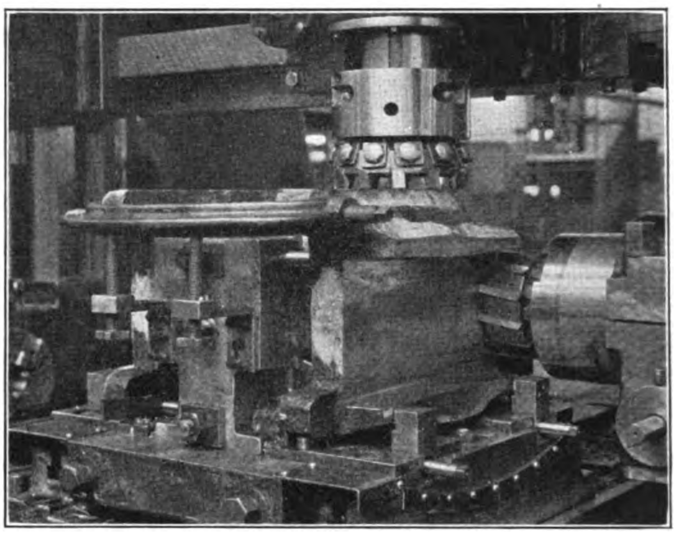

Fig. 15—Special fixture for holding driving boxes while milling three sides simultaneously

Holding fixtures

The use of holding fixtures plays an important part in obtaining the maximum production from milling machines. For single purpose machines, they are indispensable not only in time saved in quickly loading the piece and holding it securely, but by allowing an unskilled workman to operate the machine, as the fixture has fixed points for locating the work when setting up. For general purpose machines, the necessity for the fixture is not so great. However, in nearly every shop, there are certain pieces that are coming to the milling machine from time to time for which it pays to make special fixtures, and there may be a considerable number of pieces not alike, yet somewhat similar, that may be held by combination fixtures made of crossbars, screw jacks side stops and clamps.

It was found for example, on a slab milling machine that the time of loading and setting up locomotive rods without fixtures was greater than the time used in actually milling the work. This situation was corrected by making the combination fixture shown in Fig. 14 which holds almost every style of rod. The special fixture shown in Fig. 15 for holding driving boxes while milling the three sides simultaneously with inserted tooth facing cutters is adjustable to various sizes of boxes.

Milling locomotive parts

The work performed on milling machines can be segre-

gated according to the types of millers. Main and side rods, link motion levers, driving box shoes and wedges, etc., are usually finished on the horizontal or vertical miller, while gears, taps, etc., are completed on the plain or universal millers. The former machines are located in the main part of the repair shops while the latter are generally found in the tool room.

The work now handled by the two heavier types of machines was formerly finished either on the planer, slotter or shaper. Several factors must be considered when transferring the work from older types of machines to the millers. These factors are (a) the large percentage of the total power consumed by the actual cutting of the metal instead of moving the part machined and the machine table back and forth; (b) the continuous cut; (c) the reduction in time required for tool setting and grinding of the tools. The fact cannot be overlooked on the planer, slotter or shaper, that there is only from one to four tools cuting while the milling machine will have from 12 to possibly 26 cutting points. The milling machine cutter, with the greater number of cutting blades, can be removed and replaced in practically the same time it takes for the one tool on the three older types of machines. A comparative time study should be made of performing the work on the different types of machines which would show whether it would be an economical move to transfer the work. Table I shows the time, from floor to floor, of machining various parts on the horizontal and vertical millers.

Table I—Time required for milling locomotive parts on the heavier types of milling machines

	Material	Kind of operation	Cutter speed, r.p.m.	Table feed, in. per min.	Time to complete, hr.	min.
Axle box housing	Cast steel	Mill top and bottom inside faces	38	3⅛	0	25
Connecting rod	Forged steel	Mill from solid, 6-in. by 8-in. brass fit	148 (rough) 228 (finish)	⅞ 3¼	1	35
Crosshead	Cast steel	Mill underside, radius and fillet	30	variable	1	35
Crosshead gib	Cast iron	Mill fit	65	7¼	0	25
Crosshead guide	Steel	Mill bottom, top and offsets	60 (rough) 74 (finish)	2 5⅝	4	0
Crosshead guide	Steel	Three faces	16	1⅛	1	30
Driving box cellar	Cast iron	Mill sides	32	4¼	0	14
Driving box fits	Babbitt	Mill both faces	..	4.2	0	12
Driving box wedges	Cast iron	Nine milled inside	..	..	0	45
Driving box wedge	Cast iron	Mill five surface with gang cutter	20	7¼	0	8
Driving box shoe and wedge	Cast steel	Two pieces, finished inside	12	..	0	38
Eccentric blade	Forged steel	Mill top and end	65	7¼	1	38
Eccentric crank	Steel	Mill contour	59	1 3/16	4	0
Facing pedestal jaws	Steel	Both jaws	24	11/16	1	35
Link saddles	Forged steel	Mill to surface	35	½	0	40
Main rod brass	Brass	Mill sides	183	5⅝	0	45
Main rod key	Mild steel	Mill rounded edge	..	..	0	20
Mud ring	Steel	Mill four inside corners	..	..	8	0
Main rod	Steel	Milled on all four sides and fluted	21 (for fluting)	3/16	12	0
Main rods	Steel, H. T.	Profiling both ends of two rods	..	..	10	0
Main rods	Steel, H. T.	Two rods milled complete	..	..	20	0
Piston head rim	Cast iron	Mill fit	..	..	0	35
Piston rod keyway	Steel	Mill 1⅝ in. by 4⅛ in. keyway	..	..	0	55
Side rod	Steel, H. T.	Profile front end	30	1½	0	30
Side rods	Steel	Profile both ends of two rods	..	..	2	45
Side rods	Steel	Mill both ends of two rods	28	⅜	4	0
Spring saddle	Cast steel	Mill feet	38	5⅝	0	9
Trailer spring saddle	Cast steel	Mill bottom, sides, ends and top ends	25	4¼	1	40
Trailer spring saddle guide	Cast steel	Mill fit	41	1⅝	0	28
Union link	Steel	Mill clevis ends	148	2⅛	0	40
Valve bushing	Gun iron	Eight ports	228	4¼	0	45
Valve bushing	Cast iron	Mill 11, 1½-in. by 2¼-in. ports	231	4½	0	30
Valve yoke	Steel	Milling bevel to fit fillet on slide valve	..	..	0	45

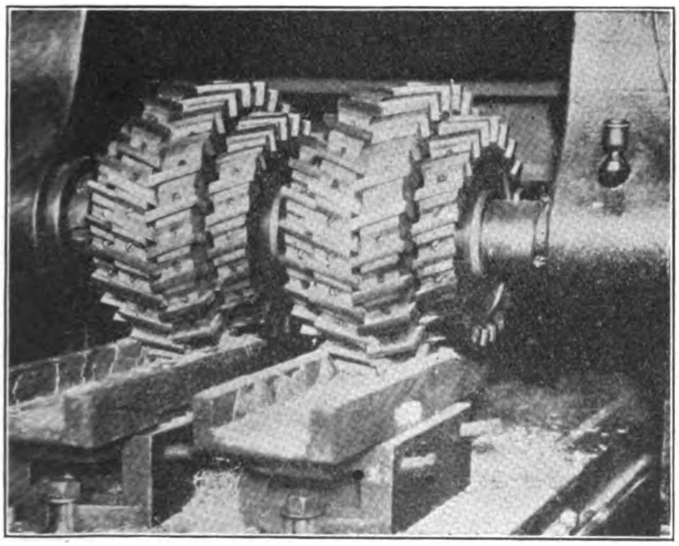

Fig. 16—Milling the guide bar fit of crosshead shoes using a gang of inserted tooth interlocked arbor cutters

The milling of driving box shoes and wedges on a horizontal miller using a gang of inserted tooth cutters is rapidly become general practice in railroad shops. Fig. 16 shows a double row of crosshead shoes being milled using inserted tooth arbor cutters and interlocking side milling cutters. On this machine, 60 shoes have been completed in eight hours. Fig. 3 shows another view of nine wedges set-up in three rows of three each which were finished complete inside, in 45 min.

To obtain the above results, the following factors must be considered. If a perfectly smooth finish is not considered essential, the milling cuts of shoes and wedges can be taken at the fastest speed the cutter will stand. With fairly good forgings and removing not over ¼ in. depth of cut, a cutter speed of 60 ft. per minute and feeds of 3 in. to 6 in. per minute, can be obtained, the rate of feed being largely governed by the ability to hold the wedge on the holding fixture. The thrust from the milling cutters on the wedge is heavy, as from 15 to 20 hp. will be consumed when milling to the limit of modern cutters on a surface of this kind. All the thrust of the cutter must be taken up by the wedge, and unless the piece is well secured, it is liable to shift or slip and damage the cutter. Therefore, it is advisable to make a holding fixture for this work.

After pouring the shoe and wedge face on locomotive driving boxes they must be machined to size. Many of the railroad shops are doing this work on a horizontal miller using two inserted tooth milling cutters. Fig. 17 shows a machine of this type with four boxes set up on the table. Forty boxes per eight-hour day, giving an actual cutting time complete per box of five minutes and a setting up time seven minutes, making a total of 12 min.

from floor to floor for each box, is considered good machine time for this work. The established feed to obtain these results is 40 ft. per min. for cutting speed, and 42 in. per min. for table feed. These speeds and feeds have proved desirable on this class of work as from 80 to 90 boxes may be machined with one grinding of the cutters.

The machining of crosshead shoes can be done to advantage on a horizontal miller. Fig. 18 shows a herring-bone type of crosshead shoe being milled on a horizontal miller. The body of this crosshead shoe is made of cast steel, while the recesses are filled with a soft metal, which gives an unfavorable surface to machine. This condition naturally requires a slower cutting speed. Notwithstanding this drawback, ten crosshead shoes are milled in an eight-hour day, using a table feed of 2 in. per min. and a cutting speed for the largest diameter of cutter of 40 ft. per min. An average of 18 crossheads are machined with one grinding of the cutters.

The machining of main and side rods on either a horizontal or vertical miller is considered the most economical method of doing this work. The rods first have their four sides machined on a horizontal miller. From two to six rods can be milled at one set-up, depending on the size of the rods. The next operation is to mill the flutes in the main rod. Fig. 10 shows two rods each having two 7-in. by 12-in. flutes milled complete in 12 hr. The rods were completed throughout in 20 hr. The next operation is to mill out and profile the back and front ends of the main rods and mill the contour of the ends of the side rods. Fig. 9 shows a radial vertical miller machining out the rear end of two main rods in two hours, and the back end in eight hours.

Crosshead guide bars are machined on a horizontal miller, using a gang of inserted tooth cutters. Fig. 7 shows the rough forging of a guide bar, having its two sides milled with a straddle inserted tooth cutter. By using a cutter between the two cutters shown, the top face and two sides can be milled at one operation in 90 min., using a table feed of 1⅜ in., and the cutters revolving at 16 r.p.m. Considerable time is saved by using the three cutters to complete the job in one set up.

The usual method of cutting the keyway in a piston rod is to drill, slot and hand file, which requires about three hours to complete. A milling machine has been designed, which will do this job in less than an hour. Fig. 4 shows a 5½-in. diameter piston rod having milled in it with a helical cutter a 1⅞-in. by 4⅜-in. keyway in 55 min., from floor to floor. This machine will also mill the keyways in crossheads. This is a single purpose machine, and its purchase is justified only for those shops which have a considerable amount of this type of work to do.

It is often necessary to face the pedestal jaws of a locomotive frame. To disassemble the frame and machine it on a planer would be an expensive operation. The pedestal facer shown in Fig. 2 is well adapted for this work. The actual time required to face the pedestal jaws shown in the illustration is as follows:

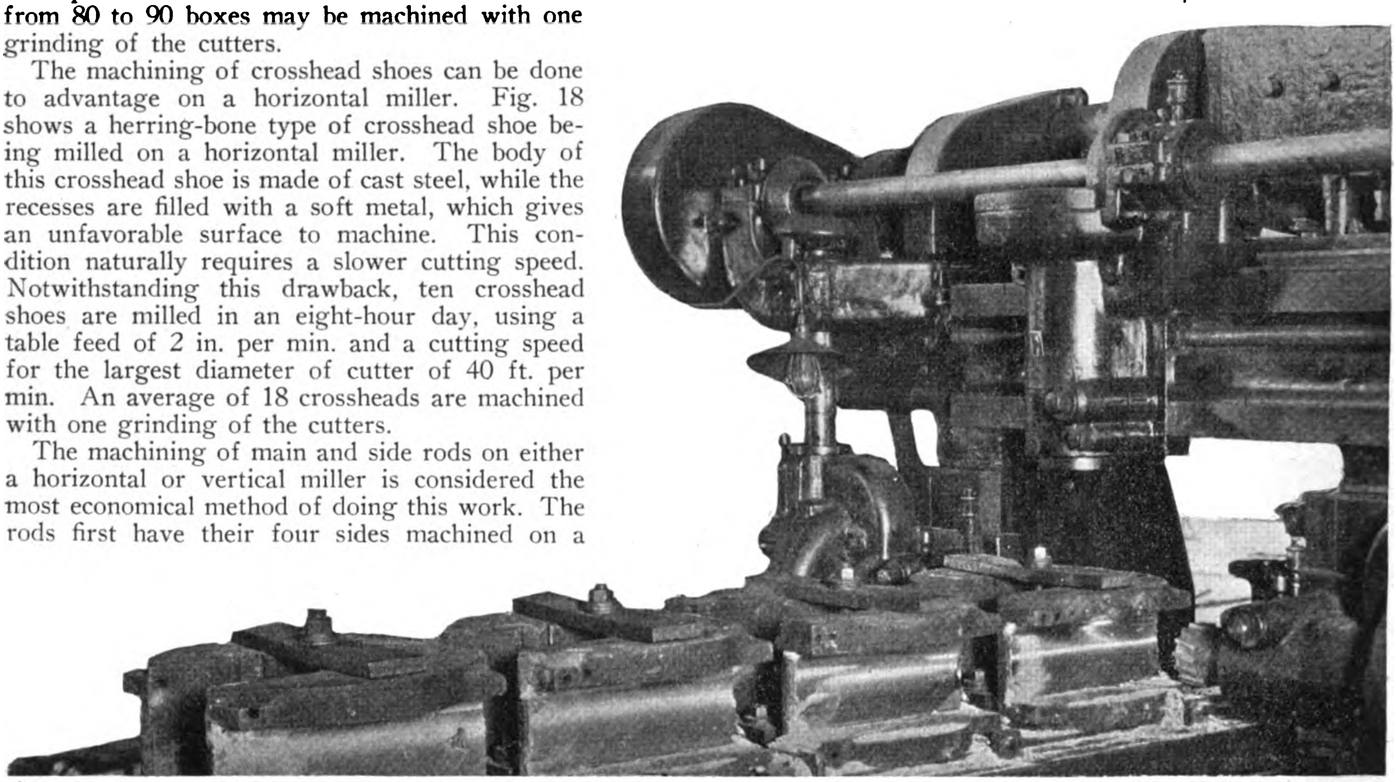

Fig. 17—Milling the shoe and wedge fits of driving boxes using two inserted tooth facing cutters

Set up the machine	15 min.
Facing the wedge side of the pedestal	40 min.
Facing the straight side of the pedestal	35 min.
Taking down the machine	5 min.
Total time	1 hr. 35 min.

A cut 1/16-in. deep was taken which required a cutter speed of 24 r.p.m. and a feed of 11/16-in. per min.

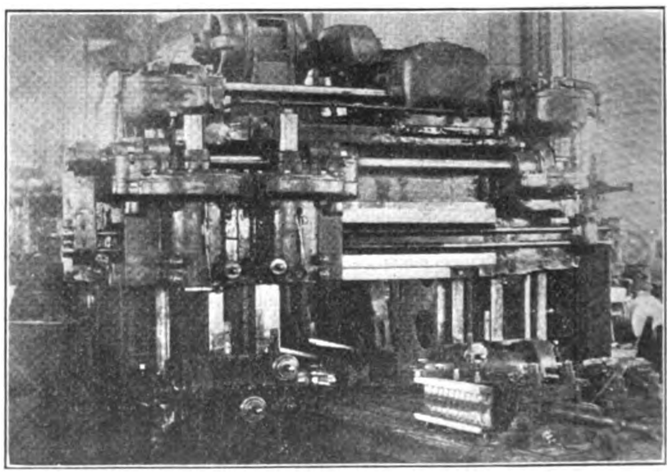

Fig. 18—Milling the guide bar fit on a herringbone type of crosshead

Fig. 11 shows a piston rim ring being milled in 35 min. on a vertical miller using an inserted tooth end mill. Another example of the application of an end mill may be seen in Fig. 5 which shows the milling of the ports

of a valve chamber bushing. This bushing contains 11 ports, 1½ in. by 2¼ in., each port requiring 2½ min. to complete, using a cutting speed of 231 r.p.m. and a feed of 4½ in. per min. By using a chuck which enables the operator to revolve the bushing quickly, the 11 ports were finished complete in 30 min.

The plain type of miller can be used to advantage in the repair shop as well as in the toolroom. Fig. 1 shows a machine of this type milling to the layout line in 4 hr. an eccentric crank using a cutting speed of 59 r.p.m. and a table feed of 13/16 in. per min. Another application of the plain miller may be seen in Fig. 6. By means of a special attachment a steel spring hanger die block in which a 2-in. diameter hole, 6 in. deep had to be milled, was completed in 3 hr.

Fig. 8 shows a vertical miller machining a mud ring which is an unusual job for this machine. The four ends of the mud ring are milled complete in 8 hr. after which it is placed on a planer and finished.

Milling machines in the toolroom

The first application of milling machines in railroad shops was in the toolroom. They were of the universal type and were used for repairing and manufacturing such tools as reamers and taps. Experience has shown that these earlier machines did not have sufficient capacity for handling some of the larger tools used in railroad work. Consequently, the toolrooms have been provided with the larger machines such as is shown in Fig. 19. In addition to regular tool room work, they are used for finishing machine repair parts and making holding fixtures, jigs and other special machine attachments.

Fig. 20 shows a universal machine milling a 4½-in. by 3¼-in., 14-thread hand tap. The same illustration shows a group of cutting tools which were made on this machine. They consist of three staybolt taps, six hand taps, one reamer, one hand bolt tap for frame equalizer spring bolt holes and one general tap. Referring again to Fig. 19 the top right view shows a staybolt tap being completed in 33 min. using a cutting speed of 40 r.p.m. and a table feed of 2 in. per min.

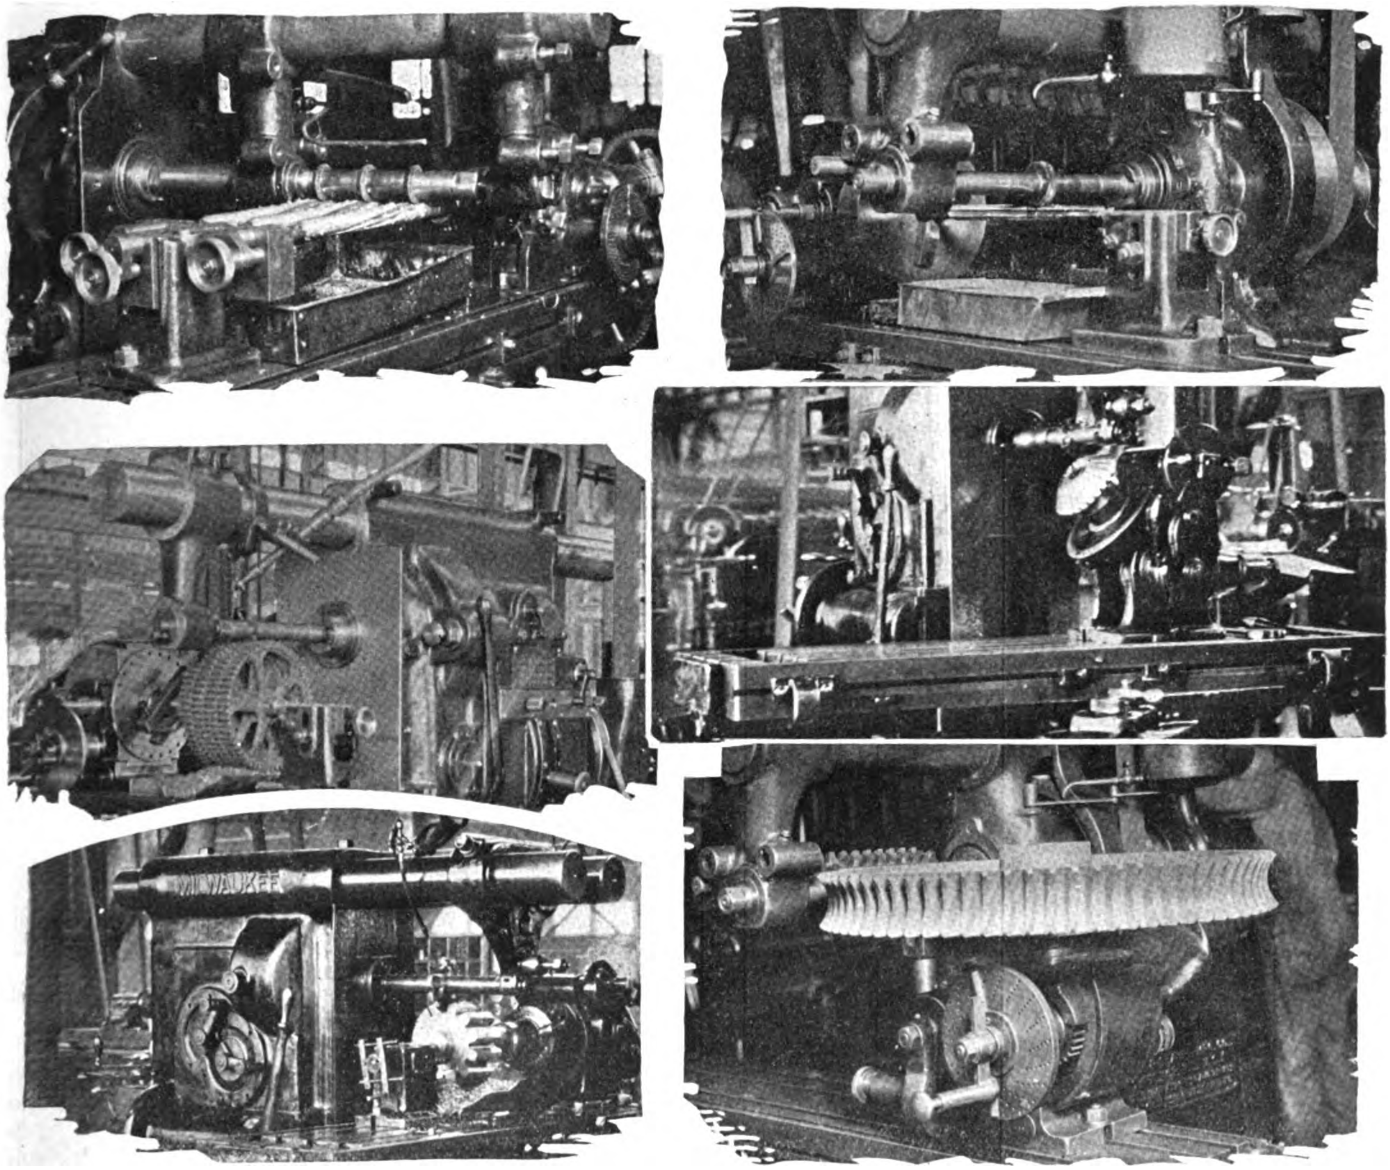

Fig. 19—Various types of jobs performed on milling machines in the railroad toolroom

One of the frequent jobs which a toolroom is required to do is the generating of various types of gears which are a part of a machine or other shop equipment. As these repair jobs are usually urgent, they are made in the toolroom instead of being purchased from a manufacturer.

The left-center view of Fig. 19 shows a universal miller

cutting the teeth in four cast-iron gears in 5 hr. using a cutting speed of 45 r.p.m. and a table feed of 1 in. per min. Each gear has 60 teeth 1 in. wide and .360 in. deep. The right-center view shows a miller cutting the teeth in a bevel gear, using an indexing head. The left-bottom view shows a miller generating the teeth in a heavy spur gear. The right-bottom view shows a universal miller cutting the teeth in the worm gear of a hoisting machine used at a car icing plant. This gear has 75 teeth, each with a 3-in. face and was completed in 12½ hr. The right hand view shows three reamers being milled at one set up.

The illustrations show only a few of the many jobs which can be machined in the toolroom on a plain or universal type of milling machine. The time required for machining other types of cutting tools and gears may be found in Table II.

Table II—Time required for milling cutting tools and gears on the plain or universal milling machine in the toolroom

	Material	Kind of operation	Cutter speed, r.p.m.	Table feed, in. per min.	Time to complete, hr.	Time to complete, min.
Staybolt tap	Carbon steel	Six, 23-in. flutes	40	2	2	33
Hand-tap	Carbon steel	Four, 4½-in. flutes	58	2½	0	32½
Spiral reamers	Carbon steel	Three reamers, nine flutes, 12 in. long	75	.036	0	32
Gears	Cast iron	Four gear, each with 60 teeth, 1 in. wide	45	1	5	0
Worm gear	Cast iron	75, 3-in. teeth	..	..	12	0
Drop forging die	Steel	Mill to size:	20	Variable	5	0
Spring hanger dies	Steel	Milled to line	..	..	3	0

Conclusion

The present-day tendency of mechanical department officers is to analyze the conditions in the repair shops so as to segregate certain classes of work and have them

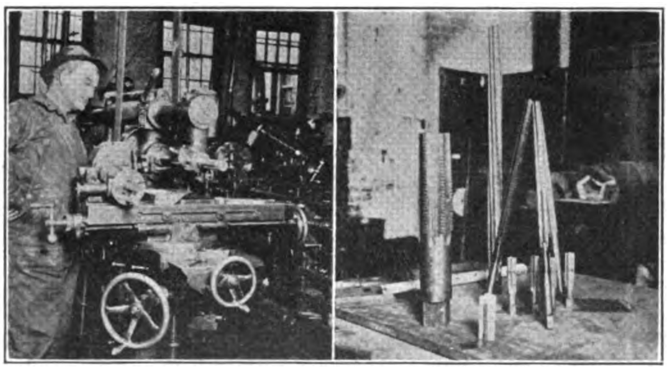

Fig. 20—Milling a hand tap on a universal milling machine—A group of cutting tools which can be made on a machine of this type

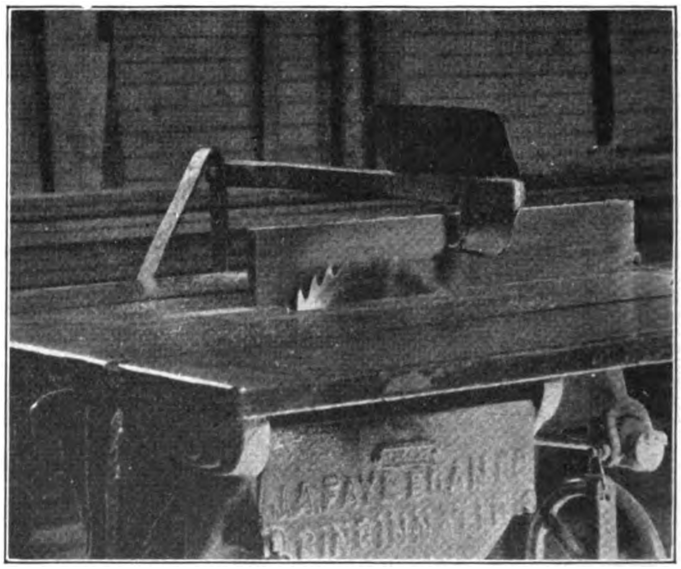
machined on machine tools particularly adapted for such work. A striking example of the results of such an analysis is shown in an article which appears elsewhere in this issue on "Rod and valve motion production," in the Aurora, Ill., shops of the Chicago, Burlington & Quincy. The shop was organized for handling new and old rod and valve motion work on a production basis and in which milling machines are extensively used. There are other locomotive and car parts which are now finished on other machines which can be more economically handled on milling machines. However, before changing over to the milling machine it is well to make an exhaustive comparative time study of performing the work on the different types of machines.

In analyzing shop conditions, it is common to find many parts which can be economically manufactured on a single purpose machine. This means that production methods and modern machinery should be installed and, with this thought in mind, the mechanical officers are giving considerable attention to the milling machine as a production tool.

A safety guard for circular saws

ONE of the most dangerous machine tools with which a carpenter has to work is the circular saw. There is always a possibility of a workman allowing his hand to rest too long on the piece he is cutting and receiving a nasty cut. It is practically impossible to use a wire-guard or cage of the usual type as such a safety device interferes with the work and it is usually taken off by the first man who happens to use the saw and finds the guard in the way.

A simple and effective device which has been designed with the special purpose of eliminating these difficulties is shown in the illustration. It consists essentially of a horizontal wood arm pivoted at one end to a bracket secured to the table and a guard of tin projecting upward and a guard of sole leather projecting down at the other

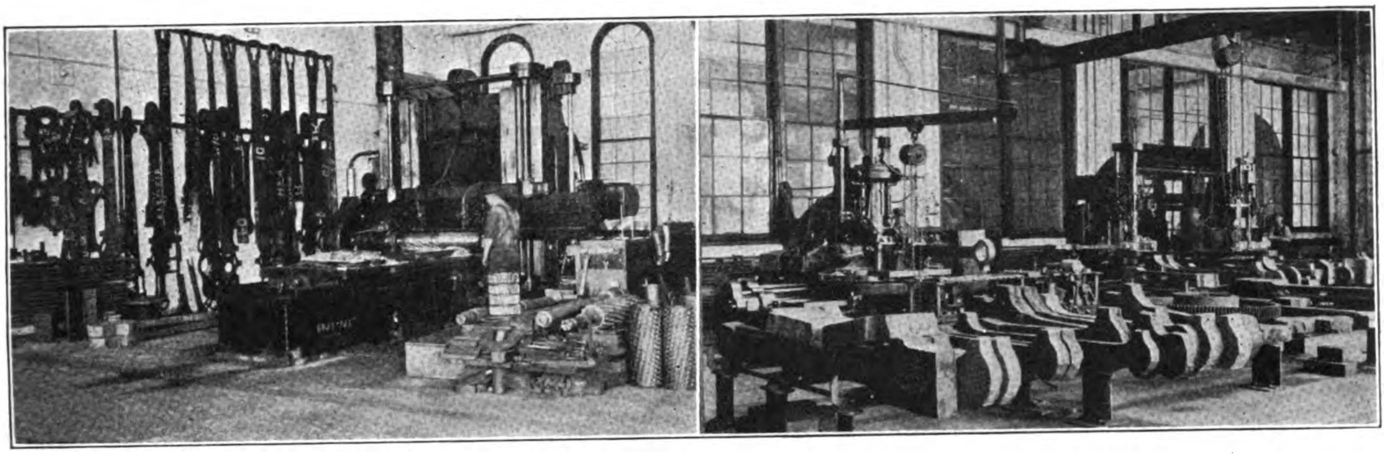


The top shield deflects flying saw-dust and the lower shield protects the head of the workman

end. The tin guard is used to deflect the saw-dust so that it will not fly into the eyes of the workman and the leather guard is used to prevent him from allowing his hand to slide onto the saw, and thus affording protection from possible injury.

There is practically no interference of the guard with the work, regardless of the size of the piece to be cut. When large pieces are being cut, the leather guard slides along on the work as it is moved forward past the saw, the sole leather being sufficiently stiff to raise the arm on its pivot.

THE INTERSTATE COMMERCE COMMISSION has granted a petition of the Chicago & Northwestern for exemption from equipping with automatic train control devices the locomotives of its Sioux City division operating between Maple River junction and Carroll, Ia., 3½ miles.

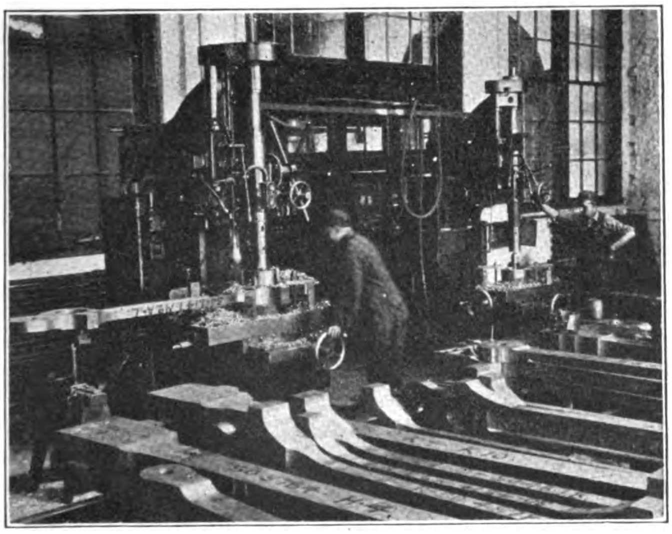


The Burlington rod shop is well lighted, the floor is clean and the work and tools arranged in an orderly manner. (Left) Heavy Ingersoll slab miller roughing out a pair of side rods. (Right) Roughing bench with Ingersoll heavy duty vertical miller and two Baker heavy duty rod drills in the background; overhead traveling crane will later be provided with an electric hoist and electric operation by push button control from the floor

Rod and valve motion production

Burlington organizes separate shop at Aurora, Ill., for handling new rod and valve motion work on a production basis

THE economies due to centralization of manufacturing work in a single plant or shop provided with modern machinery and trained men are well-known, and several railroads have taken advantage of these economies in handling certain phases of their shop work. The Chicago, Burlington & Quincy is believed to be one of the first, however, to organize a separate, fully-equipped shop devoted solely to system locomotive rod and valve motion work. Converted from an old boiler shop, this modern machine shop at Aurora, Ill., was placed in operation January 1, 1925, and, although certain additional machines and electrically-operated cranes are still to be installed, the new shop has already given a good account of itself. With a total force of 10 machine operators, two bench hands, one apprentice and two helpers, the following output was obtained in the first three months of this year: 32 new main rods, 142 new side rods, and heavy repairs to the rods on 60 engines. This shop is designed to manufacture all the new rods required for the entire system. The motion work is handled in one corner of the shop, as shown in the drawing, and, since the development of this part of the work has been somewhat delayed, a description of it will be deferred to a later issue, the present article being devoted primarily to methods of production in the rod shop.



Large holes are cut rapidly and accurately by the Baker drills equipped with three-cutter trepanning tools—Illustration shows a 12-in. hole being cut

New shop converted from old boiler shop

A new building was not erected for this rod shop but advantage was taken of an opportunity to convert the old 112-ft. by 75-ft. boiler shop at Aurora for this purpose. This shop was given a new cement floor, the walls painted white, traveling cranes overhauled, lighting improved, and in general every effort made to produce conditions in the shop most conducive to good output. Modern machinery was then installed, the location and type of each machine being shown in the drawing. The arrangement is such as to eliminate as far as possible all unnecessary movement and back travel of both material and men. The rods follow the course indicated by the dotted line, the forgings being received from the blacksmith shop, machined on the heavy millers, drills and slotter illustrated, completed on the finishing bench and delivered to the stores department for all points on the Burlington System.

The shop is now equipped with hand-operated traveling cranes, there being one over the heavy machines and roughing bench and another over the finishing bench. Plans have been made for the power operation of these cranes by means of push button control from the floor which will make possible a distinct saving in time and labor of handling the rods. Four helpers were required in the old rod shop for handling rods on trucks whereas one man is now able to do all this work in the new shop. In addition to the overhead crane, the heavy vertical spindle miller has a self-contained jib crane to assist in handling the rods for that particular machine. Another 20-ft. jib

crane provided in the corner handles rods for one of the Baker drills as well as the Sellers slotter.

While some old machines were located in the Aurora rod shop temporarily, most of the machinery installed was new, a list being shown in the table, together with those additional machines which will be provided in the 1925 budget.

Machinery installed in Aurora rod shop

No. of machines	Description
1	48-in. by 48-in. by 16-ft. Ingersoll slab milling machine.
1	36-in. by 36-in. by 12-ft. Ingersoll slab milling machine.
1	54-in. Ingersoll heavy-duty vertical milling machine.
1	5-in. Baker heavy-duty rod drill.
1	4-in. Baker heavy-duty rod drill.
1	72-in. Sellers slotter.
1	No. 4 Brown & Sharpe universal milling machine.
1	24-in. Bullard vertical turret lathe.
1	28-in. Cincinnati crank shaper.
1	24-in. by 8-ft. Boye & Emmes engine lathe.
1	C. B. & Q. 75-ton hydraulic rod press.

Additional machines to be installed in rod shop

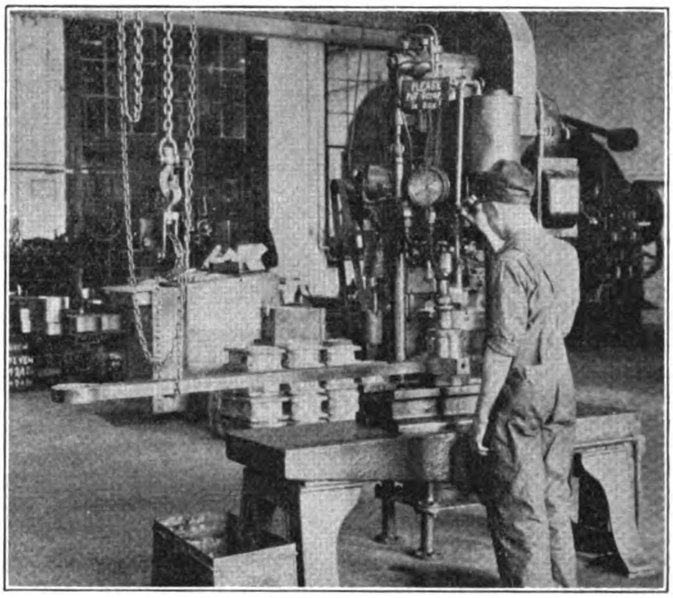
No. of machines	Description
1	18-in. by 48-in. engine lathe.
1	28-in. heavy-duty crank shaper.
1	¾-in., 2-spindle high-speed drill.
1	3-in. heavy-duty drill.

Factors promoting high production

Particular attention is paid to orderliness, neatness and clean floors at the Aurora rod shop in the thought that a better shop output will result, as well as decreased liability of accidents from stumbling over rod straps, brasses, tools and other materials often found laying around in a more or less careless fashion on rod shop floors. Rod racks are made from rails and cast iron stands and tool racks are provided for each machine.

Next to the arrangement of machinery in the shop and provision of proper crane facilities for handling the rods, perhaps the most important single factor in the shop output obtained is the elimination of hand fitting and filing. All rods are finish milled without filing, all brasses, both front and back end, being machined so that practically no hand fitting is required. The accuracy of the machine work and its influence in reducing the amount of hand fitting is indicated by the fact that two mechanics and one apprentice do all the bench work at the Aurora rod shop.

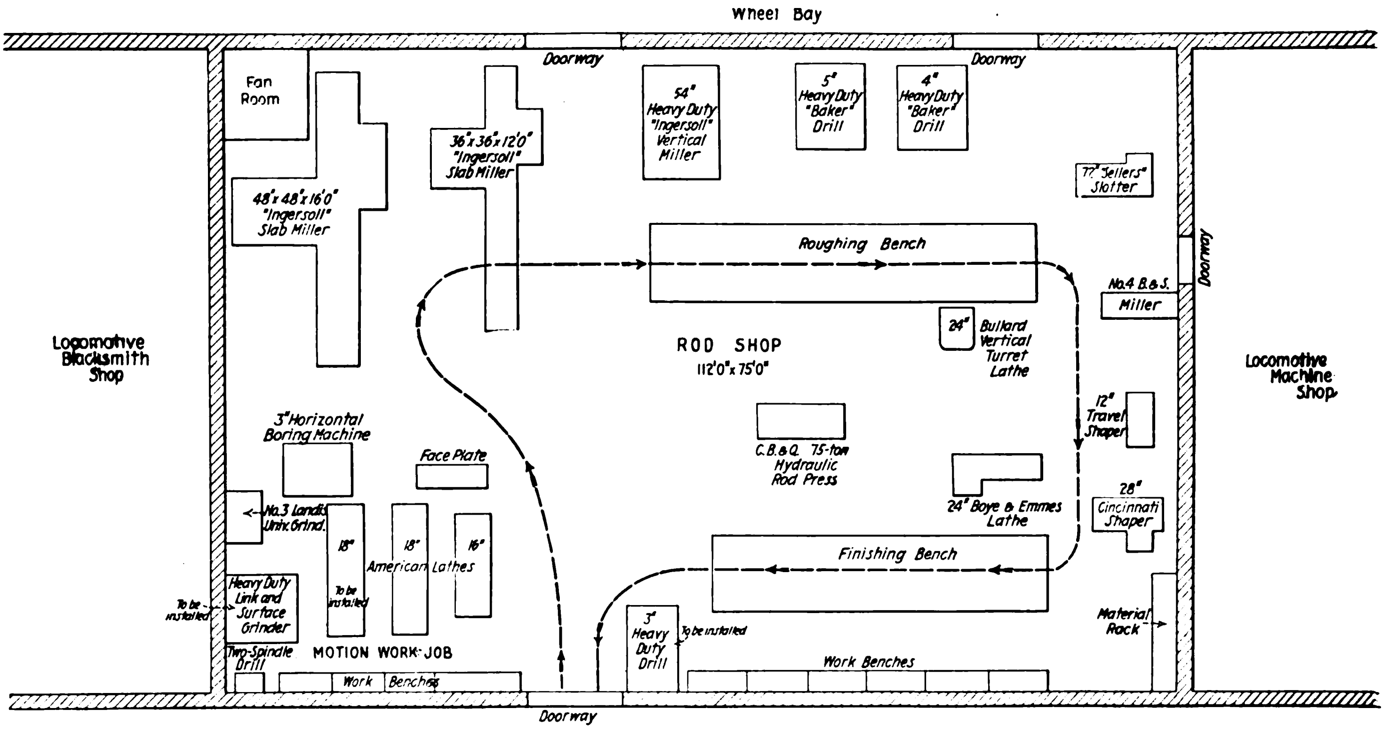
The labor and time involved in laying out is also minimized by the use of templates for new rods and straps. These templates are available for all classes of rods and straps and are kept hanging on the wall of the rod shop, as shown in one of the illustrations, where they are out



Burlington 75-ton hylraulic rod bushing press driven by self-contained 3-hp. motor and equipped with single plunger pump—Quick return of the ram is provided

of the way and there is no danger of their being damaged. It is stated that the use of these templates saves at least 1½ hr. work per rod in laying out.

In order to make the most effective use of the high power machine tools used in this shop it has been neces-

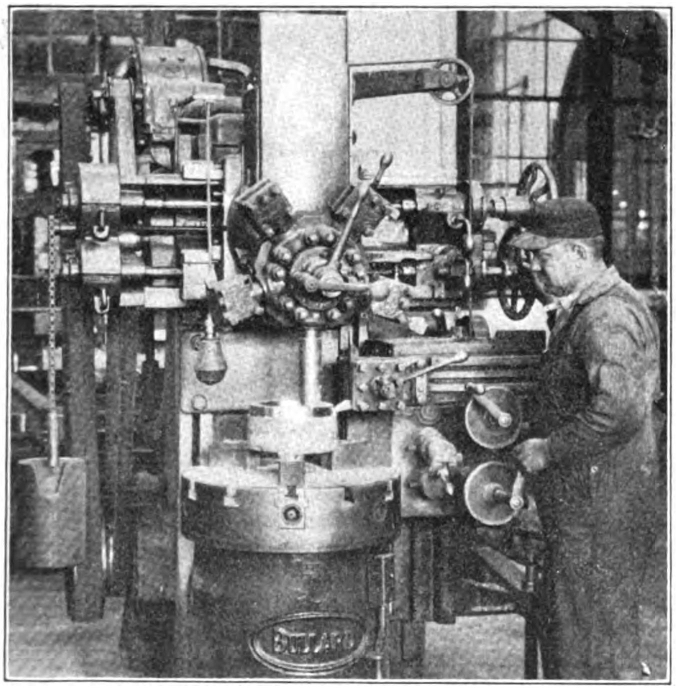


Floor plan of Burlington rod and valve motion shop at Aurora, Ill. The location of the machinery is indicated as well as the path followed by the rods through the shop from the time they are received from the blacksmith shop in the rough until delivered to the stores department finished

sary to pay special attention to the holding fixtures and methods of clamping the rods. These holding fixtures, some of which are illustrated, are featured by their rugged design, ease of adjustment and ingenious arrangement to hold different types of rods.

The question of milling cutter feeds and speeds is also highly important. While heavier feeds and speeds than those employed at the Aurora rod shop could probably be used, it is found that the actual cutting time is a fairly small proportion of the total time required for manufacturing rods so that it does not pay to use too heavy cutting feeds and speeds which will cause cutter trouble. More time can be saved by giving proper attention to methods of handling the rods and arranging for quick set-up and adjustment on the machine. The feeds and speeds mentioned later in this article are set about as high as permissible without causing excessive cutter wear and frequent grinding. About 12 cuts per grinding are secured.

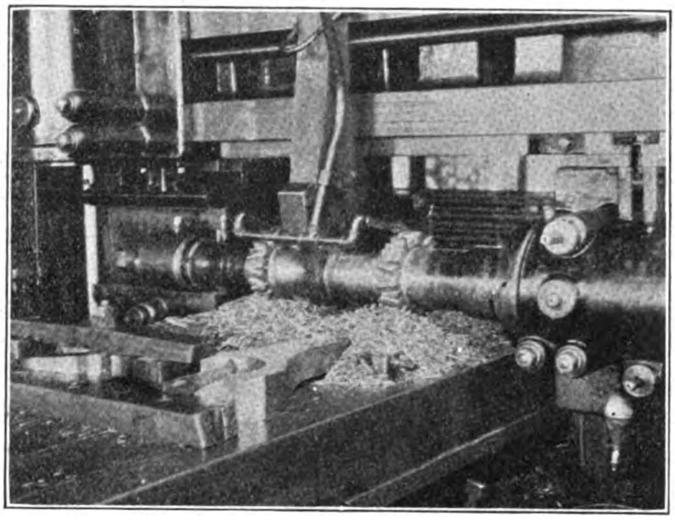
About 40 per cent of the Burlington rods are made of Nikrome steel. The 48-in. and 36-in. slab millers, driven by 75-hp. and 25-hp. motors respectively, are run at 45 ft. per minute on carbon steel rods and 35 ft. per minute



All rod bushings are machined on this 24-in. Bullard vertical turret lathe equipped with universal three-jaw holding chuck —The provision of the five-head turret and the side head to hold cutting tools, in conjunction with the convenient location of operating levers and hand wheels makes this a high production tool

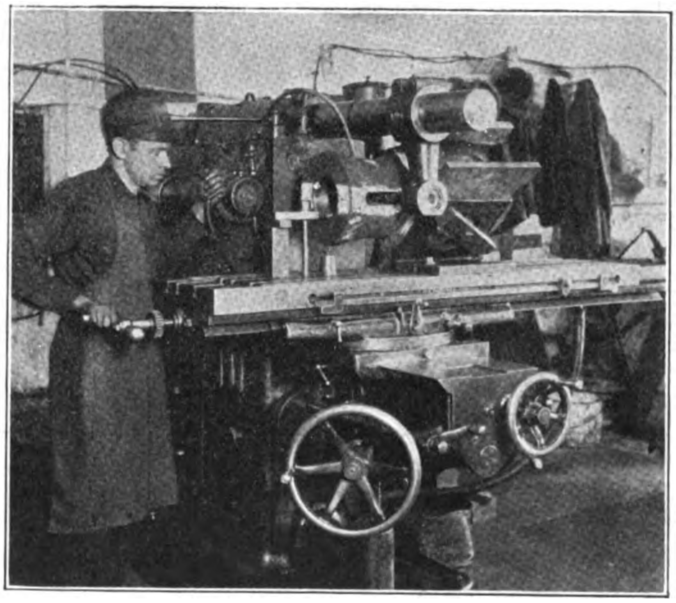
on Nikrome rods. The 48-in. machine is equipped with one 10-in. by 48-in. peg tooth milling cutter and one Goddard & Goddard inserted tooth slab milling cutter. The table feed, varying with the depth of cut, ranges from 3 in. to 8 in. per min. The rods are channelled with Helgren staggered-tooth solid milling cutters, ranging in width from 1¾ in. to 3½ in. The entire cut is milled in one operation, from ¾ in. to 1¾ in. deep, with a table feed varying from 2 in. to 3½ in. per min. Two rods are channelled at one time. These cutters are also interchangeable on the 36-in. by 36-in. slab millers.

The 54-in. Ingersoll vertical milling machine is equipped with 5-in. by 12-in. inserted tooth milling cutters and various sizes of solid milling cutters from 1 in. to 3 in. in diameter by 10 in. long for machining the rods outside and inside on the butt ends. Only one cut is taken on each end, no finishing cuts being required. Cuts on the ends of rods are taken to a depth of 2½ in., a 5-in. by 12-in. cutter being used which will permit milling two rods at a time. When cutting up to the full 12-in. length of the



Close-up view of 36-in. by 36-in. by 12-ft. Ingersoll slab miller machining the flutes in a pair of side rods

cutter it has proved advisable to reduce the feeds about 40 per cent. A feature of this machine, as shown in one of the illustrations, is the special holding fixtures which have an important bearing on the output secured. In view of the heavy cuts taken it is necessary to have unusually rugged holding fixtures and the factor of easy adjustment



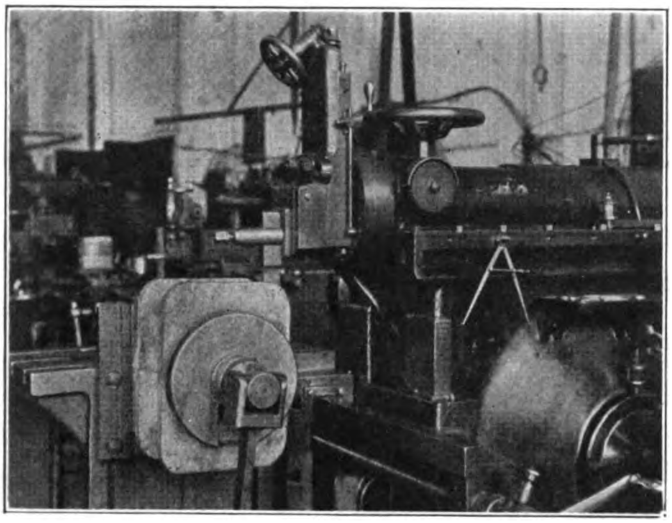
The No. 4 Brown & Sharpe universal miller is here shown machining a 1⅜-in. by 4¾-in. crosshead keyway—This machine also saves time in milling main rod keyways

to save time in setting up the work is also an important advantage. This machine, provided with a compound table with power operation in all directions, is especially built for rod work.

The heavy-duty Baker drills are also especially designed for rod work, having ample power and being equipped with push button control for starting, stopping and revers-

ing. All large side rod holes are cut by a three-cutter trepanning tool.

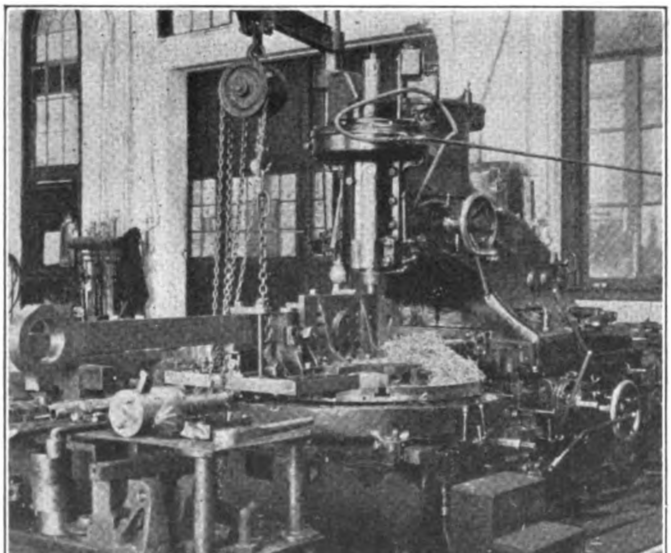
The 72-in. Sellers slotter, with power rapid traverse of the carriages and table and an ingenious method of obtaining exact speed control, is used for machining the



Main rod brasses are shaped accurately and with a considerable saving in time over older methods on this 28-in. Cincinnati shaper equipped with a Helgren indexing four-position chuck

insides of rod fork and front ends where the radius is so small that milling cutters cannot be used.

Main rod keyways are milled on the No. 4 Brown & Sharpe universal milling machine, crossheads and piston rods also being handled on this machine. Main rod key-

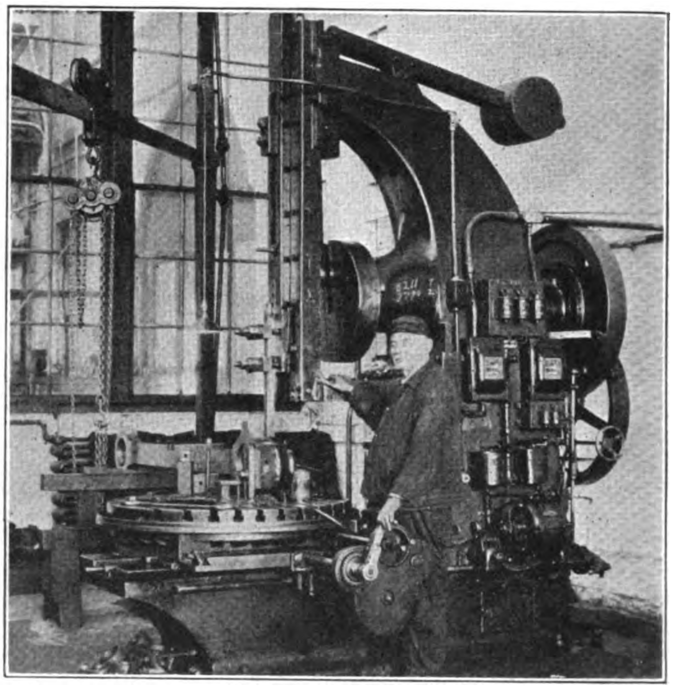


View indicating rugged character of the holding fixtures, which are also arranged for easy adjustments—The self-contained jib crane and chain hoist saves waiting for the traveling crane

ways 1 in. by 16 in. are milled in approximately one hour. Crosshead keyways, 1⅜ in. by 4¾ in. are drilled and milled complete in 1¼ hr. Piston rod keyways 1⅜ in. by 4¾ in. are milled in 45 min. This machine is said to do the same work in one-third the time required on a $12,000 machine.

The 24-in. Bullard vertical turret lathe is used for rod bushings and general rod and valve motion work. The Cincinnati 28-in. crank shaper, fitted with a Helgren rapid squaring and centering chuck, is used mostly for planing back end main rod brasses. A great deal of time is saved by this chuck and more accurate work is performed, enabling the brasses to be fitted on the machine to the exact size required for the rods. The time required for planing a back end main rod brass complete, fitted to the strap or the fork end of the main rod, is one hour. An additional 28-in. heavy-duty crank shaper will replace the 12-in. traveling head shaper shown in the drawing. The 75-ton rod bushing press is of Burlington make driven by a three-horsepower direct-connected motor. It is of the single plunger type with a quick return and handles readily the work in this shop.

Even a casual visitor at the Aurora rod shop of the



Fillets of too small a radius to be milled are machined on this 72-in. Sellers slotter—Easy power operation of the machine table in all directions is provided—The jib crane facilitates handling rods

Chicago, Burlington & Quincy can hardly fail to be impressed with the fact that this is a real production shop in which the production methods and machinery employed are on a par with those used in the best industrial shops in the country. The Aurora rod shop is conclusive evidence that the Burlington, like other progressive railroads, appreciates the importance of production methods in reducing the cost of repair shop operations and is applying these methods in cases where the volume of work involved is sufficient to justify them.

THE LOCOMOTIVE repair shops of the Pennsylvania at Sunbury, Pa., were closed on April 30. The lack of facilities for repairing large locomotives has necessitated the assignment of this work to other shops. Of the 200 men who are thus thrown out of work, many have already been given positions at other places. G. A. Schneider, master mechanic, retains his headquarters at Sunbury. Mr. Schneider is also master mechanic of the Schuylkill division. The first shop at Sunbury was built in 1865, and employed about 50 men.

A logical policy of locomotive maintenance*

Results of a study of economic factors determining the correct program of shopping cycles

By L. K. Sillcox

General superintendent of motive power, Chicago, Milwaukee & St. Paul, Chicago.

THE successful manufacturer must know the units of cost to produce his wares, for upon their application depends his profits. The universal adoption of more or less detailed cost accounts in both large and small establishments and the greater scrutiny given to them by owners and managers is real evidence of the value of such knowledge and the necessity therefor. Knowing that such information is successfully determined and applied in the commercial world, surely it can be as effectively established and employed in the matter of railroad locomotive maintenance and be the basis of executive policy with a view toward assisting the average motive power man in carrying out evident possibilities for economy and an eeffctive procedure at least cost.

Mechanical department economies are of two kinds: Internal economies which can be carried out independently by the mechanical officer of his own motion, and the much greater economies which management, as a whole, can only make possible, based on current studies as to policies and possibilities. Railroads are only typical of the more modern business organizations, and should seriously study, regardless of known obstacles, what the possibilities really are, and then constantly endeavor, item by item, to make progress along fundamental lines, all of which, for the purpose of our discussion, revolves around the question of the proper utilization of motive power. No one man, and indeed no combination of men, can evolve a best method off-hand from the foundation. It can only grow gradually, developing here and changing there, in line with economy, as the territory requires, or the nature of the traffic and competition in attracting the same becomes an issue. But the guiding idea of management having a proper and stable policy remains, nevertheless.

The expenditure for locomotive maintenance so far as it is caused by frictional wear and tear evidently will increase in direct proportion to the strain of the work done by the locomotive, and to the extent it represents outlay for replacement of parts, obsolete though not worn out, so far it is independent of the work done. Any plan used in the shopping of power involves complete considerations as to necessary maintenance and the effect from characteristics of service, as well as details of motive power construction, age and availability of shop, roundhouse facilities, etc. In not a few instances, much of the expenditure for locomotive maintenance, as reflected in the accounts, is occasioned from patching up old construction, even though in some cases this extends to the point where the actual repair cost, as renewed, exceeds the major portion of the value of the unit as renewed and, consequently, is recapitalized.

A close study will often indicate the folly of spending large sums per unit to continue obsolete designs in service for long periods when the same amount would be more than sufficient, as an initial cash payment, for an up-to-date efficient design of greater capacity and less cost to operate or maintain. Let us test by imagining a concrete case. Assume that a passenger engine 15 years old and originally designed to handle a nine-car train now is required to carry fifteen cars on the same schedule, resulting in a heavy maintenance cost due to frame breakages, racking of machinery, valve motion, running gear, etc., then it becomes a question not only of maintenance, but investment. If the original unit was of 40,000-lb. tractive force and was costing an average of $9,000 per year to maintain with a relatively low record of 3,000 miles per month, then it would seem proper to consider a new type of power, say with 50,000 lb. tractive force, which would afford 5,000 miles of service per month and yet not cost more than $5,000 per year for maintenance, making a saving of approximately $4,000 per year in maintenance cost and increasing the performance 66 per cent. This would justify making a change in power even though the original unit may have cost only $30,000 and the new unit $60,000. The original unit involved a maintenance cost of $9,000 per year plus a depreciation charge of $750 or a total of $9,750 as compared with an estimated maintenance cost of $5,000 per year for the new unit plus $1,500 depreciation charges or a total of $6,500, making a saving in the new unit of $3,250 per year, saying nothing of additional savings in fuel and transportation expenses. At 6 per cent this recovery would represent an investment of $54,000 or almost to the cost of the new unit, but if this were done on a large scale, then the amount of work would be performed with 66 per cent of the number of new units as compared with the number of old units and thus the change would be justified.

Two policies of shopping

There are many elements in the matter of executive policy which go to make a relatively high or low maintenance cost of locomotives, and the method of shopping power is one of the primary features to be considered. Two extremes of practice are found with many variations between them: One is what may be termed the high-frequency-shopping and the other the low-frequency-shopping policy. The former is that based on running locomotives through shops with an anticipated service of from 12 to 14 months with a minimum of roundhouse attention. The latter is that based on running locomotives through shops with the idea of having a service of 24 months or more and with a greater degree of roundhouse attention to attain this length of service. Vital elements in determining such a policy are the relation of the number and size of locomotives owned to the business handled, the road conditions for hauling heavy or light

*Abstract of a paper presented at the spring meeting of the American Society of Mechanical Engineers, held at Milwaukee, Wis., May 18-21.

tonnage trains, the topography of the country traversed, the distribution of industrial centers, the presence of large terminals, the spacing and capacity of roundhouses, the distribution and assignment of power, the placement of forces as between roundhouses and back shops, the rapidity with which mileage is run out and particularly the roundhouse and back shop facilities for handling certain classes of work. Furthermore, where a railroad has back shops of an obsolete character, it is practically as well off doing their work in roundhouses and it may be found helpful, under such conditions, to construct small modern back shop facilities at critical points to care for division requirements without increase in overhead expense.

The results obtaining under the two extremes of

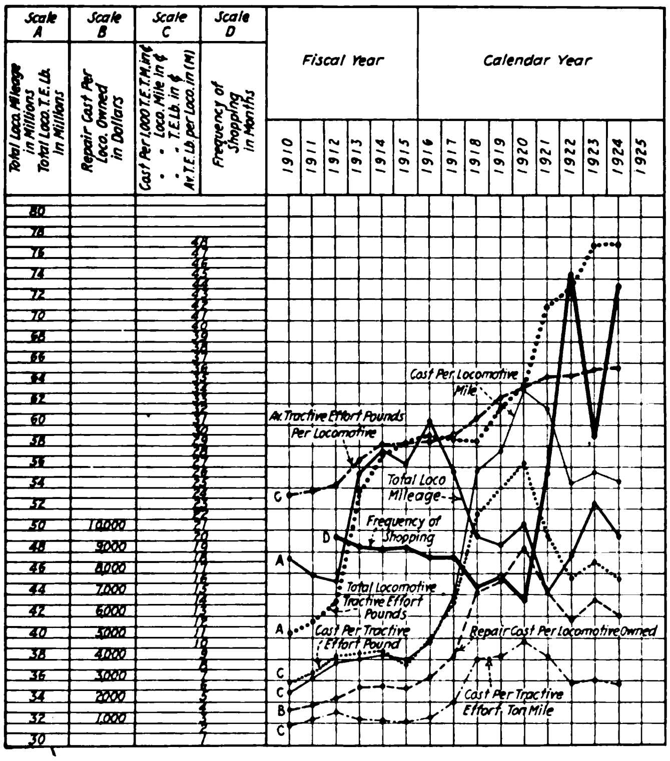


Fig. 1—Graphical illustration showing results of changing from a high to a low frequency shopping program on the C. M. & St. P.

policy mentioned have been observed for a considerable period and it appears that policy is largely governed by local conditions rather than local conditions being governed by the policy. The C. M. & St. P. has had experience under both plans, and just as a case in point, the general results obtained will be stated. Prior to 1921 a high frequency of back shop repairs was employed but after considerable study the plan was changed to a low frequency of repairs. The trend of unit costs, etc., both prior and subsequent to 1921, is illustrated in Fig. 1. This is a graphic illustration of the results obtained under these two extremes of policy, affected, of course, by the price trend of labor and material in the meantime. The lines plotted represent three general groups, one indicating the growth and size of units maintained, another representing the various unit costs of maintenance and a third representing the frequency of back shop repairs. The growth of property maintained is represented by the dotted line *A*, indicating the total tractive effort pounds owned from 1910 by years to the end of 1924. This growth was not all in the nature of new equipment, but represents power added by the acquisition of subsidiary and leased lines, as well as some new equipment, and to that extent the growth line should not be confused with the rate at which new equipment might have eliminated obsolescence. This very fact has a marked bearing on the cost of maintenance as the total growth consisted of approximately as many of the smaller and older locomotives as the acquisition of the larger and newer types. As to whether or not this extension of property was consistent with the growth of business naturally depends upon how the acquired lines may have increased the amount of business in relation to the amount of property. It is not desired to elaborate here upon the principles of the proper rate of growth of property, but merely to state that the method of computing the proper growth would be to determine the gross revenues per locomotive owned, affected somewhat by the characteristics of the lines added, as to their ability to function on a high or low unit train tonnage basis. Nevertheless, the growth of property represents a serious problem in the matter of having back shop development keep pace therewith and of getting continuous use from power.

Fig. 1 also shows (by heavy dot-and-dash line *C*) the increase in the average size of locomotive expressed by the mean tractive effort pounds per locomotive owned. The size of locomotives is an element in the unit cost of maintenance and it will be noted that this figure increased from approximately 24,000 tractive effort pounds per unit to 36,000 pounds in 1924 or approximately 50 per cent. The chart is confined to steam locomotives only, electric locomotives being a separate and distinct problem. It is not possible to state whether the growth in locomotive ownership increased more or less than the revenues or the average train load as this data is not available from the subsidiary and leased lines.

The feature in Fig. 1 deserving of closest study is the line *D*, representing the frequency of back shop repairs. This is arrived at by dividing the total yearly classified repair output into the total owned throughout the year, which expresses the number of years between shoppings thus developed and this, of course, varies from year to year according to the difference in the number of locomotives owned or used and the output. This is based upon a classification of repairs instituted during federal control and is translated back to 1912. It may be generally conceded that this classification is not sufficiently specific to be a complete measure of output, since the divisions are not based on work units to a great enough degree to permit of judging shop output in detail.

Results of low frequency shopping policy

The variation in the trend of line *D* is entirely dependent upon the allotment of labor and materials available for maintaining equipment. The shopping frequency increased gradually from 1912 to 1920, and during the latter year locomotives were going through at the rate of once every 14.28 months. In 1921 a committee was appointed to report upon the economics of shopping power, as a result of which it will be noted there was a radical change in the frequency of back shop classes of repairs subsequent thereto. This study related particularly to the situation existing on the Chicago, Milwaukee & St. Paul and is not offered as a criterion, for the reason that other conditions often determine whether or not such a policy is applicable to any but a specific case. The frequency of shopping trend, expressed both in years and in months between shoppings, was as follows:

Year	Years between shopping	Months between shopping
1920	1.19	14.28
1921	2.20	26.40
1922	3.30	39.60
1923	2.50	30.00
1924	3.70	44.40

The change in plan necessarily brought about some modification in the distribution of machine tools and facilities in back shops and roundhouses. Great care had to be employed to avoid deferred maintenance under such a transition, because of the great cost incident to overcoming deferred maintenance promptly and adequately, were this condition to have obtained. The roundhouses were partially equipped to do the necessary machinery and running repair work and in some cases rather heavy boiler work, so as to properly maintain the power for longer periods, some of the facilities being transferred from the back shops to the roundhouses. The back shop forces were reduced in proportion.

Prior to the change all judgment as to months good for, miles to be run between shoppings, etc., was based on the theory that locomotives were good for a term of 12 months only and, consequently, much data was prepared to show that this attitude was not in keeping with the operation of the property and, therefore, should be adjusted to the new method. Prior to 1921 there was no specific application of the plan of assigned mileage to be used as a basis for shopping power. This method was put into use at that time and a statement prepared showing the expected mileage to be run out after each classified repair, divided according to types of power. It is important that the same mileage should not be applied to the same type of power regardless of where or how used and in this respect an assigned mileage for each class of service, type of power and for each division instead of for the system as a whole is necessary in practice, otherwise classified repairs will be made in roundhouses, but not so reported in order to avoid breaking the mileage.

As to the results obtained from this change of plan, it should be understood that there were some wage and material price variations since 1920, but these adjustments account for approximately 14 per cent of the reductions attained. The cost trends on the chart merely indicate the actual reductions with no separation between fluctuations in the cost of material and labor, shop efficiency, etc. The cost per locomotive mile (line *C*) during the high wage period of 1920 had reached 34 cents, when the shopping frequency was 14.28 months, and since the frequency of back shopping was reduced the cost has steadily declined and in 1924 was less than 26 cents. This represents a reduction of approximately 24 per cent. The cost per tractive effort pound was reduced from 27 cents in 1920 to 16.5 cents in 1924 or 39 per cent. The cost of repairs per locomotive owned was $9,300 in 1920 and $6,000 in 1924, or a reduction of 35 per cent. The cost per thousand tractive effort ton miles was reduced from 1.075 cents in 1920 to .676 cents in 1924 or 37 per cent. In the meantime, the average size of locomotives increased 6 per cent. The method of measuring the cost of repairs per tractive force ton-mile was to take the tractive force pounds owned, reduce them to tons, multiply by the total locomotive miles run in thousands and divide this into the cost of repairs, Account 308.

This principle of shopping locomotives is in no sense special or peculiar. As to whether or not a policy as outlined could be taken as a criterion, it would be difficult to state. The plan was adopted for the C. M. & St. P. because it appeared to be properly applicable. It is a matter of interest, however, to make a study of ten carriers, where there is a wide range of policy, using the same units outlined above. The value of the units used cannot be considered as entirely intrinsic and for that reason the method employed should not be considered as absolute. Fig. 2 is offered as a result of a study of various carriers, some having a high frequency and some a low frequency method. In plotting the data, scales were used merely to throw relative items together in order to indicate those which run in a certain ratio and those which run inversely. The horizontal scale is the average tractive force pounds per locomotive owned to show the size maintained. The data is based on 12 months in 1924.

How size of power affects performance and unit costs

In the matter of performance the average miles per locomotive run per year is shown in line *A*, Fig. 2, and this indicates a difference in performance which does not follow relatively the variation in size of power, indicating many degrees in intensity of use, etc. The mileage

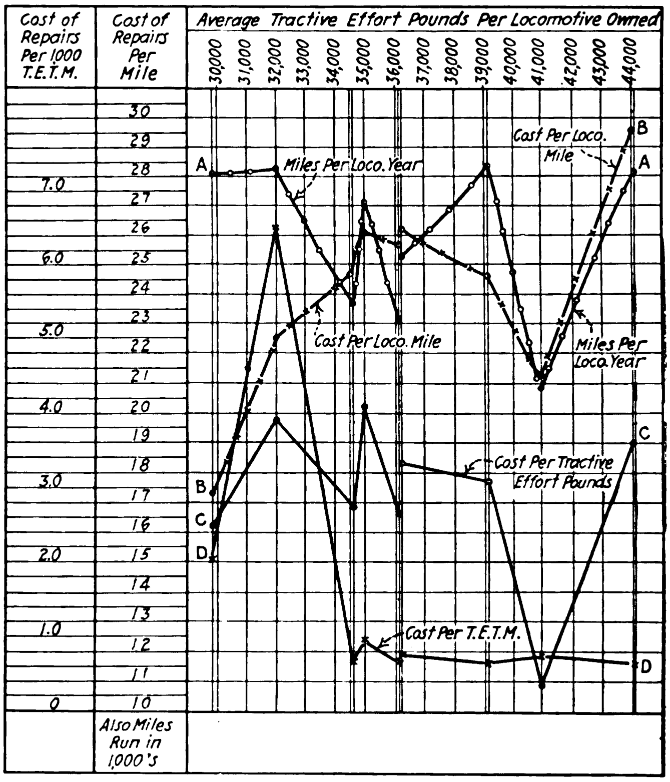

Fig. 2—Comparison of cost of maintaining steam locomotives considering average size, average miles, cost of repairs per mile per tractive force pound, and per 1,000 tractive force ton-miles

ranges from 20,800 to 28,476 per locomotive per year. The carrier with the largest size of power made practically the same mileage per locomotive as the one with the smallest size of power shown on the chart, whereas those administrations with locomotives of a size ranging between the two extremes made less mileage per locomotive. This may be considered an element of performance and demand characteristics of the lines involved. In this case the highest mileage was 37 per cent greater than the lowest shown.

The cost per locomotive miles as shown by line *B* is low for the carrier having the smallest size of power, being less than 17.5 cents and is high for the one having the larger size of power, the upper range being a little less than 30 cents per locomotive mile. The average size of power expressed in tractive force pounds was 47 per cent greater in the largest average size as compared with the smallest average size, whereas, the cost per mile was 71 per cent greater for the larger than the smaller power so that it may be said that in this case the cost increased one and one-half times as the unit size of power in-

creased. This figure itself cannot be considered as entirely significant.

The cost of repairs per tractive force pound does not run in direct ratio with the increase in size. It will be noted that while the smallest size of power has the lowest cost of repairs, the largest size of power does not have the highest cost of repairs, both being exceeded by carriers having locomotives of intermediate capacities. The composite factor of cost of repairs per thousand tractive force ton miles, followed somewhat inversely with the capacity of power owned, with variations in the intermediate sizes. Here it is interesting to note that the smaller size of power cost more than the large power, the result being due, in this case, to the carrier with the larger power running about the same mileage per unit as the carrier with smaller power.

In general, it has been found that carriers using large size of power have a fairly high frequency of back shopping, which is of great interest in this study because it is evidence, for the most part, of intensive use and a more or less uniform power demand. Thus far the frequency has been stated in terms of time only. It is affected very largely by the rapidity with which mileage is run out and, therefore, in a general way, reflects whether carriers are long or short in their power ownership.

This data indicates that as the average tractive force pounds owned increases, the cost of repairs per mile increases in a rather definite way; that the average miles per locomotive run and the average cost of repairs per tractive force pound have the same range characteristics; and that the average cost of repairs per thousand tractive force ton miles varies somewhat inversely with the average tractive force pounds per unit owned, with intermediate fluctuations.

Limitations of the units used

In using tractive force ton miles as a unit of measure, in this case, it should be understood that there is a variable feature in the actual amount of capacity employed as compared with the maximum available. Maximum or ruling gradients, scheduled tonnage, etc., are factors in determining how near the available capacity is utilized as compared with the maximum at hand and the studies shown here are made only with the intention of indicating that, regardless of any units of measure used, there are local conditions which determine the differences in the showing made. This unit of measure does not include the work performed—that is, the tonnage hauled—which if added would doubtless give trends differing from those shown on the chart. The tonnage hauled is a matter of record in freight performance only, whereas the data thus far considered applies to all classes of power.

Statistics are now available to show the gross ton miles per freight train hour, which is a fair measure of locomotive performance when considering the average size as well as the number of units employed. This reflects efficiency in train handling as well as corresponding utilization of power and where there is prompt turning in roundhouse care and running repairs fewer locomotives may be used for a given traffic and thus build up a reserve and maintain a proper shopping period. It is necessary, of course, to apply such data to road engines only and this can be done with the information at hand. The variation among carriers in such performance is quite extreme, some having as high as 26,000 and others as low as 12,000 gross ton miles per train hour. This difference is far greater than the average size of power and other influencing factors, such as grades, curvatures, signal stops, etc. This leaves open to study the question of greater development along the line of utilization of power and consequent shopping methods.

Relation between running and classified repairs is significant

Just what effect the specific policy followed has on the trend of the cost of repairs is not thoroughly ascertainable, but it would seem that a minimum cost may be expected when it has been definitely established that a proper balance between classified and running repairs has been arrived at. No specific formula for reaching this division has yet been developed. A study of the cost of repairs per mile divided between running and classified work does not present a solution, because whenever it is necessary to decrease or increase forces and expenses, the fluctuation is felt directly in the back shop and only indirectly in the roundhouse. There is no argument against the great need of having uniform forces and avoiding the closing of shops, because excessive fluctuations in forces cause repair programs and the continuity of work to be disrupted, besides it destroys discipline. Shop output is, generally speaking, directly affected by fluctuations and expenses and this seriously affects the frequency of classified repairs.

Our experience has developed the fact that the application of the assigned mileage for each type of power, regardless of its use, is not sufficiently specific and such process, when employed, needs revising by developing an assigned mileage for each type of power and for each division, so that the local characteristics as to track, curvature, gradients, service, consequent tire and lateral wear, and boiler repairs, can be considered as factors. Theoretically, it is possible to group repairs into time cycles, but time is only one of the elements of shopping power. As the frictional wear is mostly overcome in roundhouses the time element for shopping power resolves itself very largely into cycles based on necessity for heavy boiler repairs.

Factors used in fixing assigned mileage

The factors used on the St. Paul in the general plan of shopping are assigned mileage, time, and actual physical condition based on frequent inspections. Where there is a low rate of run-out mileage, time enters into the calculation to a greater degree than where mileage is run out rapidly. It can be arranged to set a limit of expenditures for the various types of power according to the class of repairs to be given, any over-expenditure to be reported and explained, so that extraordinary repairs may be a matter of record.

The regulation of frequency of repairs to locomotive parts is a matter of long range study and the cycling of repairs cannot be followed specifically in all cases, although it has been our general policy to endeavor to follow a Class 3 repair with a Class 4 or Class 5, then another Class 4 or Class 5 and then a Class 3; in other words, having two minor repairs between two major repairs. This depends on the nature of service performed and the severity as well as the rapidity with which mileage is run out. It cannot at the outset be presumed that we can obtain approximately 50 per cent of the mileage between classified repairs for the first Class 3 repairs and then 25 per cent for each of the minor repairs, as experience has developed that tire and lateral wear develop and become due for renewal just as soon after a Class 3 as after a Class 4 or 5 repair. It is well to contemplate a distribution of the mileage making it equal for each class of repairs, but regulate the cost of each shopping accordingly.

A study of shop and roundhouse facilities cannot be

summarized in terms of specific units, so as to outline the direct effect upon policy and the results thereof. It involves the number of roundhouses per mile of track, the frequency of turning locomotives or the miles run between turnings, etc. As a matter of interest, during the time the St. Paul was undergoing the change in policy referred to, we also made studies of engine house operation, not only as to repairs made, but as to the cost of turning power, frequency of turning, etc., with results shown below:

Transportation expense not maintained

	1922	1923	1924
Average turnings per month	53,572	59,784	54,911
Average cost per month	$430,492	$384,969	$331,830
Average cost per engine turned	8.30	6.44	6.04
Average cost per engine mile	10.25 cents	8.35 cents	7.68 cents
Average miles run between turnings	78	77	78

No comparison can be made with other carriers in this respect, because it is found that the methods of counting engines turned, the accuracy of distributing charges, the nature of roundhouse facilities, etc., vary too greatly. The above is merely shown to indicate that the trend in other expenses affected by locomotives was downward the same way as indicated in Fig. 1. It is very apparent that the frequency of turning power decreases with the increase in average distance between roundhouses, and that the average miles per engine turned will increase with the spread in distance between roundhouses.

We have not been able to observe any adverse effects on the turning of engines because of decrease in frequency of back shop repairs. It might have been assumed that so low a frequency as was developed in the change of policy would throw too much of a burden upon roundhouses for intermediate repairs and increase the hours of detention.

The formulation of specific policy of back shop attention to power, therefore, must consider a wide scope of performance, embracing amount of property owned in relation to the demand and use thereof, the type and size of power, shop and roundhouse facilities and their relation to each other, road conditions, rapidity with which mileage is run out and restored, the ability to maintain a minimum but uniform force in back shops throughout the entire year, the ability in addition to increase the rate of repairs in the low peak loading months so as to have a larger supply available for service in high peak months, the range of variation between high and low peak months, etc. Where back shop and roundhouse facilities are modernized by means of machine tools, power plants, handling devices such as cranes, hoists, tractors, manufacturing devices and an adequate store stock, it should be possible to determine closely the final balance between classified and running repairs with its relation to the cost of performance expressed in various units of measure, some of which were outlined above.

Effect of more intensive power utilization

The utilization of power requires careful and detailed study because any variation must, of necessity, have a marked bearing upon shopping policy. In cases where the per cent of power in service is low compared with the total owned it is usually found that the hours of service per day are low or approximately six, then it is possible to have a large waiting list and to turn locomotives less rapidly through the shops and still have ample protection.

A campaign to reduce the number of units in active service to a minimum consistent with traffic handled, based on the average miles per locomotive dispatched or the average miles between locomotive turnings (enginehouse operation) will necessarily avoid the purchase of new equipment for the purpose of increasing the complement because when longer runs are installed and fewer locomotives are used for a given service this naturally builds up a surplus. Intensive service requires a revision of the method of repairs and in some cases calls for a higher standard of repairs than where more locomotives are used in the same service. The objective should be to get more locomotive miles per month out of fewer active locomotives and to get more hours of service per day out of each locomotive, then other factors will naturally increase the gross ton miles per train hour.

Modern tools and facilities save locomotive hours

Where orders are issued to shops for locomotives of a certain character to be made ready for service on short notice, the time factor, as regulating the date of delivery, is often a matter of supreme importance. A study of this question soon brings to light an intricate problem with which supervisors and others in authority have to grapple. One of the outstanding factors is that of the machine tool and material handling equipment, with which is identified the means of producing work rapidly and to the best advantage. Many of the latest machine tools, cranes, tractors, etc., are conspicuous for the facility with which they can be operated, the controls being conveniently placed, thus saving time in setting up and subsequently handling the machine.

Another equally vital point is that of the organization of the work, which must, if time is to be saved, be planned on a definite and progressive system. All these measures are applicable to old as well as the most modern new shops, however, they are likely to lose much of their value unless the workmen themselves co-operate in the avoidance of time wastage. It is only by strict co-operation of everyone concerned, combined with proper shop systems and the use of tools and facilities fully adapted to their purpose will rapid production be assured.

Need of a comprehensive program for future improvement

One point of serious practical importance remains, namely, that the designated mechanical officer should place before his executive a practical and sound analysis of the requirements for the upkeep of motive power, shops, power plants, tool equipment and recommendations for expansion or rehabilitation to reduce existing unit expenses known to be out of keeping with the possibilities for best achievement. In making submissions for proposed expenditures, they may be grouped under items of savings as dealing with: (1) fuel, (2) labor, (3) materials, (4) delay to train movements, and (5) accident or personal injury prevention.

It is regrettable and not a little surprising that in fixing ordinary running expense and upkeep, the budget allowance to be approved by any administration should fail to be based upon the requirements of traffic or operating conditions, complying with a general policy formulated to properly care for conditions in the most effective and economical manner and not altered to fluctuate with current temporary drops in traffic, which are often seasonal. What should be arrived at is a reasonable maintenance standard for the property as a whole. The basis should be gaged from a consideration of the general earning capacity and also upon the kind and class of traffic handled. With this part correctly fixed, slight fluctuations in business should not materially alter the progress with the view toward stability of employment and proper discipline and administration of the work.

The motive power man is only as successful as his

management will let him be. This is one of the reasons why so many able men have left the railroad service for other more productive fields. Every motive power man of wide experience knows what the lack of executive support means, and is also aware of what the hearty support of the management as a whole means toward a comprehensive and successful operation. The best policy on earth avails little if it does not have the support from the top of the organization down to the lowest man of the rank and file.

The foreman and his responsibility

First prize article in the competition recently held by the Railway Mechanical Engineer

By "Bill Brown"

A NUMBER of years ago, while working in a railway shop, I became a member of the city band. It was practicing nightly as it had entered as a contestant in a band tournament to be held shortly in a neighboring city. Practically every one in the small city was interested in having our band win. Several of its members worked in various departments of the shop, although I happened to be the only one in my department. One of the foremen, in conversation with the one to whom I reported, happened to mention that quite a number of the shopmen would be off work on the following Wednesday because of the band going away.

"Well," said my foreman, "none of mine will go!"

"But you have Bill Brown over there," said the other foreman. "He is playing a clarinet and will most likely go."

I saw them talking together but had not the slightest idea what it was about. Suddenly I realized that my boss was rushing over to my machine. Almost out of breath he commenced: "I hear you are going off with the band next Wednesday."

I replied: "Those who are to go have not yet been announced. Only 25 can be entered and we have 30 members."

But before I could get that far, he was waving his finger in my face saying: "Let me tell you young man, if you had gone without first asking my permission, you would never have got back here again."

"Why, Mr. ———, I had no intention of ———"

"That's enough! I want no back talk," said he and walked away. (He sure was making use of his opportunities.)

Later, in another railway shop, I started working for 19 cents an hour as a lathe hand and was promised an increase if my work proved satisfactory. Some months later—the day after pay day—I noticed my foreman paying more attention to my work than usual, going by and looking at me quite frequently. I began to wonder if something was up. He even spoke to me about the form of tool I was using, which I thought quite nice of him, since it gave me an opportunity to air my ideas on lathe tools. Then suddenly he asked if I had found anything the matter with my pay check the day before. I innocently remarked: "Nothing more than usual, for my wife has found some difficulty in making it cover our expenses." Then he opened up and called me the most ungrateful man who had ever worked for him, because he had got me an increase of half a cent an hour and I was not man enough to acknowledge it. Well the truth was that with the broken time we were working, I had not noticed the extra 40 cents and only got in worse trying to explain matters.

He certainly was attempting to fulfill his responsibilities all right. With these two examples before me, I remember making a resolution that if ever I became a foreman, I would never be like either of them.

The new foreman

To be more concrete let us consider the opportunities and responsibilities of a machine shop foreman who has just been appointed. At first, he may find himself under something of a handicap, whether he has been brought in from an outside point and placed among strangers, or promoted to be a foreman of men with whom he has been working for years. In either case he may naturally have to contend with a certain amount of what I may call quite reasonable envy, not necessarily malicious. There is bound to be one or more among those not chosen who could reasonably expect to have been promoted instead.

I would suggest, therefore, that when he is promoted he call his men together and say something like this: "Now, fellows, without any influence being used or any extraordinary efforts on my part, I have been given this position. I expect to make a success of it, but must have your hearty co-operation. Whatever opinions we may have formed of each other in the past are buried. We are starting off with a clean sheet. I do not want any one of you to be more square with me than I am with you. I want our relationship to be one of mutual helpfulness and pleasure, consistent with making it the success expected of us by our company. I shall want things done my way because I will be held responsible, but you will find me ready at all times to discuss your way and adopt it if you can show that it is the better way. Because I am the foreman, it does not follow that I know more about everything in this department than you men and the one making a good suggestion will be given the fullest credit."

Having thus started his career, our foreman should ask himself at the end of each day just how far he has fallen short of his responsibilities and opportunities as outlined for himself at the start; also if any of his men have failed in theirs. He can be as severe with himself as he pleases, as it is his own affair, but how will he handle those of his men who he is sure are not giving their best efforts? They must be studied individually. What could be said to one with good results, would fail utterly with another. Of course, I am assuming that the foreman wishes to keep his men and get them working with him and not to make use of his authority to let them go. That should be done only as a last resort.

Keep posted about railway affairs

He should try to acquaint himself with his men's point of view of things in general; and be ever ready to explain,

if asked, such workings of railway management as he is capable of, why short hours are sometimes necessary, the operating ratios, fuel saving, taxation, rates, etc. To become fairly well posted on these subjects, it is not necessary to devote more than one-half hour each evening to the columns of *Railway Mechanical Engineer* and the Railway Age. In fact, to keep in touch with the latest railway shop practices and the workings of the other important departments, it is essential that he be at least a casual reader of these journals. The more he studies them, the more he will realize what his responsibilities and opportunities really are. The advertising columns alone are an education.

Treatment of new employees

The new man you take on is just as anxious to make good as you are to have him. The foreman's responsibilities and opportunities in this respect are very pronounced. If the new man is taken to his machine, given a job and a blue print and told to get busy, he may possibly succeed in giving a good account of himself. If, on the other hand, he is told, in a friendly manner, a few things about the shop, its methods, number of men employed, just how to obtain tools from the tool room, who to ask for information he may need, and that he is not expected to make a record the first day but to accustom himself to his surroundings first, and then go ahead, it will make a great difference. If you happened to notice when you hired him that he wore a fraternal pin, if he is an entire stranger it might be well to say to Bill Jones (if Bill also wears a similar pin on his best clothes): "Say, Bill, you might take a little interest in that fellow for a few days. He is a stranger in the shop. I believe he will make good as he has been well recommended and we will give him every chance."

Of course the foreman should first be reasonably sure that the man has the ability required. It is not necessary to hold every man who starts, but the greater number who are held, the less the labor turnover and consequently the greater ultimate shop efficiency.

New tools or machinery

The foreman should at all times be familiar with the prices and types of various tools that could be installed to advantage in his shop or department. He should be ever ready, on a few hours' notice, to state definitely just how five, ten or fifty thousand dollars could be economically expended on machinery or devices for improving the production of his department. A close study of the advertising pages of the previously mentioned journals, a few days spent in visiting shops where such machines are in service, or the writing of a few letters to other foremen, are all productive of a wonderful amount of valuable information to be kept ready at hand for just such a time as this. It is most inexcusable for a foreman not to keep himself thoroughly posted on the latest products of the machinery builders which can be profitably installed in his department.

The sales engineer

There are certain shops where the foremen are not permitted to meet any of the sales engineers. Those who are privileged to meet such representatives and discuss new machine tools with them are certainly losing opportunities in making unsound excuses for not doing so. These men as a class are far from being ordinary peddlers. They generally have an interesting story to tell and the writer has often been obliged (gladly) to work extra hours because of having spent some of his time during the day investigating the claims and merits of various machines or devices with which he was unacquainted; and has felt amply repaid for so doing.

The foreman's relationship to the foremen of other departments should be the same as that of each member of a successful baseball team to the others—team work at all times. He should not be delighted to see the other fellow get into a hole but be more than ready to assist him to keep out of one. The opportunities for this display of inter-department team work are so numerous they can not be listed. I am calling attention to them because there is an altogether insufficient amount of this sort of team play noticeable in many railway shops.

Conservation of material

A great deal has been written about the wonderful work of the reclamation departments, but foremen should realize that before a great deal of this material can be reclaimed or salvaged, it must first pass through his department as scrap. He must see that nothing goes out in the scrap to the reclamation department which is merely sorted out and returned to him to be used again.

Among the most important of his responsibilities should be the systematic gathering and indexing of many useful facts in connection with his department, such as the comparative value and cost of leather and fabricated belting, cost of such standard articles of daily use as monkey wrenches, hammers, taps, hack saws, nuts and bolts, oil for machinery (who is using the most of these things and why), the comparative cost of electric and acetylene welding and cutting processes and the amount saved weekly by their use. These are but a very few of the large number of very ordinary everyday facts foremen are frequently found to be unacquainted with. Lack of space alone prevents one from dwelling at greater length upon such an important subject.

Attitude toward apprentices

Perhaps his greatest responsibility is in his relationship to the apprentice boys under his charge. These boys come to him fresh from the school teacher. Possibly he is the first man they have ever worked for and, at first, perhaps they should be looked upon as one does upon a frisky colt when first being broken to harness. Much of the boy's future success in life depends upon how the foreman handles him during this important formative period of his career.

Even if there is an apprentice instructor devoting his entire time to the boys, or if the boy is turned over to the charge of a gang boss, take time occasionally to stop and ask him how he is getting along, and how he likes his work. Endeavor to start him thinking by asking such questions as will make him investigate things for himself, such as why do you think we superheat locomotives, why do they apply boosters to engines, is the air pump operated by superheated or saturated steam, how do they get water into a boiler, and hundreds of other and varied questions, always having one ready to ask him. Note the pleased smile when your boy at last gives you an accurate reply. Then congratulate him. A pat on the shoulder and a few words of encouragement from his boss from time to time are never forgotten and cost you nothing. Remember too, these boys are always pleased to get your mechanical journals when you are through with them. Mark an especially interesting article occasionally and pass it around among the boys; then discuss it with them later. You will hear some interesting comments.

One of the most pleasant of many experiences with boys was that of recently being surrounded by about twenty bright apprentices and listening to each one try to explain to me the reading of a 24-inch Brown & Sharpe vernier. They had been asked the week before if they could do so and upon replying they could not, were given a week to try to find out. Many went to the public library for in-

formative articles. Others looked up tool catalogues. Altogether it proved to be a very interesting talk and helped impress one with the responsibilities and opportunities of a foreman in this respect.

I cannot close without making some reference to the responsibilities and opportunities in being thoroughly systematic in so routing the work through the shop as to be able at all times to determine what caused a delay to a pre-arranged schedule of production. To be able to say justly: "Thou art the man," is a most important opportunity and until the foreman is able to do exactly that, even if the "man" is himself, he is not living up to his responsibilities.

Many other aspects of the question could be presented at some length, including the responsibilities in connection with those directly superior to him, his opportunities for boosting the worthy men under him and seeing that they are given proper recognition, his relationship to the stores department, his connection with and support of such work as safety first and first aid, and his interest in shop sports, baseball, football and even horseshoe pitching, etc. These are his responsibilities and opportunities.

Santa Fe apprentice instructors meet

The three-day conference at San Bernardino proved to be more than ordinarily successful

THERE are many features which contribute to the splendid results the Santa Fe derives from its system of apprenticeship training. Once each year the apprentice instructors of the system, some three-score-and-ten in number, are assembled under the leadership of F. W. Thomas, supervisor of apprentices, for a three-day convention in which to discuss methods and practices relative to the training and development of apprentices. Besides talking shop with each other and discussing matters directly bearing on the work of the apprentice department, they also have the benefit of the advice and council of many mechanical department officials who attend these conventions and take active part in the deliberations. The instructors also have the opportunity of listening to addresses from system staff officers on subjects relating to their respective departments and to discuss in an informal way with these officials matters in which they are directly interested.

It has been the custom to hold these conventions on a different grand division of the system each year, thus giving the instructors an opportunity to become more familiar with the road as a whole and to observe the equipment and learn of the methods and practices used in different shops. The conventions for the three preceding years were held in turn at Topeka, Kans., Galveston, Tex., and Albuquerque, N. Mex. This year's convention was held at San Bernardino, Calif., April 23-24. Last year the instructors had an opportunity to visit the company's new up-to-date shops at Albuquerque and this year to see the new shops now being erected at San Bernardino.

In order not to take up space desired by the traveling public in regular sleepers, the instructors enroute to and from the convention were carried in two special sleepers, thus giving them an opportunity of mingling with one another, of talking shop, comparing and discussing in an informal way methods and practices in which they are jointly interested. It was interesting to note how the car department instructors, or the boiler maker instructors, or some other group would get together in the Pullman smoker or elsewhere and talk over their special problems. Many of the instructors reported fully as much real help from these informal discussions while enroute to and from the place of meeting and between sessions of the convention as from the convention itself.

This year's convention was reported to be the best ever held, more interest and enthusiasm being shown than ever before. Four supervisors of apprentices of other roads, all former Santa Fe apprentice instructors or graduates, were present and took part in the discussions. H. S. Wall, mechanical superintendent, A. G. Armstrong, superintendent, San Bernardino shops, and all master mechanics of the Coast Lines attended each session, taking an active part in the meeting. Other Coast Line officials and many foremen from the local shops attended certain sessions. The following staff officers addressed the convention: George Austin, general boiler inspector, T. S. Stevens, signal engineer, E. J. McKernan, supervisor of tools, Roy Hunt, fuel supervisor, L. H. Collett, safety supervisor, and E. E. Chapman, engineer of tests. The instructors were welcomed to San Bernardino by the mayor of the city and by the president and the secretary of the Chamber of Commerce, who besides boasting of their city, as only Californians can do, stated that the railway was the backbone of their city, and that the city's welfare was closely linked with and dependent upon the welfare of the railway.

Mr. Wall in his opening address said that two prominent mechanical officials of other roads had told him that when a Santa Fe apprentice graduate asked for work, they always made a place for him; they knew he would be a skilled all-around mechanic. It was an evidence of the thoroughness of the training given apprentices on the Santa Fe that other roads not only come to study the methods used but that several of them had employed apprentice instructors from the Santa Fe to install and conduct apprenticeship systems on their roads. He pointed with pride to the list of 240 apprentice graduates who are now filling official positions on the road, seven of them being division master mechanics. He urged the instructors to renew their efforts to leave nothing undone that would make the apprentices better mechanics and better citizens.

The following outline of a few of the subjects discussed will be of interest and reflect the thoroughness of the methods used by the Santa Fe in the training of apprentices.

Boiler maker apprentices

The discussion relative to boiler maker apprentices embraced three features of boiler maker apprenticeship—Federal rules, autogenous welding, and the Locomotive Folio. Each boiler maker apprentice is provided with a copy of the company and Federal rules on maintenance of boilers and appurtenances thereto and is required to study these rules. At stated periods in the school course he is required to answer in writing certain questions. He

first roughs out the answers on a scratch pad, then submits them to the shop instructor who ascertains if he has a clear understanding of the rules covered. The apprentice then, as a part of his school course, neatly prints out the answers. The shop instructor also quizzes him while he is actively engaged in boiler work in the shop to see that he knows and understands the rules pertaining to the work on which he is engaged.

The discussion as to welding covered the amount of welding experience to be given each boiler maker apprentice, the use of the welding folio, the value of requiring the apprentices to make test welds and thereby prove their ability to do good welding, and how to provide sufficient experience for apprentices at points where opportunities are limited.

The Locomotive Folio is a book of standard practices for the system. The apprentices are made familiar with and taught to obey its instructions. The rules in the folio are taught in much the same manner as the Federal rules. At the close of the discussion of the subjects pertaining to boiler maker apprentices and after the address by George Austin, general boiler inspector, the boiler maker apprentice instructors went into conference with Mr. Austin, and discussed various features of boilers and boiler work.

Car department apprentices

Considerable time of the convention was devoted to the discussion of carmen apprentices, the schedules of shop work assigned carman apprentices, the portion of time to be devoted to steel and to body work, the relative value of the different classes of work in the coach shop and cabinet shop, the importance of all freight carman apprentices having a thorough knowledge of A. R. A. Rules, and methods of teaching these rules. It was the general opinion that the carman apprentices now in service were doing exceptionally well and that as they were graduated the road would be supplied with carmen of much greater than the average ability and training. C. N. Swanson, formerly superintendent of the Topeka car shops, was present and took part in the discussions.

School room schedules

Schedules have been adopted showing the time allotted for each series of lessons assigned the apprentices in the school room. These schedules have been effective in increasing the amount of school work completed. Each apprentice is advised of his standing and at most places the record of all apprentices is posted on a bulletin in the school room, thus creating a friendly rivalry and inspiring each to maximum effort. Moreover the supervisor of apprentices is given a monthly report showing how much each apprentice is ahead or behind the prescribed schedule. Some instructors were asked to tell why so many of their apprentices were behind the schedule, others why their apprentices easily made the schedule. In this way many valuable suggestions were received, and conditions pointed out that will be corrected.

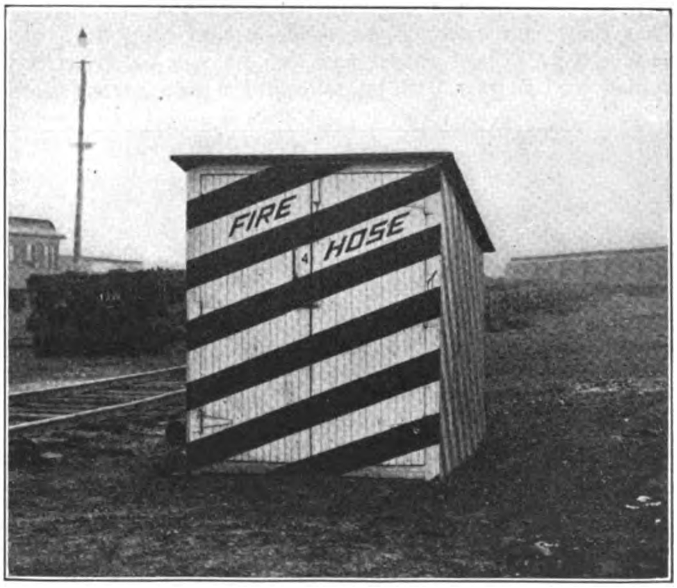
Apprentice clubs

During the past two years, apprentice clubs have been organized at practically all division points on the system. Two system apprentice conventions have been held, one at Albuquerque a year ago and one at San Bernardino the past year. These and the conferences of railroad boys conducted by the R. R. Y. M. C. A. at St. Louis and Detroit have created great interest and enthusiasm among the apprentices and have proved of much help in the development of the apprentice clubs. Through these clubs the morale of the boys has been raised. They are taking greater interest in their work and in the affairs of the community. The purpose of the clubs is to give the apprentices an opportunity for clean sport, a social good time, an opportunity to lead and direct meetings, to bring apprentices and officials and shopmen closer to each other, and to create a greater loyalty toward each other and to the road they serve.

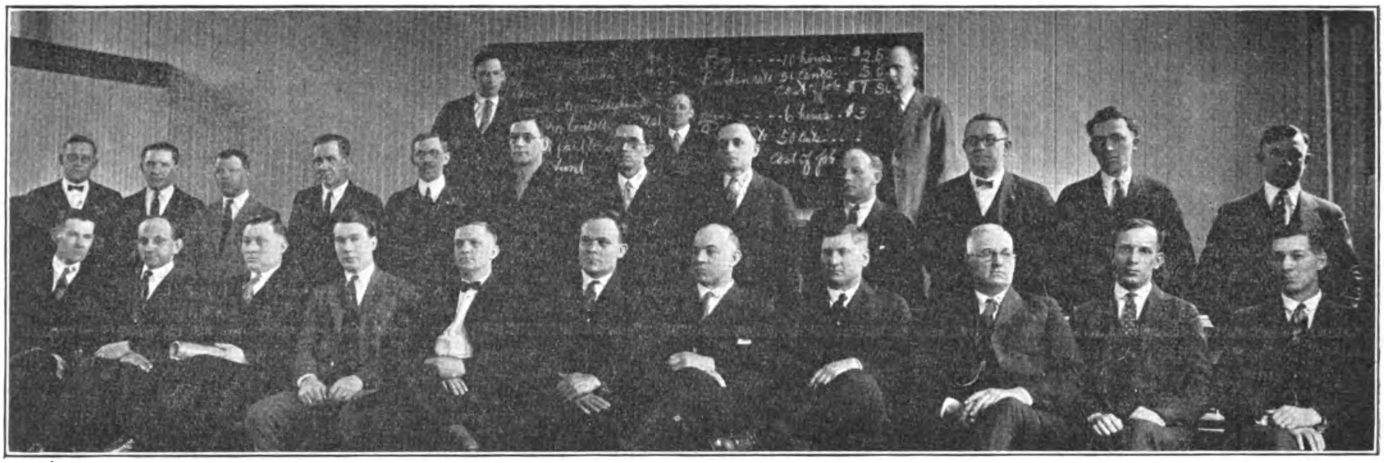
The instructors in reporting the activities of their respective apprentice clubs vied with each other in telling of the good things accomplished. Some clubs had devoted most of their activities to athletics, others had had debates and lectures, others dances and other forms of entertainment, several had put on theatrical events, one club had pulled off a real wild west rodeo, had contributed generously to the rebuilding of a church that had been burned, also to a community hospital, and through a paper of its own had carried on a successful campaign against shipping by truck. From the reports of the activities of the various clubs, the instructors received ideas which will enable them to assist their clubs in making even greater progress during the coming year. It was agreed by all that these clubs and these system apprentice conventions and the national conferences of young men were productive of much good and should receive the hearty support of all who are concerned with the training and development of young men.

There was an exhibit of shop kinks, each instructor having been asked to bring to the convention at least one jig or labor saving device, or a model, print, or photograph of it, gotten up by him or used in his shop, which he thought could be used to advantage at other shops. These proved interesting and helpful.

The addresses by staff officials were most instructive. T. S. Stevens spoke on automatic train control, Roy Hunt told how the shop man could aid in fuel conservation, L. H. Collett, talked on safety, E. J. McKernan talked on tools and shop machinery, congratulating the instructors on their assistance during the past year and showing where further reductions could be made in the expense chargeable to tool account. E. E. Chapman told of the work of the test department and of assistance the instructors could render. All-in-all the convention was a most instructive and inspiring one.



Effective method of marking fire hose stations at the North Billerica shops of the Boston & Maine



Members of the Lehigh Valley foremen's training class at the enginehouse and annex, Seneca Division, Sayre, Pa.

Training foremen in leadership

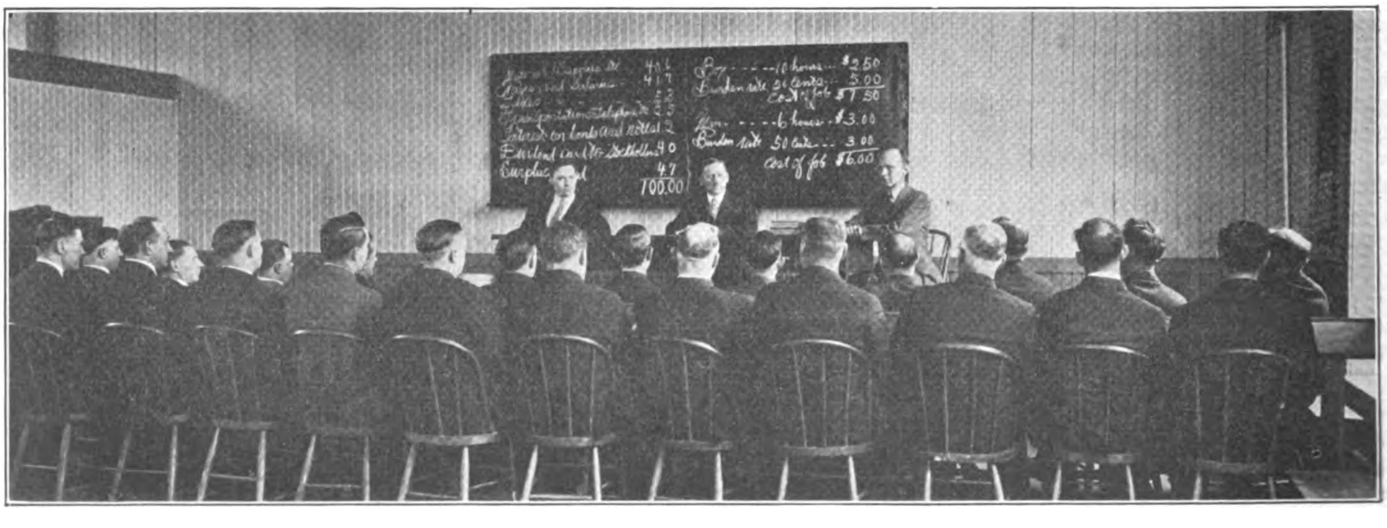
This movement, which started in a small way a few years ago, is now going forward rapidly

THERE has been no more striking development in industry and transportation in recent years than the growing recognition of the importance of leadership ability on the part of the foremen and supervisors. Much stress has in the past been placed upon materials, methods and practices, but too little attention has been paid to the human element. Henry Bruere, a director of the Chicago, Rock Island & Pacific and the third vice-president of the Metropolitan Life Insurance Company, made the statement before a recent meeting of the railway employees' magazines' editors that "the biggest undeveloped asset (on the railroads) is within the ranks."

The foremen and supervisors who come in direct and intimate contact with the men in the ranks carry the responsibility of so leading and directing the workers that they will be developed in a large way to the limit of their capabilities and will co-operate to the utmost. This does not mean that the workers will be forced or driven, but rather that each man will be used on that class of work for which he is best suited and that he will be so wisely directed and helped that he will find a real satisfaction in his work and will utilize his peculiar talents in the most effective way to the mutual advantage of himself and his employer.

Many foremen have recognized their responsibility and opportunities in this direction and have given much thought and study to developing leadership ability. Unfortunately, however, the surface has barely been scratched, so far as the railway field as a whole is concerned. A study of the situation has been made by the *Railway Mechanical Engineer* and the purpose of this article will be to outline the various steps which have been taken by different railroads to train and inspire the foremen and supervisors to become better and stronger leaders. It is significant that in many instances the inspiration or "urge" to take this step has come from the foremen themselves.

Replies from about 100 of the railroad mechanical departments indicate that about one-third of the roads (most of them, however, small in size) are giving no special attention to this question, largely because the size of the organizations is such that the head of the department



Lehigh Valley foremen's training class at the Sayre, Pa., enginehouse and annex in session

can keep in intimate touch with all of the foremen and supervisors under his direction. Of the other two-thirds of the roads, several have developed fairly ambitious plans for the training of foremen, although the greater proportion are confining their efforts in this direction to measures which are far from adequate.

Staff meetings

Staff meetings are quite commonly held, varying all the way from daily meetings at the larger shops for half an hour or so, directly after shop hours, to annual meetings in the nature of a convention. It is only fair to say, however, that in many cases these staff meetings deal almost exclusively with detail problems in connection with material and its handling, shop practices and co-ordination of departmental activities, rather than the problem which most concerns us in this article—a discussion and consideration of those things which will help the foreman to get a better understanding of human nature and of how to develop his leadership ability. It is significant, however, that there is a growing recognition of the importance of placing emphasis upon this question of leadership and that more and more attention is being given to it in the staff meetings.

Of the roads which indicate that they hold such meetings at shop or division points, three state that the meetings are held daily, lasting for a short period, ordinarily not exceeding one-half hour; 18 roads state that weekly staff meetings are held; 23 state that staff meetings are held, but the intervals are not specified. One road, the Chicago, Milwaukee & St. Paul, also holds annual staff meetings, the programs for such meetings being carefully worked up and papers prepared in advance, much as is done by a progressive railroad association.

One road has found that splendid results have followed the holding of weekly staff meetings of the foreman with the group of men who work with him. This provides an opportunity for the foreman to talk to the men as a group and to conduct an open forum discussion, thus promoting better understandings. It was said to be quite evident from observation of these meetings that the foremen needed special training and coaching in the problem of dealing with the men and properly leading them.

Several roads hold bi-weekly or monthly meetings at the shops, at which representatives of the shop employees meet with the foremen to discuss shop conditions in general. Such conferences naturally develop better and more cordial understandings and relationships, as well as constructive suggestions of benefit to both the company and the employees.

Foremen's clubs

A variety of programs have been developed by what may be called foremen's clubs, or which in some cases are designated as mechanical supervisors' associations. Readers of the *Railway Mechanical Engineer* will recall the article on "A Comprehensive Plan for Executives' Clubs", by Simeon van T. Jester in the issue of February, 1924, page 79. The foremen's clubs on the Pennsylvania Railroad were described in an address by I. U. Kershner at the meeting of the New York Railroad Club on May 18, 1923; an abstract of this address was published in the Railway Age of May 26, 1923, page 1259.

The clubs as they were first organized on the Pennsylvania Railroad and the Reading usually held seven or eight meetings during the season at intervals of about two weeks. About an hour was allotted for an address, after which the members separated into small discussion groups, spending another hour in open forum discussion, considering the application of the principles which were developed in the address to the specific departments or responsibilities of the men in the group. The successful handling of these group discussions made it necessary for the leaders to get together in advance of the meeting to talk over the points it would be desirable to develop for discussion. Some of the clubs have done away with the discussion period and are now scheduling only an address. The Reading clubs and the Harrisburg club on the Pennsylvania, however, continue to follow the original practice. The Harrisburg club publishes a bound volume each year, containing a report of the addresses and the findings or high points which were brought out in the different group discussions.

During the past year there were nine clubs in the Eastern Region of the Pennsylvania Railroad, including Altoona, Baltimore, Harrisburg, New York, Philadelphia, Renovo, Sunbury, Trenton and Wilmington. The members of these clubs pay annual dues. In most cases the high school is available for the meetings and there is little expense in connection with carrying on the work of the clubs, except for the cost of the speakers. The company shares the expense with the clubs. The end of the season for the Pennsylvania clubs was characterized by a joint meeting of the Baltimore, New York, Philadelphia, Trenton and Wilmington clubs at the Bellevue-Stratford Hotel, Philadelphia, on March 11, an address being made by Samuel M. Vauclain, president of the Baldwin Locomotive Works. A similar get-together meeting of the Altoona, Harrisburg, Renovo and Sunbury clubs was held in the Chestnut Street Auditorium at Harrisburg, Pa., on March 21, Roy V. Wright, editor of the *Railway Mechanical Engineer,* making the address.

The Pennsylvania clubs include in their membership foremen and supervisors from all departments. There is thus not the temptation to deal with detail shop methods and practices or details of operation. The subjects are naturally concerned with the larger problems of management in its various aspects. The program of the Pennsylvania clubs, for instance, included three addresses by Dr. A. F. Sheldon, one on "Principles of Service", another on "Psychology of Human Relations", and a third, "Universal Efficiency Formula". Doctor Sheldon characterized this group of lectures as a part of the science of human engineering, which he called the science and art of man-power development. The other addresses on the Pennsylvania clubs' programs differed more or less from each other. In addition to Doctor Sheldon's addresses at Harrisburg, Superintendent William Elmer made an address on "Maintenance Versus Renewals"; E. E. Griest on "The Foreman as a Business Getter"; Superintendent of Motive Power E. B. DeVilbiss, "Legislation Affecting Railroad Operation"; and John A. Oartel on "The Foreman and Safety First". In contrast to this the Altoona club, in addition to the three addresses by Doctor Sheldon, had one by Dr. A. B. Van Ormer on "Co-operation Among Railroad Employees"; one by W. D. Henderson on "Human Nature and the Changing Order"; and one by Charles Woodward on "Supervision from the Human Standpoint".

Reading Company clubs

Three foremen's clubs open to supervisors from all departments were organized on the Reading in May and June, 1923. The Philadelphia club has a membership of about 430, Reading about 395, and Shamokin about 150. The arrangement of the programs has already been referred to. During the first year the clubs held ten educational meetings and a banquet. During the past season they have held eight educational meetings, one outing and two banquets.

Boston & Maine clubs

Last year four foremen's associations were organized

in the mechanical department on the Boston & Maine. Monthly meetings were held by the members of these clubs on their own time and expense, for the purpose of discussing questions of supervision and efficient shop practice. The railroad management co-operates to the extent of furnishing speakers and, where necessary, meeting places. These four associations or clubs functioned so greatly to the satisfaction of the members that four additional clubs were formed during the past year, making eight in all. The location of the clubs with the membership is shown in the following table. These clubs have held an average of six meetings each during the past season.

Concord Car and Locomotive Foremen's Assn.	65
Billerica and Terminal Junction Locomotive Foremen's Assn.	90
Billerica and Terminal Junction Car Foremen's Assn.	90
East Fitchburg and W. N. & P. Car and Loco. Foremen's Assn.	75
East Deerfield Car and Locomotive Foremen's Assn.	60
Mechanicville-Troy-Rotterdam Car and Loco. Foremen's Assn.	45
Lyndonville-White Mountain Car and Locomotive Foremen's Assn.	50
Springfield Car and Locomotive Foremen's Assn.	30
	505

The tendency, since these clubs are made up entirely of mechanical department foremen and supervisors, has been to go more into the details of mechanical department operations, although the importance of developing a higher quality of leadership has not been entirely lost sight of. Moreover, it is only fair to say that the discussion of the detail mechanical problems has been a large factor in bringing about better understandings between the different foremen and departments and in helping to standardize the best practices. One of the most productive programs during the season was a discussion of the changes in the 1925 American Railway Association Rules of Interchange. There is no question but what the educational material which was developed by this discussion has been responsible for a very considerable financial saving for the Boston & Maine.

Undoubtedly the work of these clubs will be featured in the future by more consideration of questions affecting the directing and development of the human element in the organization. The clubs have formed an Association of Clubs and an attempt is being made to co-ordinate the programs so that the foremen over the entire system will have the benefit of the discussions and questions which arise at any one of the meetings. The Association of Clubs held a get-together dinner and entertainment at Boston on Saturday, May 9, at which brief addresses were made by several officers of the association, by President Hustis and other officers of the railroad, as well as by Prof. William J. Cunningham, James J. Hill Professor of Transportation at Harvard, and Roy V. Wright, editor of the *Railway Mechanical Engineer*.

Other foremen's clubs

The foremen and supervisors on a number of railroads are carrying on activities of a somewhat similar nature.

Central Railroad of New Jersey.—The foremen have recently organized a club at Elizabethport, N. J., taking in the Central division supervisors; and a club at Ashley, Pa., including the Lehigh and Susquehanna division supervisors.

Chicago, Burlington & Quincy.—Supervisor's clubs have been organized and meet regularly at all of the larger points. Foremen prepare papers for discussion on questions pertaining to the handling of men and improved shop practices. Addresses on the art of leadership and other questions of particular interest to the foremen are made by qualified leaders from other fields.

Delaware, Lackawanna & Western.—There is a supervisors' association on this road which holds meetings at least once a month. Officers are frequently asked to make addresses and a monthly leaflet, "The Lackawanna Supervisor", is published under its direction.

Duluth & Iron Range.—A supervisors' club is giving a good account of itself, its purpose being to elevate "the social, moral and intellectual standing of the supervisory force and to cultivate a general spirit of harmony."

Kansas City Southern.—The Mechanical Department Supervisors' Association has a northern division with headquarters at Pittsburg, Kans., and a southern division with headquarters at Shreveport, La. Each group meets once a month and the meetings are alternated in such a way that representatives from one group can find it possible, if their duties permit, to attend a meeting of the neighboring group. Two or three papers are discussed at each meeting. Frequently committees are appointed to follow up some of these subjects and present their findings at a later meeting.

Minneapolis & St. Louis.—A Supervisory Officers' Club has been organized at Marshalltown, Iowa. It holds regular monthly dinner meetings at which papers are presented and topics of interest discussed. It has been a large factor in promoting harmony and co-operation.

Nickel Plate.—A foreman's club is conducted in the local Y. M. C. A. at one of the shops. The programs include addresses on various topics relating to the foremen and their interests, and the railroad.

Northern Pacific.—The foremen at the large shop points have club meetings and other activities in connection with the International Association of Railroad Supervisors and Mechanics. In addition to this, bi-monthly meetings are regularly held at the large shop plants, alternating between safety meetings and staff officers' meetings. The shop crafts representatives attend the safety meetings. Both the staff officers' meetings and the safety meetings are attended by all of the supervisors in the locomotive and car department, as well as representatives from the stores department and the division accountant's office. Ordinarily two papers are presented, prepared by members of the group. This is followed by a general discussion. A report of the meeting, including the papers and the discussions, is furnished to each of the supervisors and copies are also sent to the general officers. It is believed that the preparation of the papers by the foremen and supervisors is helpful in broadening their point of view.

Union Pacific.—Monthly meetings are held by the Mechanical Supervisors' Association, in addition to the staff meetings which are held at the larger shops and division points.

Wabash.—There are supervisors' clubs at Moberly and Decatur, all foremen and supervisory officers in the mechanical and stores departments being eligible. Monthly meetings are held at which technical papers are presented and discussed. Entertainment features are introduced at these meetings and occasionally the meetings take the form of social functions or smokers, with the idea of getting the members and their families better acquainted and promoting a spirit of good fellowship.

Clubs which failed

It is only fair to say that all of the foremen's clubs that have been organized have not made good. We have learned of two such clubs which failed—apparently because they were organized on too ambitious a scale and did not grasp their possibilities in developing leadership ability. But let the brief account which we have received tell its own story:

"The purpose of their organizing was more of a social and educational nature than a railroad business proposition. At ———— the foremen fitted up club rooms which at first were very well patronized by them-

selves and friends. It was not long, however, until interest lagged and this together with the expense entailed soon caused the club room plan to be abandoned. Interest in the meetings they held, which were addressed by different gentlemen on different subjects, also soon diminished and it was not long until we heard no more of the club. No doubt one of the reasons for the loss of interest so soon was the fact that the foremen represented all departments and kinds of work—carpenter, blacksmith, boilermaker, machinist, etc.—and a subject that would be interesting to part of the men would be tiresome and like Greek to the others."

Foremanship classes on the Lehigh Valley

The Lehigh Valley has approached this question of foremanship training in a rather different way from the other roads, although similar practices have been followed in other industries in recent years with excellent results. The foremen enroll in a course on foremanship which has been developed and promoted by the Engineering Extension Division of Pennsylvania State College. The men pay $15 each for the course. The company has co-operated by seeing that adequate facilities are provided for carrying on the class work, and the officers, whenever they have been called upon, have taken a keen interest in participating in the program. Meetings of an hour-and-a-half duration are held once a week. At Sayre, Pa., the foremen at the enginehouse and on the Seneca division form one group and meet in a room adjacent to the enginehouse which has been fitted up for class work of this sort, as well as a social center where the foremen and men may gather at lunch time. This was the first group to form a class of this kind and it has completely covered the course laid out by State College; it is continuing to function as a class and is developing its own topics for study and discussion. A similar and somewhat larger group of foremen and supervisors from the system shops at Sayre hold their meetings in the apprentice school room. There is another group at Easton, Pa.

The first unit of the course is devoted to the responsibilities of the foremen. These are considered in a general way and include a discussion of the characteristics of a successful foreman. The second unit considers aids in production and includes a discussion of those things which have both a direct and indirect influence on production. The third unit discusses costs and their relation to the foreman. The fourth, the foreman's relation to employment; among other things it considers the selection and following up of the worker, a discussion of the cost of turnover, methods for reducing it, etc. The fifth unit is devoted largely to a consideration of safety and the foreman's relation to it. The units following this include other important phases of the problem of leadership and production and also a brief review of the history of industry.

The members of the class first read one of the study units. A member of the class or an officer or representative of State College may then give a talk, discussing the application of the principles from his point of view. This is followed by an open forum discussion, which frequently is carried over to include the class period of the following week. After the study unit has been thoroughly discussed the men answer certain questions in writing and send them to State College, where they are corrected and graded.

The Lehigh Valley people are enthusiastic over the results which have been obtained. The advantages of definitely organizing the study work are obvious. The thinking of the men is directed along a specified program, which has been found to meet the needs of the foremen and supervisors in industry generally. The important principles are discussed in logical sequence. It is true that the Pennsylvania State College course was not specially devised for railroad supervisors. It was developed and outlined after conferences with men from industrial organizations throughout the state and has been very carefully checked up in the industries. The principles of successful leadership are the same on the railroads as in the industries, but there would be certain advantages in considering these principles more particularly from the railroad mechanical department point of view. This would lead to the emphasis of certain parts of the course, while other parts would be given less attention.

The foremen at the system shops of the Lehigh Valley at Sayre, Pa., hold their classes in the apprentice school room

A pertinent suggestion

Unfortunately the programs of most of the foremen's clubs or supervisors' associations are made up of subjects or topics which are not as closely related or co-ordinated as they might be, or are not presented in a logical sequence. Too frequently also the programs are largely in-

spirational in character and no organized attempt is made to follow them up. Study classes have a considerable advantage from this point of view.

One superintendent of motive power who was greatly impressed by this feature and by the fact that more must be done to cultivate and develop real leadership ability, makes this suggestion: During certain times of the year the shop hours are reduced and in many cases the men do not report for work on Saturday. The foremen, however, are expected to report and to plan and discuss the work of the coming week. The suggestion is that the foremen hold a staff meeting at such times, giving whatever attention is needed to the routine problems, and then setting aside a definite part of the time for classes conducted along much the same lines as those on the Lehigh Valley. This suggestion would appear to have great possibilities and its working out will be watched with much interest.

On the Burlington

At one point on the Chicago, Burlington & Quincy a night school class for the supervisors is directed by a representative from a nearby college. The course of study includes plant operation, supervision and other matters of special interest to the foremen and supervisors.

Visits to other shops

Several roads have adopted the practice, when work is light, of having the foremen and supervisors visit other shops on their own system or on other roads. The result is said to have a broadening and inspiring effect on the foremen. Visits made to other shops on the same road help to bring about and promote standard practices, as well as better understandings. Visits to shops on other roads often develop new points of view and frequently result in changing or reorganizing the handling of the work.

When foremen are sent to make such visits it is sometimes well to indicate specifically that they are to look for those things in which their neighbors excel. Nothing is gained if the foreman comes back with nothing new, but with a lot of satisfaction in telling how he is doing things better than the foreman at the shop which he visited.

Technical magazines

Several mechanical department superintendents report that they either furnish the foremen or encourage them to take and study technical magazines. In some cases the foreman's attention is specifically directed to articles in the magazines, and he is asked to give in writing his opinion of the value of the practice or device which is described, and indicate whether it can be introduced in his department to advantage.

Papers such as the *Railway Mechanical Engineer* are clearing houses for the best methods and practices. The value of systematically reading and studying them is commented upon in the first prize article in the contest on the Opportunities and Responsibilities of the Foreman, which appears elsewhere in this issue.

Books

The number of books dealing with problems of leadership and management has been steadily increasing in recent years. These books cover all phases of the broad problem of management and personnel administration. It is surprising how little they are known or read by railroad foremen and officers. Two or three roads have furnished their foremen and supervisors with copies of "Spark Plugs" by Sherman Rogers. This is a small book, easily read and inspirational in character. Between it and "Personnel Administration" by Tead and Metcalf, there is a broad area. The latter book is a standard work on personnel administration, going into all phases of the question in detail.

Thus far but one book has appeared which is related definitely and entirely to the railroad field. That is "Personnel Management on the Railroads" prepared by the Policyholders' Service Bureau of the Metropolitan Life Insurance Company and published by the Simmons-Boardman Publishing Company. It has only recently been published. It does not go into the details or principles of leadership, but does outline what the progressive railroads are doing in different ways to improve the standard of efficiency of management and bring about better relations and teamwork.

R. E. Woodruff, superintendent of the Erie, in speaking at the May meeting of the New York Railroad Club, made this significant statement: "Our men do not know how to oil the human machines properly and, worse yet, they are not aware of it. A check of one organization developed that only 14 per cent of the officers of all grades had actually read or were reading anything that would help them improve their knowledge of human relations. Forty per cent read only technical magazines and papers; 46 per cent admitted that they read nothing but daily newspapers. Some of these men did not appreciate that they were standing still—each was ambitious for promotion but was not studying to qualify for advancement. * * * * Many of these men did not appreciate that there was anything to be gained from reading or studying. They did not know that there were any books on the question of salesmanship or of securing co-operation."

Bulletins

It is the practice on the Delaware, Lackawanna & Western to hold weekly meetings of all shop and enginehouse supervisors and also to issue semi-weekly bulletins to the supervisors. These contain comprehensive information about conditions and include discussions of such things as the human equation, the proper method of planning, costs, shop schedules, etc. These bulletins have been found to broaden the perspective of the supervisors and to give them a better idea of the railroad as a whole and the way in which the different departments can work together to the best advantage.

Study courses

Many of the roads encourage the foremen and more ambitious men to enroll in the correspondence schools or to take special study courses which may prove helpful to them. Several of these schools have courses on foremanship. The Railway Educational Bureau at Omaha has prepared a course of study particularly directed to the needs of the supervisors on the railroads; it was only recently completed, but has attracted favorable attention on several roads.

The course includes a study unit or instruction paper on personal considerations, which includes the following points: The responsibility placed upon the supervisor by his position and title, the desirable ends to be accomplished by the supervisor in carrying out his duties, the supervisor's attitude of mind toward his work, the supervisor's attitude of mind toward his men, the desirability of training one or more understudies, and the supervisor's duty to himself as regards preparation for his own further promotion.

Following this is a unit on the man problem. Attention is also given to the Americanization question in a unit entitled, "The Melting Pot," which is supplemented by a special unit which includes the Declaration of Independence and the Constitution of the United States. Then

follow units on methods of creating co-operative efficiency in railway work, the handling of the present forces, a series of studies on discipline covering the Brown system, the handling of minor offenses and the handling of major and dischargeable offenses. This is followed by a unit on the employment and handling of new men and two units on money values, including one on costs and values and the other on the budgeting of expenses. One unit which has been specially devised to inspire or stir up the student is entitled, "Seeing, Hearing, Thinking." Then come several instruction papers covering the general considerations for planning and scheduling work, on routing work, dispatching work, standards and standard practice instructions, and records. The series as now outlined closes with units on additional personal considerations, promotions and day-by-day supervision.

The Railway Educational Bureau does not require written tests, but the material is so arranged as to encourage the student to think and study along the right lines, the Bureau agreeing to answer any questions that he may ask for further help or information. A question which naturally suggests itself is as to whether a discussion group or class at a local point could not follow such a course to advantage.

Special instruction

One road has found it profitable to provide special instructors to visit the various points on the railroad and conduct schools or classes for supervisors in the mechanical department. Special attention is given to such matters as the federal locomotive inspection rules and the Interstate Commerce Commission safety appliance rules. This movement was started because of the large number of new foremen who were taken into the service in 1922. The returns upon the investment have been so large that this special educational work is being continued.

Apprentice training

At least one mechanical department superintendent insists that the training of foremen should begin when the boys start to serve their time as apprentices. The point that this officer wishes to make—and he is not connected with the Santa Fe—is that one of the best things that has been done in training foremen is the remarkable development of apprentice training on the Santa Fe, which has been so frequently commented upon in the RAILWAY MECHANICAL ENGINEER.

An inquiry, inspired by this suggestion, brought forth the information that the Santa Fe apprentice department keeps an "Honor Roll" which contains the names of the young men who have completed their apprenticeship courses in the last 12 or 14 years and have been promoted to official positions. This honor roll shows that 240 apprentices have been promoted to the following positions:

Division master mechanics	7
Division and general foremen	23
Roundhouse foremen	16
Assistant roundhouse and gang foremen	63
Machine and erecting foremen	38
Boiler foremen	18
Car foremen	6
Miscellaneous foremen	7
Miscellaneous positions	16
Apprentice instructors	46
Total	240

Selecting men for promotion

Another mechanical department superintendent indicates that the responsibilities and requirements upon the foreman are so great that we must not only give greater attention to training and coaching them, but must in the future select as foremen, men who have had a reasonably high and broad education.

Other mechanical department superintendents place particular stress upon the importance of using the greatest possible care in selecting men for promotion and in seeing that they are carefully coached on dealing with the human element before they are actually placed in charge of a group of men.

General railway clubs

Some of our correspondents have drawn attention to the fact that the railroad clubs throughout the country have given more and more attention in recent years to this question of management and human relations on the railroads. A survey of the topics which have been discussed at the railroad club meetings indicates that one or two of the clubs have been giving an unusual amount of attention to these questions. Apparently this has been appreciated, for these particular clubs have been growing in strength and numbers and the consensus of opinion is that the members appreciate a reasonable amount of this sort of material.

Conclusions

This survey is not intended to be complete or thorough. It is based upon replies to a letter which were received from the greater percentage of the heads of the mechanical departments on the larger railroads of this country and Canada. This has been supplemented by observations by members of the staff of the *Railway Mechanical Engineer*. One thing, however, is clearly evident and that is, that there is a growing recognition of the importance of having the foremen and supervisors secure a better understanding of those principles upon which successful leadership must be based. There are several ways in which this problem can be approached and much progress has already been made on some roads in helping the foremen to improve themselves. The natural result of this has been a better understanding and an improvement of relations between the managements and the workers. It is one of the first steps that must be taken if we are to develop that degree of real teamwork and co-operation which is so much desired.

Master Boiler Makers meet at Chicago

The sixteenth annual meeting of the Master Boiler Makers' Association proves to be one of the most successful in its history

THE sixteenth annual meeting of the Master Boiler Makers' Association opened Tuesday morning, May 19, at the Hotel Sherman, Chicago, with about 700 members, guests and supply men in attendance. President Frank Gray, was in the chair at the opening session.

After the invocation, H. T. Bentley, general superintendent of motive power, Chicago & North Western, addressed the meeting. During his talk he suggested that the name of the asociation might appropriately be changed to Railway Master Boiler Makers," without altering the by-laws or limiting the membership to the railroad field. Practically all members are railroad men and he felt the name should convey this thought.

His suggestions were of a practical nature and dealt with better maintenance, cleaner tubes, the prevention of front end air leaks, and steam leaks—all working for better fuel economy, performance and safety. He also touched on the all important apprenticeship problem. Some incentive must be given young men to enter the railroad trades including boiler making, he said. Foremen and all others should work with the boys and help them in every possible way. When an apprentice completes his course he should be able to handle any and every phase of his trade with facility. He will be able to do this only if his supervisors have worked with him.

The competition between motor truck, bus and railroads received comment. Mr. Bentley said that these vehicles, performing the duties of common carriers, should carry some of the burden of taxation, road maintenance and other items to which the railroads are subjected if they are to be allowed to compete with them. Without such an equalization of tax burden, the motor transport service receives what is in effect a public subsidy and cuts materially into railroad business.

Following Mr. Bentley's address the president delivered his annual address. The remainder of this session was devoted to reports of the secretary and the treasurer and to routine business. Letters were received from A. G. Pack, chief inspector of the Bureau of Locomotive Inspection, and A. R. Ayers, assistant general manager, New York, Chicago & St. Louis, expressing regret at their inability to be present at the convention.

The Wednesday session opened with an address by W. J. Tollerton, general superintendent of motive power, Chicago, Rock Island & Pacific. Economy in operation and maintenance was the keynote of Mr. Tollerton's talk. The executives of the railroads look to the motive power department for the accomplishment of economy in maintenance. To a great extent the members of this association can make savings possible in maintaining in good condition the boilers under their care. Mr. Tollerton also discussed the loss of revenue due to the competition of the motor bus and truck in handling passenger and freight traffic. Following the discussion on this point, he touched on the possibility of fuel saving through the application of thoroughly tested devices such as the thermic syphon, the feedwater heater, the superheater and other appliances. One other matter was emphasized in his talk—the absolute necessity for boiler shops being properly equipped with machine tools so that work may be handled economically and efficiently.

Frank Gray
President

T. F. Powers
1st Vice-President

H. D. Vought
Secretary

W. H. Laughridge
Treasurer

The report of the Recommended Practice and Standards Committee on the subject of "proposed boiler welding practice" was read and each section discussed and acted upon by the convention. As a result of the discussion, the report will be put in final form with such changes and additions as were found necessary to meet the approval of the body. The report in its final form will be acted upon at a later meeting.

The morning and afternoon sessions on Thursday were devoted to the discussion of special topics prepared by committees of the association. The following subjects were included: "Acetylene and electric welding of firebox sheets"; "Flue sheets in combustion chamber boilers"; "Repairing of cracked bridges and cracks in flange knuckles"; "Renewal of staybolts adjacent to those found broken"; "Method of applying arch tubes"; "The train-

ing and developing of boiler inspectors and assistant foremen boiler makers"; "The most reliable water level registering device on a locomotive boiler"; "What is the most economical pump station boiler"; "Boiler corrosion, pitting and grooving."

Officers elected for the coming year

The final session on Friday, May 22, was devoted to routine business. The following officers were elected for the coming year:

President, Thomas F. Powers, assistant general foreman, boiler department, Chicago & Northwestern; first vice-president, J. F. Raps, general boiler inspector, Illinois Central; second vice-president, W. J. Murphy, general foreman boiler maker, Pennsylvania; third vice-president, L. M. Stewart, general boiler inspector, Atlantic Coast Line; fourth vice-president, S. M. Carroll, general master boiler maker, Chesapeake & Ohio; fifth vice-president, George B. Usherwood, supervisor of boilers, New York Central; secretary, Harry D. Vought; treasurer, W. H. Laughridge, general foreman boiler maker, Hocking Valley; executive board, one year, E. J. Reardon, Locomotive Firebox Company; H. J. Raps, general boiler foreman, Illinois Central; L. E. Nicholas, general boiler foreman, Chicago, Indianapolis & Louisville; two years, C. H. Browning, foreman boiler maker, Grand Trunk; L. R. Porter, foreman boiler maker, Soo Line; A. F. Stiglemeier, general boiler shop foreman, New York Central; three years, I. W. Clark, general foreman boiler maker, Nashville, Chattanooga & St. Louis; F. T. Litz, general boiler foreman, Chicago, Milwaukee & St. Paul; C. J. Longacre, foreman boiler maker, Pennsylvania; A. F. Stiglmeier was elected chairman of the board and H. J. Raps, secretary.

Air Brake Association at Los Angeles

Power brake problems are discussed—Address by W. J. Patterson of the Bureau of Safety

THE Air Brake Association held its thirty-second annual convention at the Hotel Alexandria, Los Angeles, Cal., May 26 to 29, inclusive. The association was welcomed by a representative of the city and on behalf of the railroads by W. K. Etter, general manager of the Atchison, Topeka & Santa Fe Coast Lines. Addresses were also made by President C. M. Kidd, air brake inspector of the Virginian, and W. J. Patterson, assistant director Bureau of Safety, Interstate Commerce Commission. Abstracts of these addresses follow:

President Kidd's address

The question was raised of the advisability of holding this convention at such a distant western point as Los Angeles, but our selection of this city is justified by the large attendance. Los Angeles was selected to follow our practice of taking the convention to the different parts of the country to accommodate not only the members of the association, but in order accommodate railroad employees in general.

The character of the Air Brake Association is different from that of any other railroad association. It is purely and wholly an educational institution. The more thoroughly air brake education is disseminated, the better will be the operation of freight and passenger trains and railroad transportation will be correspondingly benefited. Perhaps no separate division of railroad operation carries the same responsibility as the air brake. If one road does not follow recommended practice in the maintenance of triple valves, with standard triple valve test racks, codes of tests, properly adjusted piston travel and properly maintained retaining valves and pipes, and another road does this work, the air brakes will operate at a low efficiency. All must work together in harmony and co-ordination. This can be brought about only by proper education and that is what the Air Brake Association is striving for. It should have the moral and practical support of all railways and railway officers.

Undoubtedly the coming year will bring with it important developments in air brake work. Better conditioning of the equipment and the intricacies of automatic train control will call forth the fullest attention and best efforts of air brake men. We must be ready!

Address by W. J. Patterson of the Bureau of Safety

At the annual convention of this association in 1919, I presented a paper which set forth quite fully the requirements of law and orders of the Interstate Commerce Commission with respect to air brakes, as well as policies and practices of the Bureau of Safety in their administration. At that time I requested this association to co-operate with the government in bringing about general improvements in air brake conditions throughout the country. That is being done, yet still better observance of the rules governing maintenance and conditions of air brakes is necessary for the protection of employees and travelers on our railroads. At that time I said, "I am a very strong advocate of air brake tests on trains when arriving at terminals, and I believe that incoming air brake tests, together with prompt repair of air brake defects, will result in such great improvement in air brake maintenance conditions as to preclude the necessity for more stringent action on the part of the Bureau of Safety than a reasonable interpretation of existing law and the orders of the commission which are in effect at the present time."

What was true at that time is true now and in view of the increasing train length that I then advocated is even more necessary at the present time. Since the date of that meeting there have been several events of outstanding importance affecting the maintenance and use of power brakes. In February, 1922, the Interstate Commerce Commission began an investigation of power brakes and appliances for operating train brake systems, to determine whether and to what extent power brake equipment in common use was adequate and in accordance with the

requirements of safety, what improved devices were available, and what improvements should be made to provide increased safety. The condition of repair of air brake equipment which existed at that time is indicated by results of inspections made by the Bureau of Safety.

In the fiscal year ending June 30, 1922, approximately 1,100,000 cars and locomotives were inspected, on which a total of 55,427 safety appliance defects were found. Approximately half of all these defects, or 27,271, were defective air brakes. In that year inspectors of the Bureau of Safety also tested the brakes on 244 trains upon their arrival at terminals; these trains consisted of 8,898 cars, of which 9 per cent were cut out or had otherwise inoperative air brakes; on 294 cars the brakes were cut out and on 508 cars the brakes were inoperative from other causes.

The number of inoperative brakes in service was altogether too large, indicating a lack of proper attention.

In addition to this altogether too large percentage of defective air brake equipment, the necessity for this general investigation by the commission into the use and operation of power brakes was revealed by representations which were made by certain railroads that freight trains could not be controlled with a proper degree of safety on heavy grades by means of power brakes alone as required by the law. In this investigation, after considerable evidence had been taken and tests conducted, the commission issued a report dated July 18, 1924, and among other things stated that "Improvements in the operation of power brakes for both passenger and freight trains are essential and must be effected." They further stated that "Throughout this proceeding the necessity for better maintenance of present power brake equipment in order to secure proper operation and safely control trains was repeatedly stressed, and this necessity was recognized by both carriers and employees. It is beyond question of argument that piston travel should be maintained within proper limits, triple valves should be kept properly cleaned, brake pipe and brake cylinder leakage should be kept below certain prescribed amounts, and retaining valves with their pipe connections should be kept in good condition; furthermore, rules should provide and proper tests should be made to insure that trains will not leave terminals with defective, inoperative or cut out brakes on any cars."

During the commission's hearings it was noted that no witnesses either for the carriers, the brake manufacturers or the employees testified that power brake systems as a whole were maintained in an efficient or satisfactory oprating condition. On the contrary witness after witness testified that improved performance would result from better maintenance and that such better maintenance should be required.

Following the issuance of this report several conferences were held between representatives of the American Railway Association—who by the way were members of this association—and representatives of the Interstate Commerce Commission, which resulted in an agreement to adopt certain recommendations for maintenance as a measure for carrying into effect the requirements of the commission's report. These rules will be put into effect at an early date and I know that the members of this association will do their part to see that they are religiously observed. The result of their operation will be observed by the commission to determine their effectiveness. Should it be found that these rules, or rules issued in this manner, are not effective to secure the required improvement in air brake maintenance and operation it will become necessary to consider other means and adopt other methods to secure such improvement.

The revised rules establish minimum requirements to which brakes in service must conform, and set forth tests which will disclose whether or not equipment in service meets the prescribed requirements. Each carrier is, however, left free to determine the detail methods and means which it will employ to place and keep the air brake equipment used on its line in the condition required by the rules. Carriers are expected to issue necessary additional rules and instructions, provided, however, that such additions are not inconsistent with the rules which set forth minimum requirements applicable to all carriers.

Another event of great importance in connection with the maintenance and use of air brakes was a decision of the Supreme Court of the United States, handed down April 28, 1924, which construes the associated car provision of the air brake law. In the fiscal year, ending June 30, 1923, inspectors of the Bureau of Safety conducted terminal tests of the brakes on a total of 1,602 trains which were made up and ready for departure. These trains consisted of 50,254 cars, and on 7 per cent of these cars the brakes were cut out or inoperative. On 615 cars the brakes were cut out, and on 2,809 cars the brakes were inoperative from other causes. In the following year some improvement was indicated. A total of 1,504 trains consisting of 50,910 cars were tested; 3.3 per cent of these cars had cut out or inoperative brakes, 296 brakes being cut out and 1,408 being inoperative from other causes. It should be borne in mind that these tests were made after the trains had been made up and inspected by railroad company employees and the trains left the points where the inspections were made in the condition indicated.

In the case decided by the Supreme Court, cars with their brakes cut out were intermingled with operative brakes in the train and hauled from a point where repairs could be made. The court held that the failure of the power brake on a car did not take the car out of the power brake class; that the cars involved in this case were associated with other power brake cars, that the act specifically requires all power brake cars so associated shall have their brakes used and operated; and that cars on which the power brakes have been cut can lawfully be hauled only when placed to the rear of all cars having their power brakes operated by the engineer. For many years the Bureau of Safety has contended that all air brakes on each train should be operative leaving a terminal or other point where repairs could be made. This decision supports that view.

In a meeting of this association, it is entirely unnecessary for me to discuss the question of how to maintain brakes. The records of your previous annual meetings are full of descriptions of such work and suggestions as to what is required to be done. From the standpoint of the Bureau of Safety, in connection with the administration of the law, it is entirely immaterial what detailed methods are employed by the carriers to place and keep air brake equipment in condition to conform to federal requirements. Our only concern is that it shall be done, and that tests are made at sufficiently frequent intervals and repair facilities provided to insure that the air brakes on all cars in trains are in effective operating condition. The distance between points at which inspection, tests and repairs are to be made must be determined separately for each carrier according to their requirements and character of service. The Bureau of Safety will continue to make air brake tests, on both arriving and departing trains, at suitable points to determine the actual condition of brakes on trains operated on each line of railroad.

In improving air brake service on the American railroads, I want to assure you that you have the hearty cooperation and support of the Interstate Commerce Commission.

Big attendance at Fuel Association convention

Many operating and mechanical officers register—L. F. Loree makes the opening address

THE opening session of the seventeenth annual meeting of the International Railway Fuel Association, which was held at the Hotel Sherman, Chicago, May 26 to 29 inclusive, was characterized by an unusually large attendance in which many operating and mechanical officers and supervisors were included, as well as the officers of the fuel departments, traveling engineers and a number of delegations of enginemen and firemen, whose duties bring them directly in contact with the consumption of fuel on the locomotive.

For the first time the program this year has been grouped so that matters primarily of interest to the operating officer were discussed on the second day while those subjects of primary interest to the mechanical department were grouped together on the third day.

L. F. Loree, president, Delaware & Hudson, delivered the principal address at the opening session and his address was followed by that of the president, P. E. Bast, fuel engineer Delaware & Hudson. The program included addresses on the following subjects: How can management effect fuel economy? by A. R. Ayers, assistant general manager, New York, Chicago & St. Louis; How can fuel purchases effect economy? by H. C. Pearce, director purchases and stores, Chesapeake & Ohio, discussion of Fundamental fuel factors, by G. M. Basford, and a discussion of the relation of signals to fuel saving, by B. J. Schwendt, superintendent of signals, New York Central. Abstracts of some of these addresses and a number of important reports will appear in later issues. Following is an abstract of the address by L. F. Loree.

A look into the future

By L. F. Loree
President, Delaware & Hudson

As a lad I read a story of James Watt seated at the fireplace, watching the boiling pot, noting the lid lifted by the expanding steam, and later working out upon this hint his great invention—the steam engine.

The story was, of course, without foundation, and is typical of much purely imaginative matter that is dished up to us. Sometimes I have thought that to no inconsiderable degree the inertia and closed mind of the public is due to the mass of misinformation that is gathered in youth, and the ill result goes even farther, since there is truth in the warning of the Greek philosopher "that we should not lie to the children, if for no other reason than that when they grow up they will not believe even the truth that we tell them."

The first pumping engine

Then, in 1712, Thomas Newcomen, an ironmonger or iron merchant of Dartmouth, England, "fixed the first engine that ever raised any quantity of water, at Wolverhampton." There is still in existence an engraving of it. Looking at this drawing one cannot but be surprised at the maturity to which the engine had been brought and the wonderful achievement that it really was.

John Smeaton, a celebrated civil engineer, turned his attention, about 1765, to the atmospheric engine, and having collected data from some 100 engines, and conducted a series of experiments, set out rules for the best proportion of the parts. The effect of Smeaton's efforts, which were largely reflected in a decreased fuel consumption, is seen in comparing the results he obtained raising 9,450,000 lb. of water one foot high by a consumption of one bushel—84 lb.—of coal, as against the average of the 100 engines he examined, which gave a performance of 5,590,000 lb.

Where James Watt comes in

In 1757 James Watt was in the service of the University of Glasgow, Scotland, living and having a shop within the college walls under the title of "Mathematical Instrument Maker to the University." Here he enjoyed intercourse with professors and students interested in his branch of activities, and here he carried on many experiments with the force of steam.

The University owned a small model of Newcomen's engine, and in the winter of 1763-4 it was given to Watt to be repaired. Watt was surprised and interested by the great amount of steam consumed by the little engine, and set about seriously to investigate the matter.

Early in 1765 the idea occurred to him that the steam, instead of being condensed in the cylinder, might be drawn off into a separate vessel and there condensed. By this means the cylinder might be kept as hot as desired, the condenser as cold as necessary, no steam be wasted and a perfect vacuum obtained. At the time he secured his patent, on January 5, 1769, for "a new method of lessening the consumption of steam and fuel in fire engines," he estimated the saving of steam at one-half.

Watt's purpose was fuel economy

The extent to which Boulton and Watt were dominated by the idea of fuel economy is clearly indicated in the terms they adopted in marketing their engine. They stipulated to receive the value of one-third of the fuel saved by each engine when compared with a common one (not with Smeaton's improved engine) burning the same kind of coal, to be paid annually or half-yearly, with an option of redemption at ten years' purchase. In Cornwall a committee canvassing the situation found that the average duty of the Newcomen engine was 7,037,800 lb. raised one foot high by the consumption of a bushel—84 lb.—of coal. Boulton and Watt's low-pressure engines performed an average duty of about 18,000,000 lb.

The first engines built by Boulton and Watt were atmospheric engines, the open-topped cylinders being surrounded by a steam case, but further economy was found by covering the top of the cylinder and admitting the steam above the piston.

On March 12, 1782, Watt patented his double-acting steam engine, using the expansive force of steam below as well as above the piston, and at once solved the difficulty of applying it successfully to produce a continuous rotative motion.

Little new has been introduced in the mechanism of the engine; in its main features it is today very much as Watt

made it. Watt had mastered the difficulties in the way of employing steam at high pressure; he knew that the steam could be discharged into the open air instead of into a condenser chamber; he was alive to the availability of the expansive force of steam; but he was afraid of the danger attending its use. The materials at his disposal did not command his confidence, nor was there sufficient skill on the part of the engineman.

The commercial success of Watt's invention, designed, as we have seen, to produce an economy in fuel consumption, had been very great; but here the wealth and influence, the energy and tact of Boulton, were invaluable complements to his inventive genius.

A prediction of thirty years ago

Looking to the future, we have to form some conception as to how the coming motive power shall be designed and equipped. There is nothing at the present time that seems promising in electric, Diesel, turbine and various non-reciprocating steam engines. We must continue to fix our attention upon the reciprocating steam-engine locomotive. Here we may discern a number of factors which may be utilized to improve its service and reduce its expense of operation.

In March, 1895, Matthias N. Forney, the author of "The Catechism of the Locomotive," writing as editor in the American Railroad Journal and Engineering Magazine, said:

> Let it be assumed that the fuel consumption on a road is represented by $1,000,000; if 14 per cent was saved by simply testing it and learning which was the best quality to buy, the $1,000,000 would be reduced to $860,000. If, now, we save 10 per cent by an improved valve gear, the million is reduced to $774,000. If feed water heaters should save 14 per cent, then the cost of fuel would be lowered to $665,640; and if superheated steam should fulfill its promise of 30 per cent saving, the fuel account would be brought down to $532,512.

In 1915 the typical large freight locomotive of The Delaware & Hudson was its Class E-5 of the consolidation type, using saturated steam, slide valves and single expansion cylinders, carrying 210 lb. boiler pressure, weighing 227,200 lb. on driving wheels, and rated at 50,600 lb. tractive force. In moving 1,000 actual gross ton-miles, including its own weight, on a 0.5 per cent grade, at average freight train speeds, this locomotive consumed 160 lb. of coal. The first marked improvement was the application of superheaters and the substitution of piston valves for the slide valves, increasing the weight of the engine on the driving wheels to 231,700 lb., and the tractive force to 55,100 lb., and reducing the fuel consumption under like operating conditions to 130 lb. of coal, or by about 19 per cent.

What the "Horatio Allen" has done

Last year we developed a type of consolidation locomotive, changing the E-5 class as little as was necessary, which we named the "Horatio Allen," after the engineer who ran the first locomotive in this country. This locomotive carries 350 lb. boiler pressure, weighs 298,500 lb. on the driving wheels and has developed 75,000 lb. drawbar pull, as measured by the dynamometer. The "Horatio Allen" uses a moderate degree of superheated steam admitted to and exhausted from the multiple expansion cylinders through large valve and port openings. It has a water tube type of firebox with extraordinarily large evaporation surface and a fire brick baffle wall extending the full width and length of the firebox which insures full utilization of the hand fired coal, with long flame travel, securing maximum radiant heat effect and minimum cinder and stack losses. With this engine 1,000 actual gross ton-miles under like conditions require 55 lb of coal.

It is probable that within the year a satisfactory feed water heater will be on the market and that the equipment for burning coal pulverized to about the fineness of talcum powder will be brought into practical use.

Possibilities of the next ten years

Looking over this score of years from 1915 to 1935, and following Mr. Forney's example, the following changes may be anticipated during the next ten years:

Typical steam locomotive coal consumption per 1,000 actual freight train gross ton-miles on equivalent to a 0.5 per cent grade

Year 1915		160 lb.
Reduction in total fuel consumption by means of—		
1. Superheating	to	130 lb.
2. Fire brick baffle wall	to	124 lb.
3. Feed water heating	to	113 lb.
4. 350 lb. boiler pressure	to	96 lb.
5. Improved boiler design, circulation and evaporation	to	84 lb.
6. Multiple expansion cylinders	to	70 lb.
7. Improved steam distribution and reduced cylinder back pressure	to	60 lb.
8. Burning powdered coal in suspension	to	44 lb.
9. Reheating of high pressure exhaust steam in multiple expansion	to	42 lb.
10. Miscellaneous items, such as increased train loading through the use of an auxiliary locomotive, utilizing the dead weight of the tender for tractive purposes, greater sustained boiler horsepower capacity, substitution of poppet valves for piston or slide valves, and higher superheat on account of the use of powdered coal, may bring the final figure down to about		38 lb.

This is somewhat less than one-quarter of the 1915 locomotive fuel consumption. The effect of this would be to reduce the 90,000,000 tons of fuel now used in freight train service to about 27,000,000 tons, effecting a total economy of something like $200,000,000 per annum.

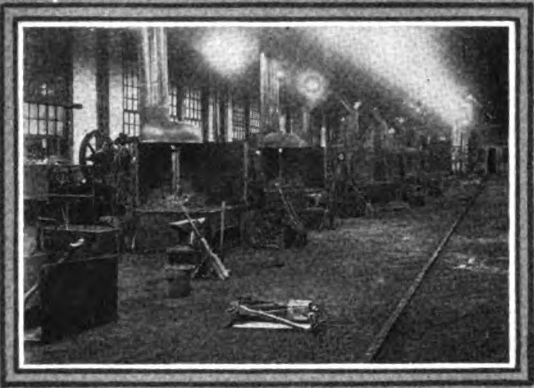
I have had these figures carefully checked with available cost and performance sheets of various railroads, with dynamometer-car road and other tests made by various steam roads, and with laboratory tests made at Purdue University, University of Illinois, and the Pennsylvania, at Altoona, Pa. Discussing them with my own people, they do not seem to me extravagant. There are, of course, debits to be set off, the cost of these appliances and their upkeep, determinable only by experience. But the possible savings are large, and that they will not be confined to those I have listed, no one can doubt.

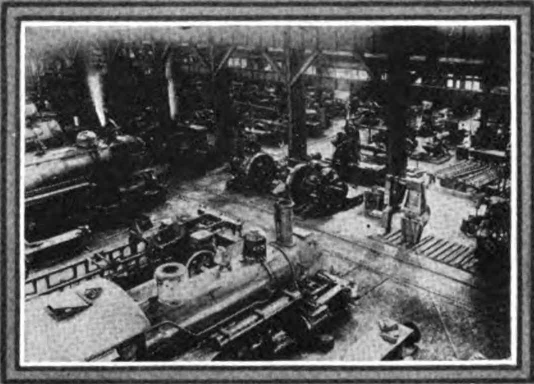
The joy of our occupation is not alone in the service we render but in the knowledge that the industry is alive and vigorous, expanding and improving, exacting from us our utmost effort, inviting every exertion from the dullest of routine duties to the liveliest flights of the imagination. Let us enjoy fully the opportunities it offers, meet adequately its drafts upon us and demand for it the respect it merits from those it serves.

Closing business

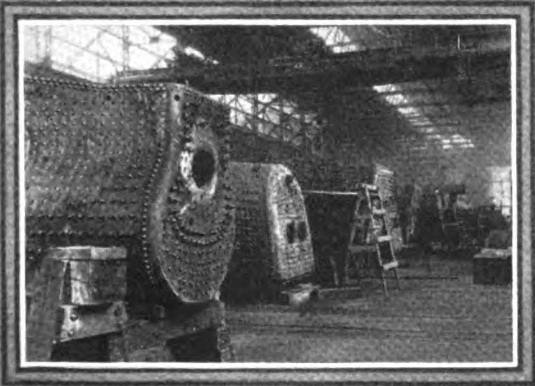
At the closing session of the convention, the following officers were elected for the ensuing year: President, J. W. Dodge, Illinois Central; vice-presidents, E. E. Chapman, Atchison, Topeka & Santa Fe; W. J. Tapp, Denver & Rio Grande Western, and J. E. Davenport, New York Central. The following were elected members of the Executive Committee to serve two years: W. G. Black, New York, Chicago & St. Louis; T. F. Carbery, Missouri Pacific; Carl B. Smith, Boston & Maine; J. J. Stahl, Southern. C. H. Dyson, Baltimore & Ohio, was elected to serve one year.

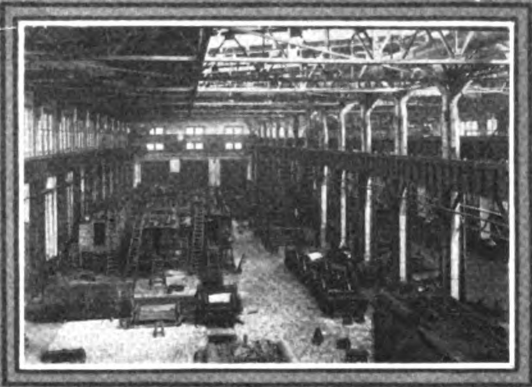
In the ballot taken to indicate the perference of the association for the next meeting place, Chicago received the highest number of votes. Final decision, however, rests with the Executive Committee. The Executive Committee has already announced the tentative dates for next year's convention as May 11 to 14, inclusive, two weeks earlier in the month than this year's convention.





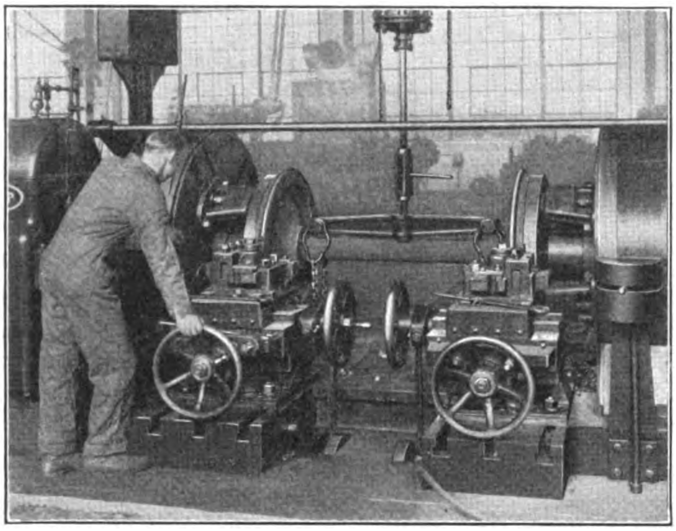
New and Improved Machine Tools and Shop Equipment





Car wheel lathe of the open center type

A HEAVY car wheel lathe of the open center type has been recently placed on the market by the Niles-Bement-Pond Company, New York. It has a capacity to turn wheels, from 26 to 52 in. diameter on the tread, when mounted on axles having either inside or outside journals. In designing this machine special care has been taken to eliminate all unnecessary power losses



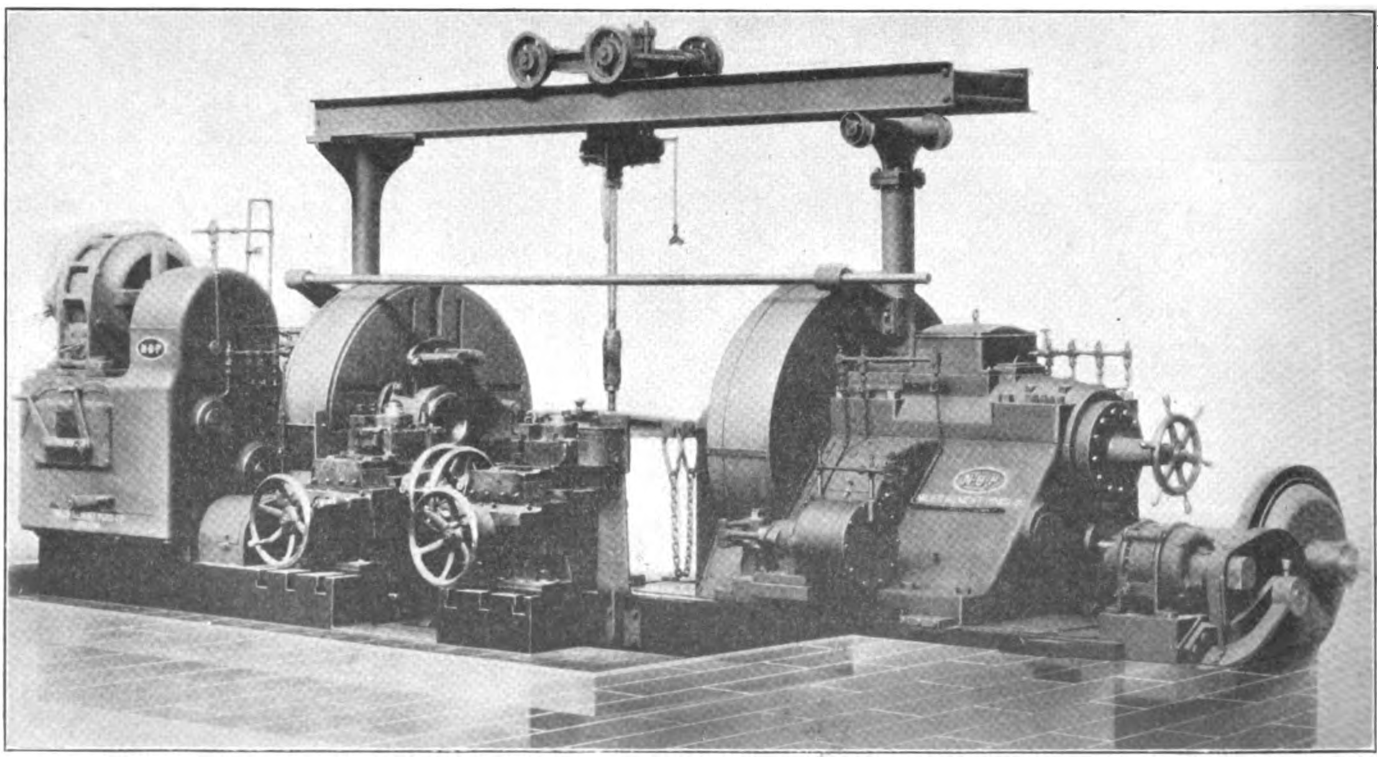
Control levers arranged for the convenience of the operator

so that the maximum power available can be delivered at the tools. The main driving gears have been so arranged that the spindle bearing pressures are greatly reduced—the internal gear face plate drives are claimed to be exceptionally efficient and all heavy end thrusts are taken up by ball bearings.

This lathe is considerably heavier and more powerful than any machine of this type previously built by this company. Its production is limited only by the present day high speed steel used and a reserve capacity capable of taking care of a 50 per cent increase in the quality of tool steel has been built into the machine. The unit system of construction has been adhered to, making all parts very accessible. The most modern and improved time and labor saving devices such as power traverse and clamping to the sliding headstock, semi-automatic driver dogs, wheel hoist, turret tool posts, and automatic lubricating system are included.

The machine is driven by a 50 hp. motor mounted on the drive box with which it forms a self-contained unit. The drive box is totally enclosed, jig drilled and planed so that a speed box of the constant speed or adjustable speed type is interchangeable with the head-stock. All gears are of steel with wide faces and coarse pitch. They are mounted on large diameter shafts which run in bronze bushed bearings of liberal proportions. All overhung gears have been eliminated and each gear is mounted against a shaft bearing.

Both headstocks are of massive construction. The left headstock is stationary and is rigidly bolted to the bed while the right hand headstock is movable and is adjusted to a sliding fit on the bed. It is secured to the bed both front and back by long shoes sliding in large tee slots, the clamping surfaces of which are provided with re-newable steel liners. The face plates, one on each head, are mounted on extra large spindles and are driven in unison by steel internal gears securely bolted to them. The driving pinions are forged steel and are mounted on an auxiliary shaft located at the front of the machine about on a line with the tools. This construction de-creases the torsional strains on the drive shaft and tends to counteract cutting strains, thus reducing the pressure on the main spindle bearings. A large self-alining ball thrust bearing takes the end thrust of each spindle.

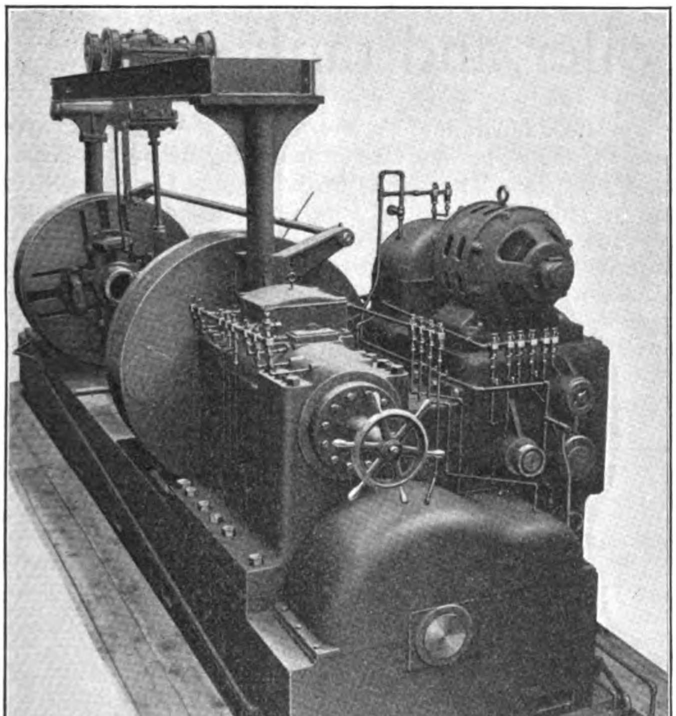


Niles-Bement-Pond open type car wheel lathe driven by a 50-hp. motor

These bearings, it is claimed, absorb but one-seventh of the power consumed by a plain step bearing. They reduce the power loss through friction and increase the power delivered at the cutting point of the tool. Four semi-automatic drivers are fitted on each face plate and firmly grip the rims of the wheels. These drivers are adjustable radially for different wheel diameters.

The right hand headstock is traversed along the bed by power through a large screw driven by a separate motor located at the end of the bed. A self-alining ball bearing takes the thrust from this screw. A safety feature, called a torque limiting friction, is located on the end of the screw. It can be so adjusted that the drivers on the headstocks can be brought up against the wheels with just the proper amount of lateral thrust to grip the wheels firmly. When the headstock is withdrawn this slip friction becomes a positive clutch. An electric switch acts as a safeguard against accident by limiting the lateral motion of this headstock. Pneumatic power clamps, one at the front and one at the back, clamp the right hand headstock to the bed simultaneously. If air is not available an electric clamp can be used.

The bed is of execeptionally heavy, deep box section and is reinforced at suitable intervals by rigid box braces.

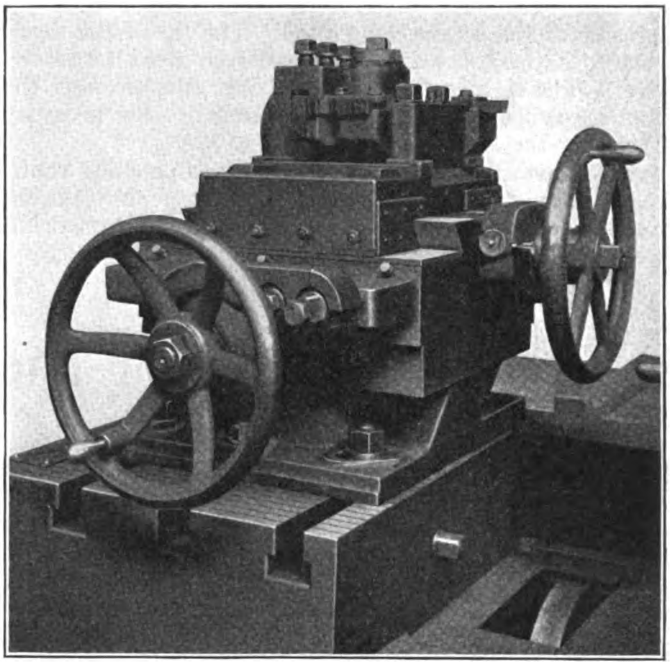


End view of car wheel turning machine, showing lubricating system

The flat ways on the right hand end of the bed which are subject to wear from the sliding headstock, are provided with renewable steel wearing plates. The left hand end of the bed projects beyond the driving head to accommodate an out-board bearing for the large driving gear on the drive shaft and its pinion.

The lathe is thoroughly lubricated. A special automatic lubricating system has been developed which greatly reduces friction, power consumption and should greatly reduce expensive repairs, shut-downs and maintenance. A geared pump keeps the oil level in a large tank located in the upper part of the drive box filled to the high level of the lubricating system. From this tank, trunk lines carrying adjustable sight feed lubricators supply each bearing with the proper amount of oil. The gear trains are continuously flooded with an unrestricted flow of oil. All used oil from both headstocks drains to a reservoir under the floor where it is filtered and again pumped to the upper tank for circulation.

A new design four sided flat turret tool post carries the four cutting tools for roughing, flange roughing, flange and tread finishing, and chamfering operations. Each tool, when indexed, comes into its cutting position



The left hand headstock, showing the arrangement of the tool holder

with a minimum amount of horizontal adjustment. Tool blades are securely clamped to the tool blocks and can be quickly removed for sharpening or replacing. Each tool post is mounted on a lateral feed slide which fits into the top surface of a cross feed slide. The wearing surfaces of both cross slides and lateral feed slides are covered by renewable hardened steel plates. The cross slides provide in and out adjustment for setting the depth of cuts. They are mounted directly on top of heavily built bases which are adjustable on the bed by rack and pinion to accommodate different size wheels. Four bolts clamp each firmly to the bed when set in the desired position.

There are power lateral feeds to both right and left hand tool rests. The feed ratchets are totally enclosed and so arranged that the feed may be thrown on or off by means of a pawl which also controls the direction of the feed. A feed change disc readily accessible to the operator makes it easy to change to any of the six available feeds which vary from 3/32 in. to 9/16 in.

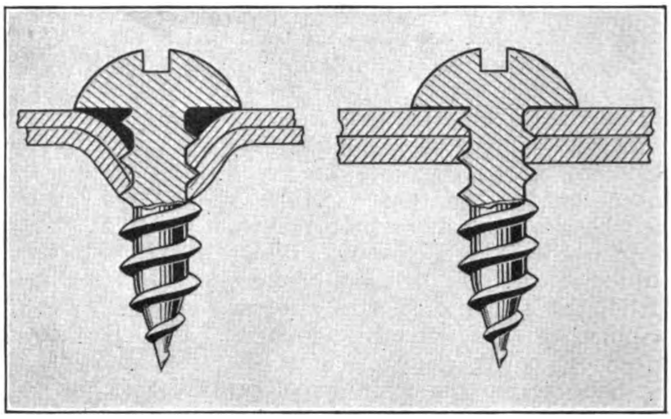
Short ends of tracks, attached to a steel telescoping cover which extends between the face plates, line up with the shop tracks when the movable headstock is in the charging position. Wheel sets are then rolled in and raised by a pneumatic hoist for chucking. A calipering device consisting of an adjustable pointer on a bar rigidly supported by the headstocks makes it easy to turn both wheels to the same diameter.

Self-tapping hardened steel sheet metal screws

SELF-TAPPING, hardened steel screws have been designed expressly for sheet metal work by the Parker-Kalon Corporation, New York. They differ from the ordinary wood screws in that they have a straight body and a special thread which extends all the way to the head so that the screws can be driven until the head is flush with the metal. The screws are hardened by a process which makes it capable of cutting into sheet metal without injury to its thread.

To use these screws it is only necessary to punch or drill a hole through as many sheets of metal as are to be held together. The hole must be a trifle smaller than the diameter of the screw being used. The tip of the screw is placed in the hole and the screw driven in with a screw-driver. The tighter the screw is driven, the stronger the fastening is made. This method eliminates the necessity of tapping the sheets.

The screws can be used in such work as patching roofs, car interiors, etc., repairing water tanks, fastening lagging thimbles to engine jackets, and erecting and repairing sheet metal work around shops, building, etc. The screws are made in six different sizes each of which can be furnished with round or flat heads.



Sheet metal screws which cut their thread as they are driven through the metal sheets

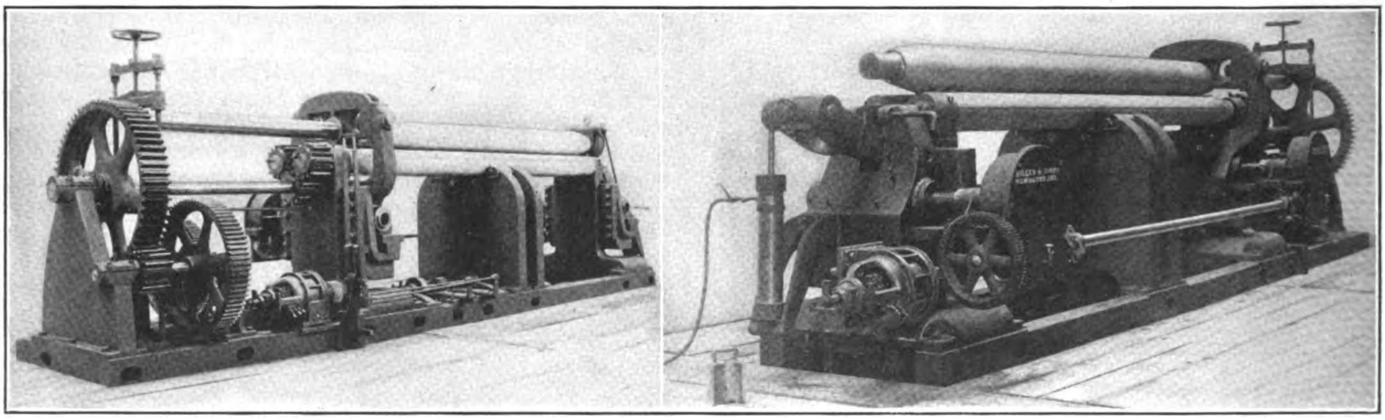
Bending rolls for the boiler and tank shop

ONE of the most troublesome problems in a tank and boiler shop is the flat place that is usually left on the edges of plates after being rolled on plate bending machines. Various methods of curving these edges have been employed for years, one the use of a heavy press, another mauling, and another the use of forming blocks on pyramid type rolls.

For a number of years the Hilles & Jones works of the Consolidated Machine Tool Corporation, Wilmington, Del., has been trying to evolve a plate bending machine, that would curve the sheet completely to the edge so that if desired the two edges may be welded, making a full cylindrical surface without any further work. Such a machine has recently been developed.

The capacity of the machine is rated to roll ⅜-in. soft plates 14 ft. wide, or corresponding duty, and the same type of roll is made in other sizes. On the particular machine mentioned, the upper roll is 13½ in. in diameter and is adjustable vertically to provide for pinching the plate and also has horizontal adjustment so that it may be brought over to the center of either one of the lower rolls. It is this combination of the vertical and horizontal adjustment for this upper roll that provides the means for bending a plate to a true radius to the edge. The top roll is also provided with a solid forged extension for counterbalancing it when the back housing is dropped down for the removal of plates rolled to full circles.

The mechanism operating the vertical adjustment of the upper roll is such that both ends of the roll are raised and lowered simultaneously or each end independently. Positive clutches provide for this arrangement and there is a vertical adjustment of 4 in. to the upper roll. The horizontal adjustment of the upper roll is 14½ in., or 7¼ in. each side of the center. The adjustments of the upper roll are by independent 10-hp. motors, one motor for the vertical adjustment and another for the horizontal adjustment. This is necessary to provide an independent flexible control for the two motions. The lower rolls are each 10½ in. in diameter. with a center to center distance of 14½ in.



Front and rear views of bending rolls which curves the sheets completely to the edge

An important feature of this design is the air cylinder which is provided for lowering the yoke for the removal

of plates rolled to full circles. This air cylinder serves to eliminate the use of a crane, which is the usual practice for lowering the yoke, and this one feature materially increases the speed at which plates may be handled through the machine. The plate travel is 15 ft. per min. The driving of the lower rolls is by a 20-hp. reversing motor.

Worm and worm wheel drives are used for both the vertical and horizontal adjustments of the upper roll. Each worm and worm wheel are totally inclosed and run in oil. All gears have teeth cut from the solid. The weight of the machine without electrical equipment is 72,000 lb.

Bullard power operated chuck

ANY analysis of machining time on chucked work includes, in the aggregate, a considerable amount of time required to chuck the piece in either standard chucks or fixtures. While the function is, of course, necessary to production, it is not directly productive and any saving which is made decreases idle time and increases productive time. On single spindle machine tools, chucking time is a definite factor in the process no matter what portion of the productive time it comprises. In the multiple spindle machine, where loading is done simultaneously with machining, this factor only becomes important when the rate of machining crowds the operator beyond his capacity.

As a definite step forward in the elimination of idle time and constructively increasing machine production, power chucks of various designs have been used. Some of them have been designed to reduce only the fatigue factor in the operation, while others have made definite steps toward increased production and greater economy in the process. The design of a power chuck should provide for only a simple motion by the operator. Its action must be positive and dependable while its mechanism must remain simple and of ample strength. Insofar as possible its complete function should be self-contained with power derived from the same source as the machining function rather than dependent on accessory or external forces which may be subject to fluctuation and interruption separate from the primary machine operation. A power chuck should also permit a definite control of the gripping power exerted on the work; for proper chucking requires simply the holding of a piece against the machining operation, and both accuracy and efficiency of the job may be as adversely affected by over-chucking as by insufficient support against the cutting operation.

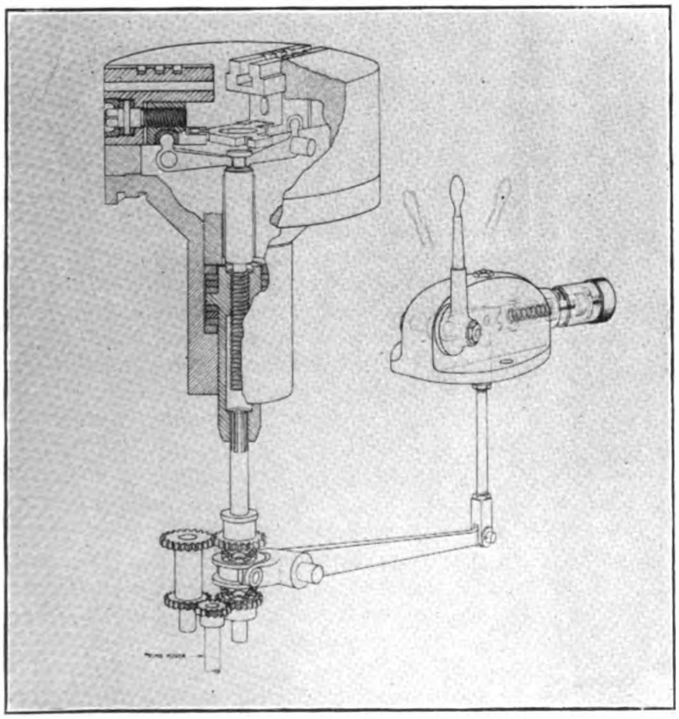


Diagram showing the construction of the Bullard power operated chuck

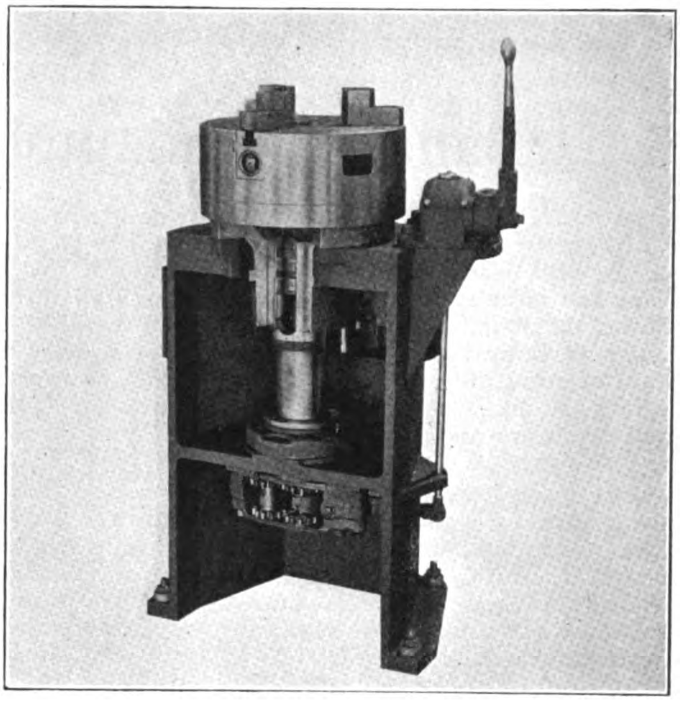
With these points in mind, a power chuck has been designed by the Bullard Machine Tool Company, Bridgeport, Conn. and placed in used on its various types of machines. The primary actuating motion of the mechanism is a vertical pull exerted by a screw and nut. This motion is transferred to the three jaws of a standard chuck by a bell crank lever and may also be adapted to the operation of special fixtures designed with its use in mind. The construction, as shown in the illustration, clearly indicates that when once the pressure is set by power it cannot be released except by reversing the motion. Its operation is controlled by a double clutch with angular teeth and compound gears which provide power in either direction from a common source. The driven member of the clutch is brought in contact with either forward or reverse drive by connection with a hand lever operating through a dart. The spring tension is so calibrated as to actually weigh the load of the pressure on the jaws. In operation it is simply necessary to throw the lever engaging the clutch for either forward or reverse

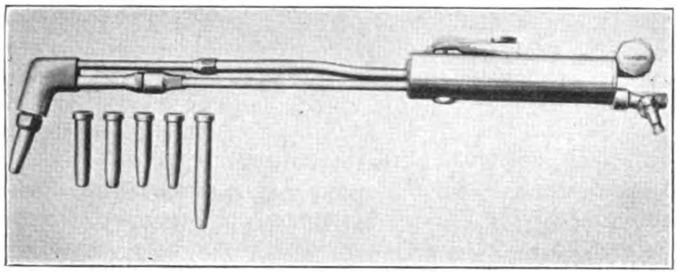


Power chuck which receives its primary actuating motion through a screw and nut

movement. The clutch is automatically disengaged when the movement has been accomplished; and it is impossible to build up an excessive jaw pressure by holding the clutch lever in the engaged position. The time required for operating the chuck in either direction is two seconds.

Low pressure cutting and welding torch

A LOW pressure torch which will operate on either low or high pressure gas with equal efficiency is being manufactured by the Alexander Milburn Company, Baltimore, Maryland. It is especially constructed to operate with the low pressure acetylene gas, city gas or hydrogen. It may also be used with a low pressure acetylene generator.



Low pressure torch provided. with solid copper tips

The manufacturer has utilized in the design of this torch the various parts of its standard cutting and welding torches. A correct and intimate mixture of the oxygen and acetylene has been obtained with non-flashback qualities. The torch may also be adapted for welding as well as for cutting by the interchange of tips. It is claimed that it can efficiently perform practically all the cutting and welding operations within range of the process.

It is constructed of bronze forgings and special seamless tubing, designed to withstand constant service. The tips are made of solid copper and are interchangeable on a large number of low pressure torches of other makes.

Band saw adaptable for motor drive

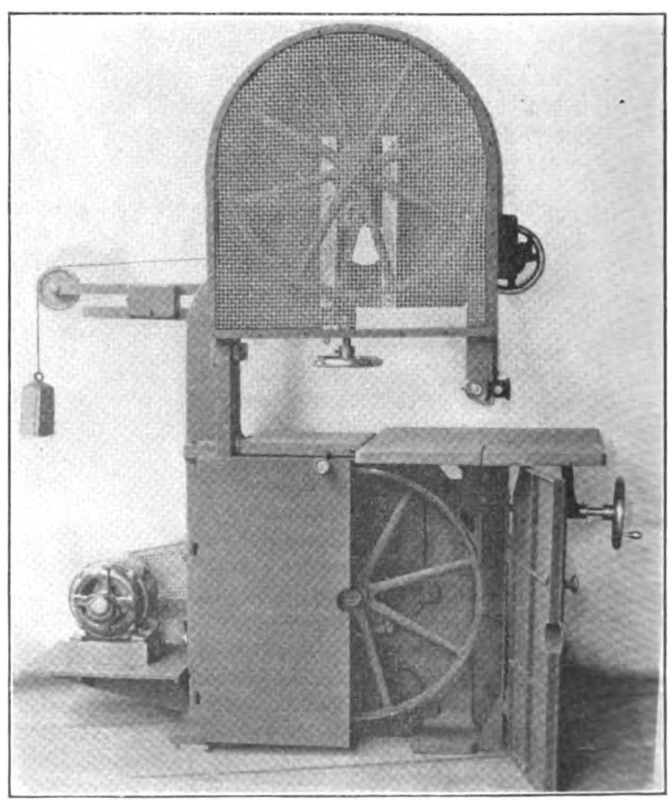
A LINE of band saws of improved design has recently been brought out by the American Saw Mill Machinery Company, Hackettstown, N. J. This line includes various sizes ranging from 20 in. to 36 in., the 30-in. size of which is shown in the illustration. These machines have been designed with the principal objective of providing convenience of operation, accuracy and durability. The design for all sizes is massive and the column and frame is of sufficient weight to insure against vibration.

The upper and lower wheels for the 30-in. size are of the solid spoke type 30 in. in diameter and have a 2-in. face. The manufacturer has also provided an optional design in which, if preferred, the lower wheel can be equipped with a special brake attached to the bolt shifter to stop rotation of the wheel quickly. Both wheels are keyed to ground steel shafts. The collar is forged solid on each shaft against which the hub of the wheel is firmly held by a large nut. Both the top and bottom shafts run in extra long bearings, made in two parts to take up the wear and are adjustable to provide for alinement of the saw blade. The upper wheel bearing is hinged for tilting of the wheels by means of a lever located in a position convenient for the operator.

The saw guide is of a special anti-friction design and is mounted on a counterbalanced square post. A hand wheel is provided for raising and lowering the guide post with one hand so that the workman may devote his entire attention to the work. The straining device for the upper wheel is of wide range and is sensitive due to the use of both a spring and weight. The slide head which carries the upper wheel bearings slides in a groove in the column and is held in place by steel gibs.

The table is 20 in. by 32 in. and is made rigid by extensive ribbing on the underside. It is cast face down to insure a clean surface and after being machined is scraped and polished. A hand wheel and screw are provided for tilting the table to 45 deg. for bevel sawing and it is equipped with a brass index and pointed to register its position. A lock fastens the table in any position.

As shown in the illustration, the various moving parts of the band saw are well guarded. The front side of the upper wheel is protected by a hinged wire guard and iron doors are provided for the lower wheel. The saw is fully



Motor driven band saw fully protected with safety guards

protected by the upper and lower guards in the rear and a guard follows the guide in front. An iron cover is also provided to enclose the machine back of the wheels. The lower pulley and belt are protected by wire mesh.

A feature of this machine is the provisions made for motor drive. A two or three horsepower motor is recommended to operate it. The two-horsepower size is sufficient for ordinary shop work, but the three-horsepower is recommended for heavy work. The design is such that the motor can be set on the floor and bolted to a pulley drive or set on a special bracket attached to the body of the machine and provided with a gear drive.

A 26-in. high power turret lathe

THE International Machine Tool Company, Indianapolis, Ind., has developed a 26-in. high power turret lathe of improved design. The general description of this machine is somewhat similar to the general purpose lathe of the same size which has been manufactured by this company for some time. The method of drive and the design of the headstock has been changed, making the drive more direct. The general method of feeds, speeds and rapid traverse for the tool post and the turret are the same as in the older machine.

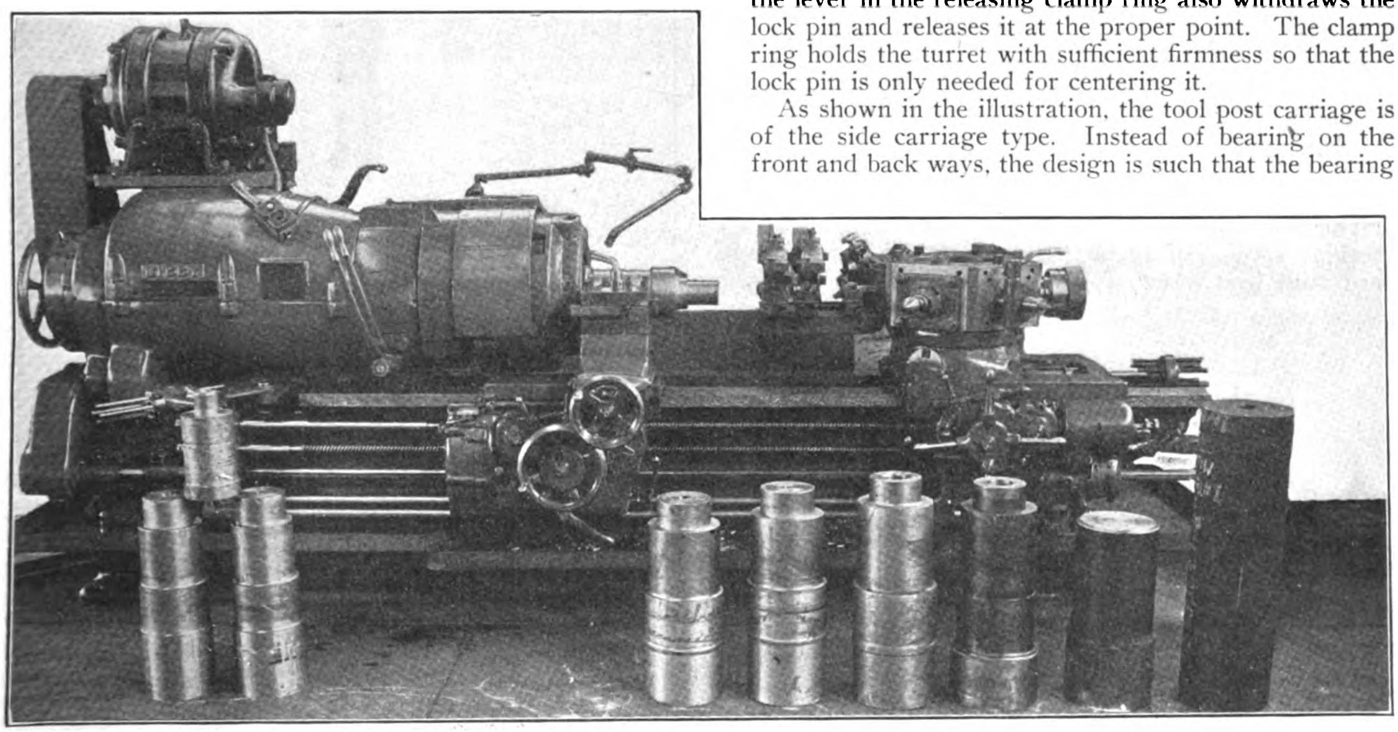
The gears in the headstock are made of steel with a wide face and course pitch. The two driven gears on the spindle are located one on either side of and close to the front main bearing. The chuck ring gear is 22 in. in diameter, keyed and bolted solidly to an 18½-in. flange, forged on the spindle. The friction drives are of large diameter and are located on the high speed drive shaft. Eight gear ratios are available ranging from 3.36 to 1 up to 57.6 to 1. The spindle and shaft bearings are of phosphor bronze. The main spindle bearings are adjustable for wear and are equipped with ring oilers. The point of the spindle is of .50 per cent carbon steel and the nose is threaded to receive the chuck. The seat is tapered so as to centralize the position of the chuck which is of special design and has three 23-in. movable jaws.

The bed and bedstock housing is in one casting. The bed is cross-ribbed every 11 in. and has a longitudinal rib through the center. The ways are of flat design, the front way being 6 in. wide and the back way 4½ in. wide. These ways provide a wide bearing surface for the carriages, the design of which is such that the force of the cutting strains on the spindle is transferred direct to the ways. The front way is undercut 15 deg. to receive the long taper gib for both the tool posts and turret slides, which takes care of the side thrust of both carriages. The turret slide is of heavy construction, 30 in. long and having 315 sq. in. of bearing surface on the bed. It is gibbed to the front way by a long taper gib and is also gibbed to the underside of the ways. A positive clamp to hold the slide stationary when using the centers is also provided.

The turret is a hexagon 18 in. across the flats and has six 4¼-in. holes. The faces are 9 in. wide by 8 in. high. The turret rests on a base 17 in. in diameter which is centralized by the cone seat. It can be securely clamped on the outside diameter of the seat by a double clamp ring operated by an eccentric and lever. A similar action of the lever in the releasing clamp ring also withdraws the lock pin and releases it at the proper point. The clamp ring holds the turret with sufficient firmness so that the lock pin is only needed for centering it.

As shown in the illustration, the tool post carriage is of the side carriage type. Instead of bearing on the front and back ways, the design is such that the bearing on the back way is transferred to a taper gibbed bearing on the bottom of the front side of the bed. The 15-deg. undercut on the front way permits the tool posts to pass the chuck and permits turning and facing it up to the full swing of the machine. This design also allows the turret to be moved up flush with the chuck so that short stocky tools instead of long overhanging tools may be used. The tool post is of steel and will carry four tools at one time, each independently adjustable for height. It can be locked in any of the four positions and clamped in any desired intermediate position by means of a double acting clamping device.

Independent power rapid traverse is provided for each carriage. The carriages can be operated in either direction at a rate of 35 ft. per minute. None of the head-



Libby turret set up for turning out locomotive crank pins

stock or feed gears are used in the rapid traverse feed mechanism. The slides are operated by means of a hand wheel on the tool post slide and pilot wheel on the turret slide. One revolution of either wheel will advance the slide one inch. The power feeds are gear driven, the feed changes being made in the apron. The feeds for the turret and tool post carriages are independent of each other both as to direction and amount. They can also be reversed independently in either apron. All gears in the headstock are either steel or semi-steel. The gears in the aprons are of steel and are bronze bushed or run on hardened pinions. All gears and pinions are heat treated. Force feed lubrication is provided to all main bearings of the machine.

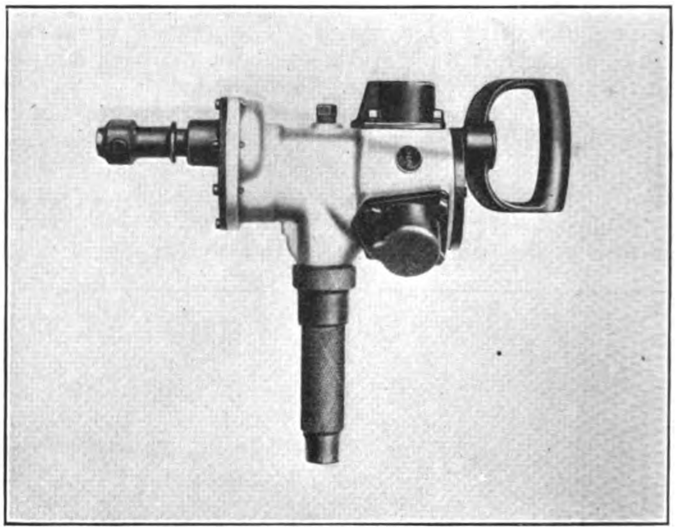
Pneumatic wood boring drill

A LIGHT, reversible wood boring machine has recently been placed on the market by the Ingersoll-Rand Company, New York, which is suitable for boring holes in wood up to 1 in. in diameter and is known as the size DD drill.

The features of this type of machine are briefly a special three-cylinder motor, a light weight aluminum case with steel bushings cast in place in all the bearing holes and the throttle hole, a renewable crank pin sleeve and cast iron cylinders which are renewable and interchangeable. The renewable cylinders permit any one cylinder to be easily replaced. The rotating parts of the three-cylinder motor are all accurately balanced, which eliminates vibration and reduces the wear and tear on the machine. All of its parts are readily accessible for inspection.

These drills are furnished with a spade handle and a bit chuck; a breast plate or feed screw can be substituted in place of the grip handle when so desired and a drill chuck in place of the bit chuck. The drill is thus made adaptable for a wide variety of work.

The following are a few of its specifications: Average working speed, 705 r.p.m.; total weight, 15 lb.; length of feed with feed screw, 2½ in. length overall (with grip handle), 15 in.; distance from side to center of spindle, 1 9/16 in.; size of hose recommended, ½ in.



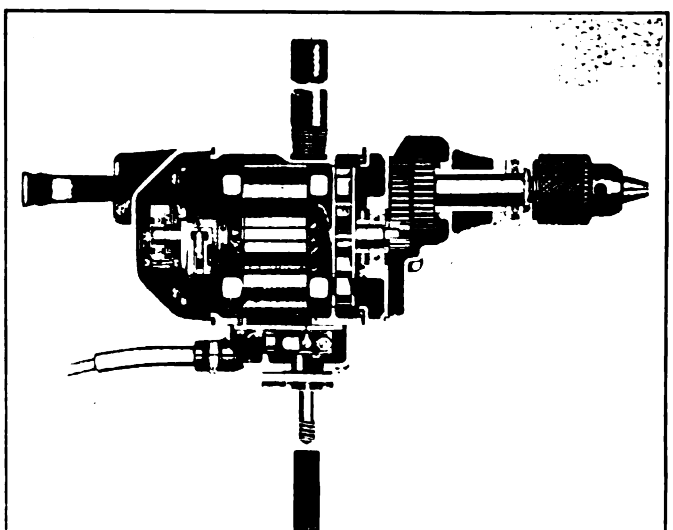
Ingersoll-Rand, three-cylinder wood boring drill

Standard duty half-inch universal drill

A STANDARD ½ in. universal drill is a recent addition made by the Hisey-Wolf Machine Company, Cincinnati, Ohio, to its list of portable electric machine tools. It can be furnished with either a 115 or 230-volt motor with a no-load speed of 525 r.p.m. capable of drilling or tapping steel up to ½ in.

The motor is designed particularly for electric drill service. The armature is hand wound with the lead ends firmly banded in place. The heavy armature runs in ball bearings which cannot slip, as the inner races are locked. The bearing on the gear end of the armature is mounted with a floating fit in a hard cast in sleeve, which is intended to obviate binding and internal friction. A tooth type stator gives an efficient magnetic flux distribution. The brush holders with an adjustable spring tension are mounted as a separate unit on a bakelite yoke. This arrangement permits brush adjustment when necessary. At each end of the motor shaft are felt washers for retaining the lubricant. They are firmly held between steel collars to prevent them from working loose or wedging. The motor is cooled by force ventilation drawn into the motor by a fan keyed on motor shaft.

The electrically heat treated gear on the armature shaft is removable. The spindle gear is carried on an oversize chuck spindle which is hardened and ground and automatically lubricated through the gear case. The chuck end of this spindle runs in over-size thrust bearings. The chuck is fitted to a hardened and ground tapered spindle. The Jacob's chuck is standard equipment.

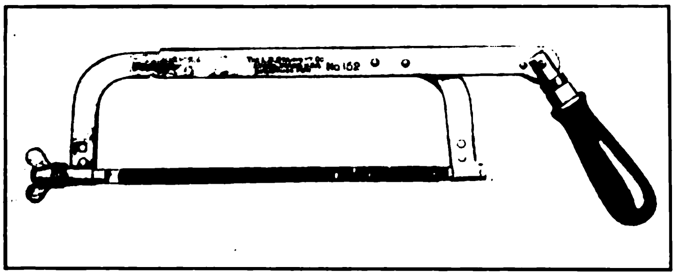


Removable end plate provides easy access to the motor of this machine

The end cover is a separate piece which carries all of the pressure applied to the spade handle, and being independent of the motor and motor bearing, relieves them of all strains. This construction also affords a convenient access to the carbon brushes for adjustment or renewal by the removal of three screws. The spade handle is directly in line with the drill chuck which tends to eliminate side pressure and reduce friction. For close quarter work it can be removed and the pressure applied directly on the end cover casting.

Starrett feeler gage and hacksaw frame

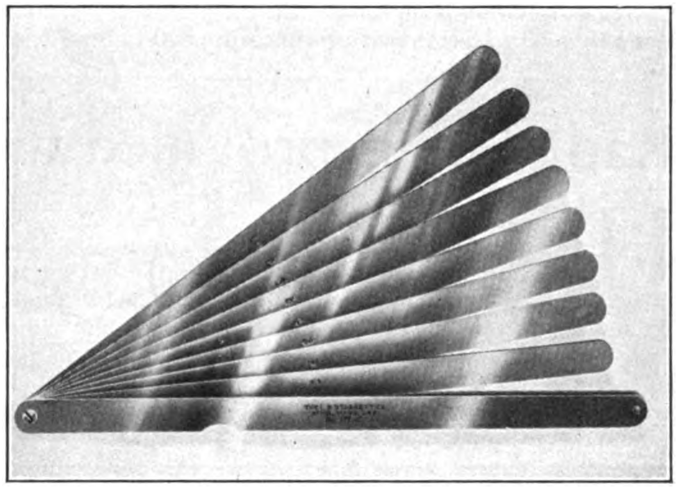
RECOGNIZING the demand, created by the maintenance of the many gasoline motors recently acquired by the railroads and in a lesser degree by the repair of machine tools, for a long leaf thickness or feeler gage, the L. S. Starrett Company, Athol, Mass., has brought out such a gage with eight leaves in the following thicknesses: .002 in., .003 in., .004 in., .005 in., .006 in.,



Hacksaw frame the handle of which can be adjusted to 13 positions

.008 in., .010 in. and .015 in. The leaves are ½ in. wide and 9 in. long and should one become damaged it can be easily replaced. The possibilities of this gage will be particularly appreciated when regrinding motor cylinders to take over size pistons.

Another tool of interest to those repairmen whose work calls for the use of a hand hacksaw in cramped quarters or strained positions, is the hacksaw frame shown in one of the accompanying illustrations. It will take any length of blade from 8 to 12 in. and has a handle which may



Feeler gage with unusually long blades

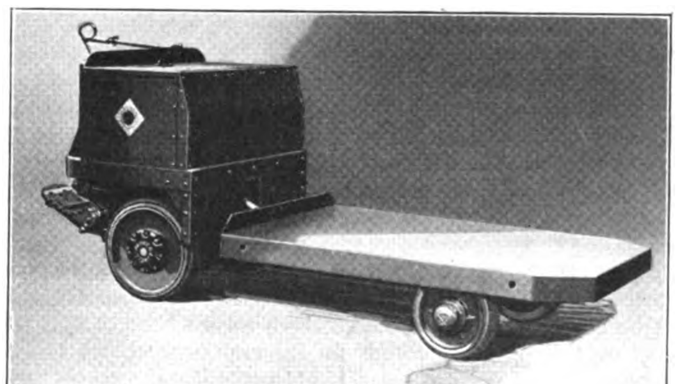
be adjusted to 13 positions in each of which it may be locked. The saw may also be quickly set to cut in any one of four directions with respect to the plane of the frame.

Large capacity electric lift tractor

THE success of the electric lift tractor within buildings has tempted many users to increase the range of this type to more distant points on the premises where runways are in poor condition. In most instances this has required the extension of runways, although some concerns have not given proper values to such improvements. On the other hand, yards and storage spaces often are so extensive that the laying of ideal trucking surfaces would possibly require a prohibitive investment.

The improvement of the trucking device has kept pace with the encouraging interest taken by the average user in its employment. The Elwell-Parker Electric Company, Cleveland, Ohio, has developed a heavier unit of the electric lift-type especially suited to travel runways not altogether smooth. This haulage unit is of broader gage than those designed particularly for inside operation. The gage of the front and rear wheels is the same, i.e., 30 in. They are fitted with 22 in. drive and 15 in. front wheels and with either 3½ in. or 4½ in. tread. The drive wheels are equipped with double row ball bearings weighing 13 lb. each, and radial and thrust bearings measuring 7 in. in the outside diameter.

These wheels are carried on drop forged knuckles with drop forged levers pressed on tapered serrations, assuring a firm union of the two. These knuckles support the weight of the axle, frame and load on a steel ball bearing recessed in a cup at the upper ends. The levers are fitted with ball ends received in the steering rod sockets. All



Electric lift tractor specially suited to travel over uneven runways

the rods are placed high beneath the platform to avoid contact with obstructions on runways. The full-floating, alloy steel, drive shafts are pressed into drop forged clutch

plates bolted to the outside of the drive wheels, these shafts being fitted with chrome-vanadium universal joints and engaging the splines of the differential.

An innovation in tractor design is found in the all-drop forged differential. The differential carries a special Brown & Sharpe phosphor bronze worm wheel, lock bolted between the two halves of the drop forged differential cage. A multi-thread steel worm on radial and thrust bearings with the above parts of the differential, are assembled and adjusted at the bench and the whole dropped into the axle differential pot. A new type of universal joint, inside the brake wheel, connects the drive worm to the motor shaft with a demountable armature. The motor is fitted with ball bearings.

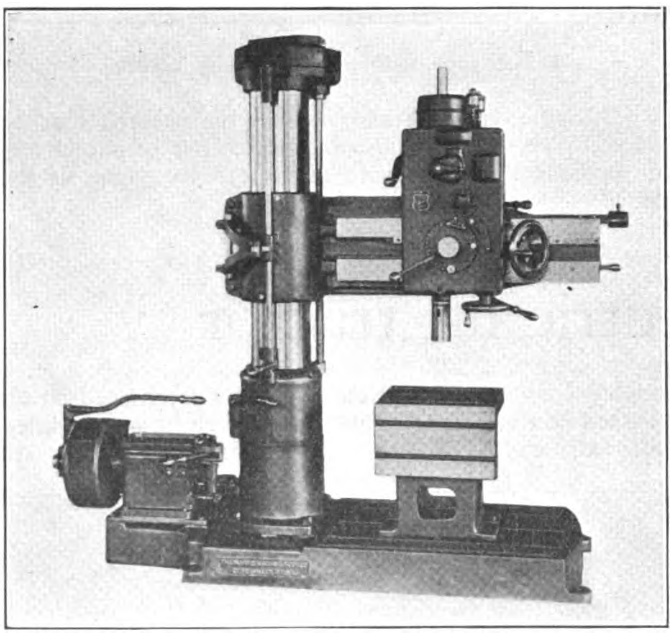
Another feature is the flexibility of the drive unit when traveling over rough surfaces when the platform is loaded unevenly. The tractor platform measures 40 in. by 72 in. and is formed from a single steel plate with deep side flanges. The platform nose is tapered to aid its insertion beneath a skid even though approached from an angle. The lift of the platform is 6½ in. It is 17 in. high when in the lowest position and 23½ in. when raised. Clearances are important when the tractor crosses door-sills, passes over the crest of an incline or a wheel drops into a runway depression. The frame on this tractor is of standard commercial angles and heavy channel sections, hot riveted throughout, and offers possibilities for varying platform lengths.

The low set, all-steel battery compartment at one end is fitted with removable end doors and a hinged cover to facilitate the inspection or quick exchange of the storage batteries. The wire leads between the controller and the battery are continuous—no splices—to the motor brush studs and the motor field coils.

Radial drill provided with a tapping attachment

HIGH speed radial drills in 2-in., 2½-in. and 3-in. sizes, and heavy duty radial drills in 3-in. and 3½-in. sizes have recently been brought out by the Morris Machine Tool Company, Cincinnati, Ohio. The design of all of these machines is basically the same.

The head is fully enclosed and well balanced on the arm so that it travels freely. An adjustable taper gib is provided to take up the wear. One lever operates two clamp screws which securely clamp the head on the arm without affecting the alinement. Oil is properly distributed throughout the head from an oil reservoir at the top of the head by filling an oil cup once a day. The feed worm wheel dips in a trough of oil.



Morris radial drill provided with a tapping attachment and a well designed lubricating system

The spindle is a steel forging which runs in phosphor bronze bearings in the sleeve and is driven by two keyways. It is fitted with ball thrust bearings and the spindle gear is mounted on a ball bearing. The sleeve is of steel, fitted with bronze bearings and the rack is cut directly in the steel sleeve. The helical spindle gears are made of a special alloy steel and are of small diameter, keeping the peripheral speed down to a minimum and thus reducing the possibility of trouble when reversing on high speeds.

The feed gears are enclosed within the head and provide six feeds. These are marked on a dial in .001-in. increments per revolution of the spindle. The feed can be automatically tripped at any depth within the traverse of the spindle. The tapping attachment and back gear bracket is a unit mounted on the back of the head. The friction plates in the tapping attachment are of the multiple disc type. A simple and quick adjustment is provided from the outside of the casing. The tapping capacity in cast iron is up to 2½ in. using a pipe tap. The back gears, back gear clutches and spindle gears are Chrome nickel steel.

A speed chart at the change-speed lever permits the operator to quickly select any one of the 18 spindle speeds. The speed box is of the sliding gear type and is equipped with ball bearings. The gears run in oil and the ball bearings are lubricated by the splash from the gears. The driving pulley is fully enclosed and fitted with a friction clutch operated by a single lever. It runs on ball bearings when the clutch is disengaged.

These machines can be arranged for a constant speed motor drive in connection with the speed box, or a variable speed motor with a 4 to 1 ratio, mounted on the base in place of the speed box and geared to the lower shaft. The variable speed motor may also be mounted on the back of the arm or a constant speed motor and ball bearing speed box, mounted on the arm. This construction eliminates four bevel gears and three spur gears.

The cone drive in connection with a double friction countershaft gives 20 spindle speeds. The countershaft pulleys are 12 in. by 3¼ in. and run at 520 and 600 r.p.m. The column or sleeve which is 9¾ in. in diameter, is mounted on an inner column which extends through to the top and revolves in a ball bearing. The column cap is equipped with an oil reservoir with oil leads to all the bearings.

The arm is designed to resist torsional and lifting strains and the bearing on the column is extra long so that the arm can be clamped in any position by a single lever convenient to the operator. The arm is raised or lowered by a power controller through a lever at the bottom of the column. This lever accomplishes two purposes. First, it automatically unclamps the arm before the elevating or lowering gears are engaged by the movement of the lever. A little further movement of the lever engages the gears and the arm is raised and lowered to its desired posi-

tion. In bringing the lever back to its central position until the latch catches, the gears are disengaged and the arm clamped by one movement of the lever. This is not only a positive safety, preventing the gears from being engaged while the arm is clamped, but it performs the operation three to four times faster than the old method of unclamping the arm before raising and lowering it.

The base is heavy, deep and well ribbed and is provided with T-slots. The oil channel around the base drains through a screen to a large reservoir, having an overflow partition to keep the chips and dirt out of the pump and thus preventing clogging of the lubricating system.

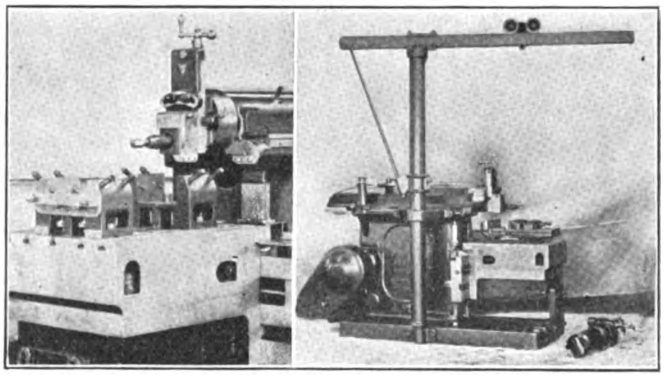
Shaper designed for the railroad shop

A 32-IN. shaper intended principally for railroad work, and arranged particularly for the complete machining of locomotive driving boxes and their accompanying shoes and wedges, driving box crown brasses and rod brasses has recently been placed on the market by the Cincinnati Shaper Company, Cincinnati, Ohio. It is equipped with a special table, extended circular feeding head as well as a standard head, special shoe and wedge chuck, standard vise, and a 1,000-lb. boom crane, and an indexing fixture for planing driving rod brasses. A power-driven rotating fixture for crown brasses can also be supplied, if desired. The machine is arranged either for belt or motor drive.

The special table is arranged with a removable top, 9½ in. deep, which provides a wide range of distances between the ram and the working surface of the table. This top is left in place when planing the crown brass fit in the driving box, as shown at the right in Fig. 1, planing shoes and wedges, or when doing the usual run of shaper work, either with or without the standard vise. It is removed when planing the shoe and wedge fits in the driving boxes, and, when used in this way, provides sufficient height between the table and the ram to permit the largest driving boxes to be placed directly on the table. As can be seen at the left in Fig. 1, mounting the work in this way keeps it directly in line with the outer table support and insures the greatest possible stability for the cut.

The working surface for the upper table is 32 in. by 24 in. and that of the lower table 24¾ in. by 24 in. Both are provided with suitable T-slots and the upper table has holes conveniently located into which stop pins may be inserted. The outer support for the table is effective at all heights whether the removable top is on or off. Also, at no time does any part of it project above the surface of the table in use.

The circular feeding head, as shown at the right, Fig. 1, is used in planing out the crown brass fit in driving boxes and will plane out such fits from a minimum of 8 in. in diameter to a possible maximum of 18 in. in diameter. It is strong and rigid, the extended body being bolted directly onto the end of the ram with four heavy bolts. It may be rotated either by hand or automatically in the same manner as the down feed on the standard shaper. This circular feeding head is furnished in addition to the standard head and interchanges with it on the circular T-slotted end of the ram.



At the left the shaper has the shoe and wedge chuck mounted on the special table—The right view shows the circular feed head removed and the vise mounted on the table

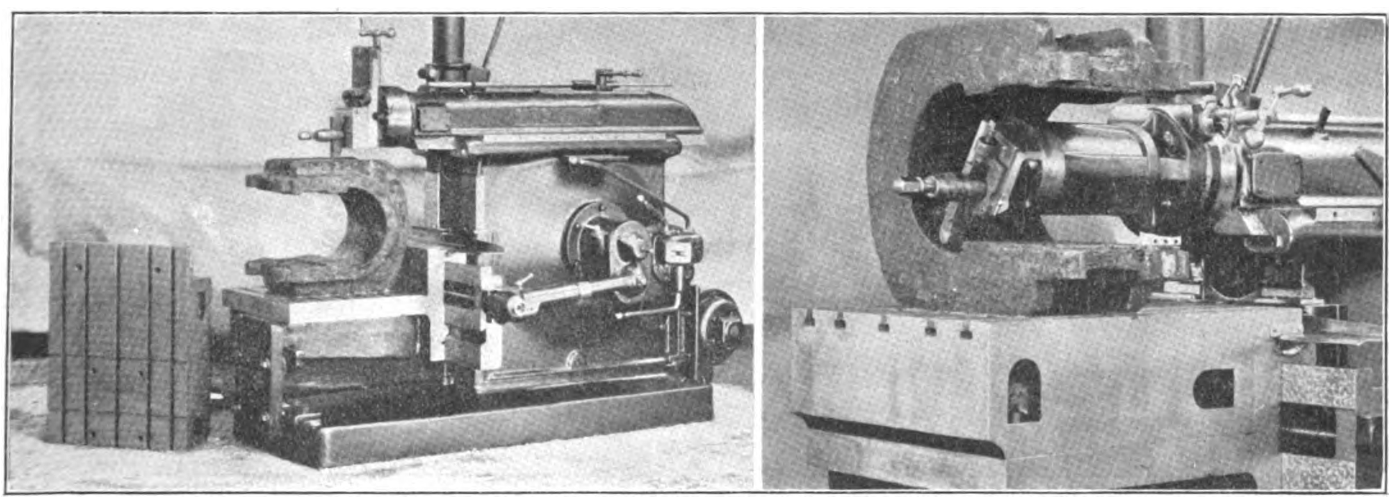


Fig. 1.—The view at the left shows the shaper set up for machining the shoe and wedge fit of a driving box with the special table on the floor—The right view shows the special table on the shaper with a driving box set up for machining the crown brass

The special shoe and wedge chuck is arranged to handle both small and large shoes and wedges, and is made in two parts which can be adjusted on the table to suit short or long work. Making the chuck in this way permits the operator to set his surface gage directly on the shaper

table when lining up the lay-out marks or punches. The work rests on four adjusting screws which are conveniently located and very accessible, and which can easily be adjusted to line up the layouts, and is held down by eight screws coming in at an angle from the sides. The front half of the chuck is provided with an end stop bar so that very heavy cuts can be taken.

The boom crane is comparatively light for quick handling, but strong and rigidly constructed with ample capacity for carrying loads up to 1,000 lb.

An unusually strong and heavy vise also is furnished. It is of the double screw type and is of compact design having its working surface but 5 in. above the working surface of the shaper table. The jaws are 3 in. high and 15 in. long, and the vise opens 15 in. An unusual feature of this vise is that but four bolts are used, the same bolts being used for swiveling and for securing the vise to the table. One size wrench only is required for the vise, table support screws, and all the various other clamping nuts which the operator uses for making his settings and adjustments.

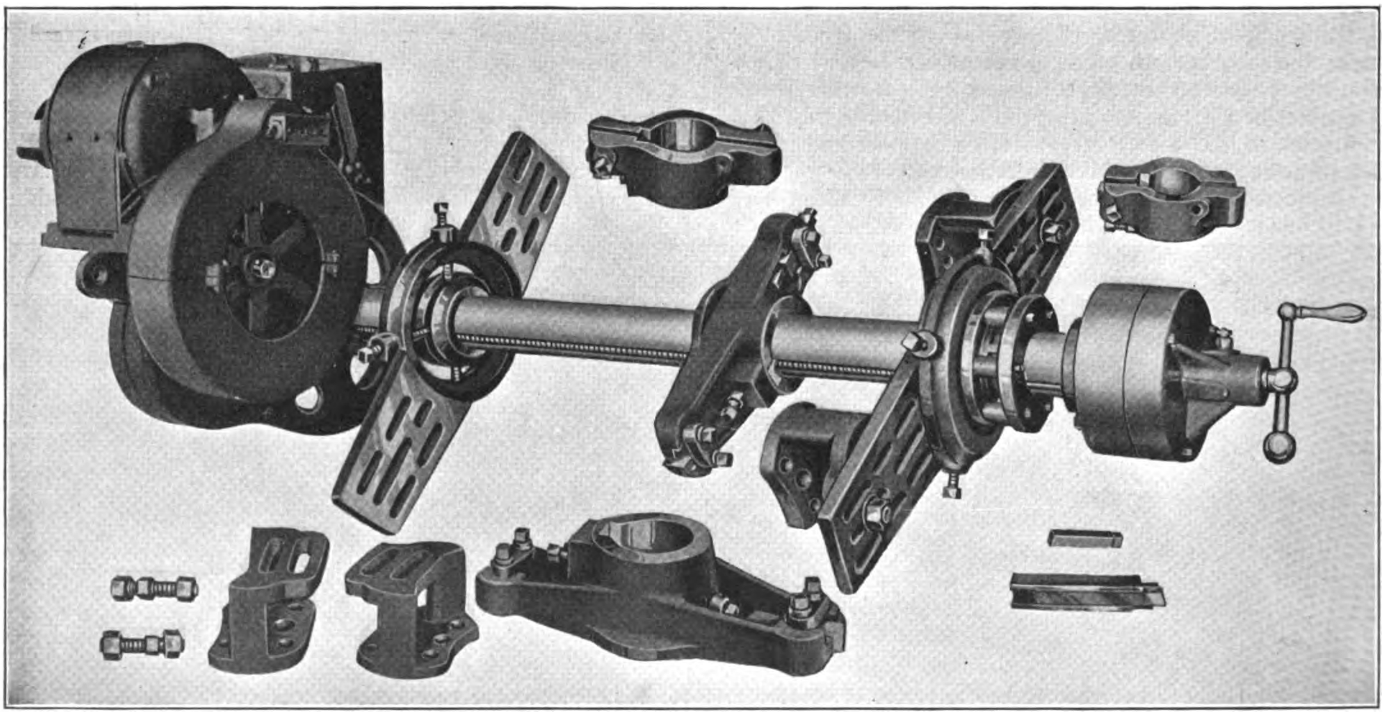
The machine is automatically oiled, which provides adequate lubrication to all the moving parts of the machine including the ram ways and rocker arm mechanism. Eight speeds are obtained through the internal transmission which is entirely within the column and runs at all times in a bath of oil. The various feeds are operated by cams which insures smoothness of action. The feeding mechanism is fully enclosed and also operates in oil. The stroke lengths are rapidly and positively set without necessity for starting the machine to determine the length of each stroke.

Motor driven cylinder boring bar

MANY locomotive repair shops and engine houses are equipped with motor-driven machine tools. Conforming to this practice, E. J. Rooksby & Co., Philadelphia, Pa., has developed and placed on the market a motor driven portable cylinder and valve chamber boring bar.

The improvement in the design of this machine consists principally in the manner of driving the bar by means of an electric motor. The motor is mounted on a suitable base on the gear drive frame, forming an integral part constant speed motors. Should a variable speed d.c. motor be desirable, the speed gear box is not required. The motor may be controlled by an ordinary switch or by an automatic remote control magnetically operated switch, with a start and stop push button station. This latter type is particularly desirable in portable tools as the push button station can be mounted on the gear drive and the switch box placed in a convenient place out of the way of the operator.

The main gear drive is provided with gear guards cast



The motor forms an integral part of the boring bar for boring out locomotive cylinders and valve chamber bushings

of it, the speed reduction being accomplished by mechanical gearing. The gear box is provided with four changes of shifting gears which gives the operator a selection of four cutting speeds, suitable for the various diameters of cylinders within the range of the bar. The gears, which have a positive lock shifting device, are completely protected and are enclosed in a gear case and run in grease.

These machines are furnished with either d.c. or a.c. integrally with the frame, adding materially to the strength and safety of the machine as well as affording complete protection to the operator.

The bars are made of machine steel accurately finished. Long experience has shown that where more than one tool is required to be used at a time, two tools placed on directly opposite sides of the bar produce the best results. Double arm cutterheads have been designed to accomplish this. They are fed along the bar by a totally en-

closed feed box which is automatic and continuous in operation.

The economical and successful operation of any machine tool is very largely governed by a properly designed tool holder and cutting tool. An extra heavy tool holder for use with high-speed steel or Stellite cutters is provided with this machine.

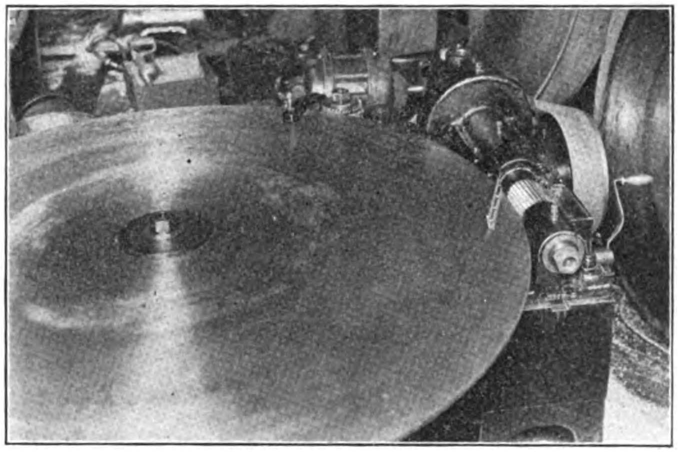
The machines are made in bar sizes of 3 in. to 6 in. in diameter and designed to bore valve chamber bushings or cylinders ranging from 7 in. to 48 in. in diameter.

Machine for reconditioning friction saw blades

THE usual method of sharpening friction saw blades by forming the teeth in the periphery with a hammer and cold chisel seldom resulted in a blade nicked uniformly and to the proper size. The metal is merely displaced by the chisel, thereby widening the rim which increases the power consumption necessary in cutting and also increases the amount of waste on each cut. The rounded mushroom edge results in considerable chipping, and burrs are often left on the work. Blades sometimes fail in service on account of the small cracks or fissures between the teeth, often caused by nicking.

Recognizing these conditions the Joseph T. Ryerson & Son, Inc., Chicago., has developed a machine which sharpens and trims the blades, making them ready for use practically as good as new. The machine consists primarily of a centering and leveling frame, which holds the blade horizontal while a milling and serrating hob applied to the edge of the blade revolves it and at the same time mills the desired grooves, trimming the rim so that the periphery is left true. At another point on the circumference of the blade, a pair of milling cutters removes the slight mushroom effect from both sides of the blade. The hob and milling cutters used, will form teeth in any standard blade regardless of the hardness of the steel.

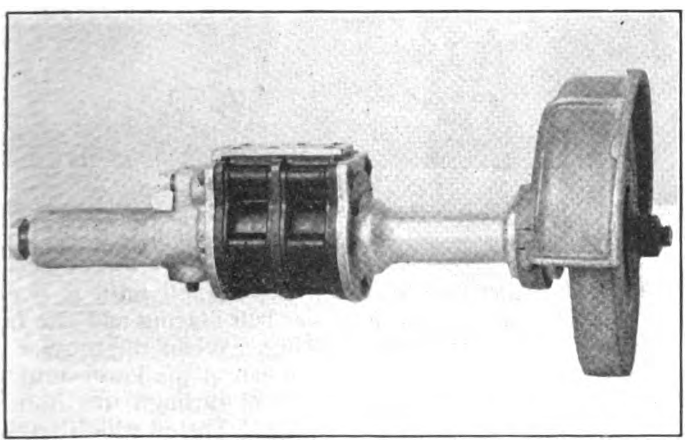
The work is performed quickly and the teeth cut perfectly according to the specified size and spaced evenly at the proper angle to the radius of the blade, so that they have all the strength and resistance of a new blade. The ease of operation of the machine makes it possible for a comparatively unskilled workman to use it.



Friction saw blade sharpener which mills and trims the blade in one operation

Pneumatic grinders driven by rotor principle

A LINE of pneumatic grinders which operate through the usual air line supply, but differing from the recognized types in that they use a rotor mounted on the drive shaft with the valve mechanism, controlled by a sliding valve, instead of pistons, has been developed by the Warner & Swasey Company, Cleveland, Ohio. This design confines the work to three parts.



Grinding machine which has only three moving parts

The method of rotation is as follows: Air enters through the air inlet; a small portion of it being conducted upward to the air cushion chamber and then deflected downward, exerting a constant pressure on the upper edge of the valve blade. This pressure maintains a sealing effect between the eccentric surface of the rotor and the valve blade, no matter what position the grinder is in. The main portion of the air entering the air inlet rushes in the cylinder causing rotation of the rotor in a clockwise direction. When the rotor has revolved about three-fourths of its cycle, the air moves upward to the exhaust chamber, and is exhausted through the ports. The two rotors which rotate in their respective cylinders are mounted directly opposite on the shaft so as to give a balanced effect, and overlapping power strokes. This gives a steady flow of power with a motion that is noticeable for its lack of vibration.

The three moving parts consist of the shaft assembly to which the two rotors are fastened by means of keys, all of which are made from Chrome Nickel steel. The two valve blades are made of a special light material which reduces momentum due to reciprocation.

Parts subject to wear have been reduced to a minimum. Disregarding ball bearing friction between the shaft and the two ball bearings on which the shaft is mounted there are but two points of friction contact. These are the points of contact of the two valve blades as they rise and fall on the eccentric surface of their respective rotors. The blades are made of a special fibre material, but since they are in contact with steel surfaces they must absorb such wear as occurs. When it is necessary to replace these blades, a screw driver is the only tool necessary. The cap is removed at the top of the grinder cylinders,

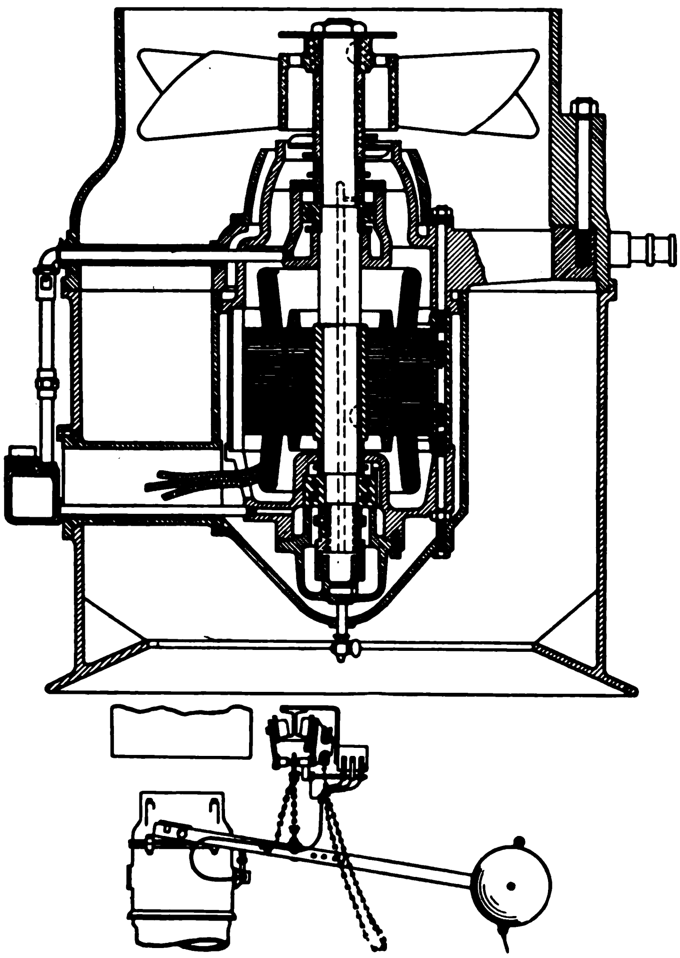
the new blades are inserted, the cap replaced and the grinder is ready for service.

There is no friction contact between the surface of the rotors and the cylinder walls. Ample clearance of from .002 to .003 in. is provided. The constant oil film present seals this clearance, preventing any air leakage past the rotor surface. An oil reservoir in the air inlet holds an ample supply of oil for the average day's run. This oil is fed into the cylinders in the form of a mist, and is easily adjusted by means of a needle valve. The grinders will operate efficiently at air pressures varying from 65 to 90 lb. with an air consumption of from 32 to 40 cu. ft. per min.

The machine is made in three sizes. The Type D-2 size is for general grinding with a free speed of 4,500 r.p.m. and weighs 15 lb.; the Type D-2-X size is for high speed buffing and polishing with a free speed of 6,000 r.p.m. and weighs 15 lb.; and the Type D-1 size is for the light grinding work with working speeds of 3,500 to 7,000 r.p.m. and weighs 8¼ lb.

Blower for drafting locomotives in enginehouse

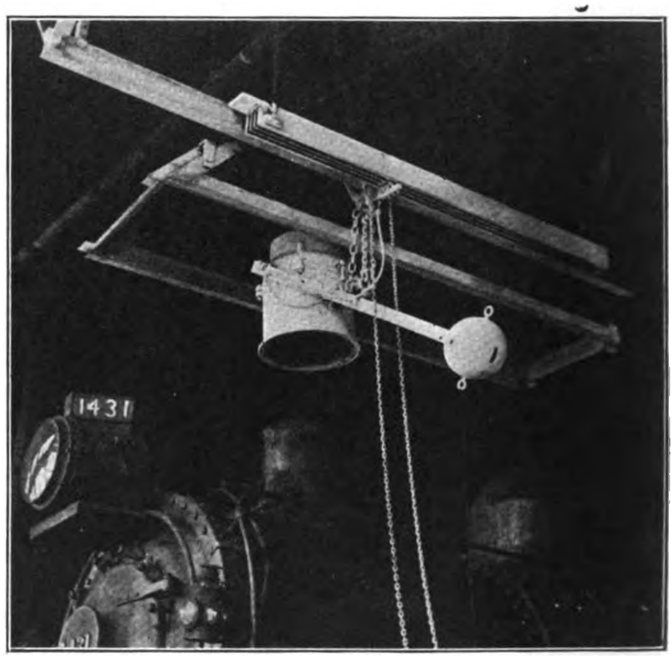
EVERY time the steam pressure in a locomotive is let down, it is necessary to draft it in the enginehouse so that it can pull out under its own power. The present method of drafting a locomotive is to connect the engine steam line to a steam jet blower located at the bottom of the stack. The Coppus Engineering Corporation, Worcester, Mass., has designed and placed on the market an electric operated blower known as the Locoblow which is a redesign of the blower of the same type which was first introduced to the railroad field in 1923.



Cross-sectional view showing arrangement of the motor and fan

The motor of the blower is essentially the same in capacity and design as that of the earlier type and the whole unit is similarly suspended from an I-beam monorail. The new blower, however, is more compact and lighter in weight and is much easier to handle from the enginehouse floor due to a balancing feature which makes it possible to raise the machine through the entire range of lift by a light pull on a rope attached to the end of a counterbalance. It may then be rolled over the stack by means of pulling the endless chain in the desired direction and lowered down upon the stack by releasing the rope. Current from the switch is led to three contact rails and is then carried to the motor through sliding copper contactors.

As some trouble was experienced with the earlier blower due to the lack of lubrication this feature has been given special attention in the design of the Locoblow as will be seen by referring to the cross-sectional drawing. Oil is poured into the reservoir shown to the left until it overflows: This submerges the lower ball bearing and the oil-filling chamber below this bearing. When the blower is in operation the screw thread shown at the lower end of the rotating element pumps the oil through the hollow shaft to an outlet over both bearings. The oil which passes over the top bearing enters a reservoir immediately below from whence it is returned into the oil chamber by way of suitable piping.



Motor driven locomotive blower which can be placed over the stack or swung out of the way by an endless chain

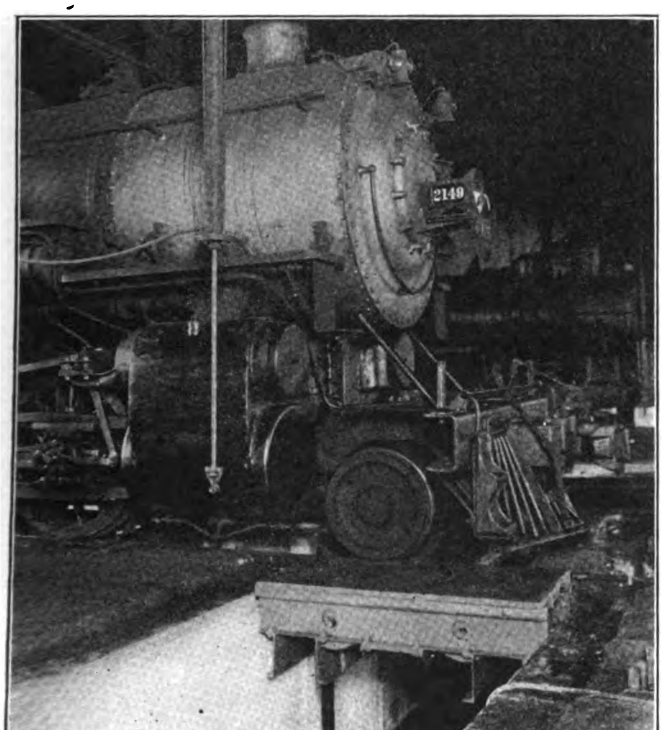
As the motor is suspended in the center of the blower in such a way that the gases must pass around it, special attention has been paid to ventilation. The motor is encased and a strong current of air passes between the outside of the motor and this casing, this current being in-

duced by the action of the main fan. Just below the main fan is located a smaller fan through the hub of the main fan and the air which goes between the motor and casing surrounding the motor is discharged over the hub of the fan so that no great quantity of heat is transmitted to the shaft. The lead wires to the motor pass through one of the two tubes connecting the casing which encloses the motor with the fan casing proper. Care has been taken that none of the motor parts comes in contact with the hot gases or metal parts heated by the gases.

The advantages claimed for this device are that it can be operated with much less noise and dirt; a more constant draft is induced due to being less subject to line fluctuations; the cost of firing up a locomotive is reduced and the work is done in much less time. It has been thoroughly tested in an enginehouse under normal conditions which tests showed a saving of 15½ min. to get up 65 lb. steam pressure from cold water. A saving of 92½ per cent in the cost of firing up a locomotive was shown by the tests.

Whiting screw-type electric drop table

THE screw-type electric drop table shown in the illustrations may be designed to perform any dropping operation on locomotives or cars. In dropping locomotive drivers, it is not necessary to take the locomotive weight on the jacks before starting as the table has a capacity of 50 tons. Neither is it necessary to spot the locomotive closely as the entire rail section drops. As there are no heavy rail beams to be moved out of the way, only a mechanic and helper are needed to do the work. In replacing the drivers with a drop pit, they are first replaced, the rail beams moved in place and the scaffold erected. With the drop table, the operator can stand in the table pit and come up with the drivers. The shoes can be placed first and held by shims. The pedestal binders may be set on blocks and fitted with wedges. In this way all the operations can be performed at once, thus saving considerable time.

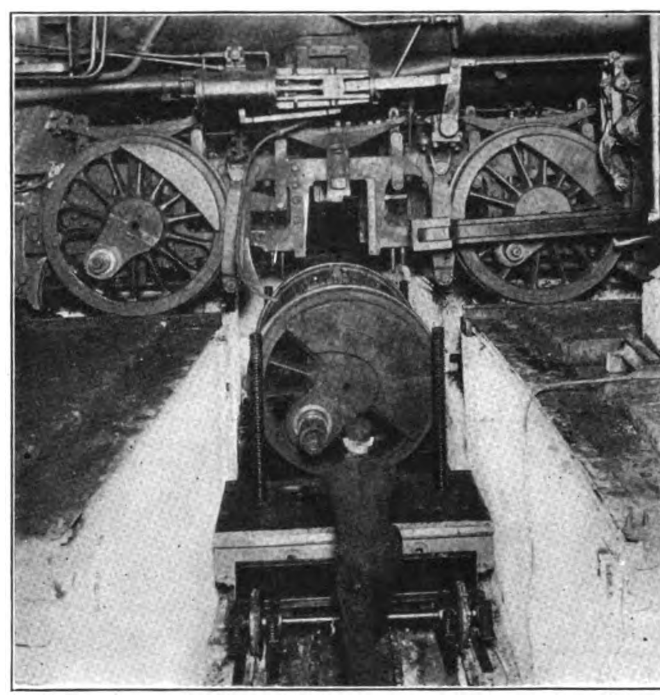


Truck wheels on the table ready to be dropped

If of sufficient length, a complete four-wheel engine or tender truck can be dropped in a single operation. On the other hand, a single pair of tender wheels can be removed by running them out on the table and blocking under the spring seat. If there is a cradle casting on the trailer, it can be blocked on the table and dropped without using extra blocks and tackle.

Boosters are readily removed on the drop table. This is a very difficult operation on a drop pit jack on account of the shifting weight, due to the overhanging weight of the booster engine and the spring weight, which drops to zero after a few inches. As the drop table has four legs any shifting of weight does not affect it.

Spring work can be done quickly and easily without disturbing any box packing. To renew a spring, the table is raised 2 in. above the rail and the spring rigging blocked. The table is then dropped, relieving the weight off the spring. It can then be readily renewed. The same method can be employed in spring equalization.



The main driving wheels of a Mikado removed and lowered to the bottom of the pit on the drop pit table

The drop table consists essentially of a truck with four stationary screws, the table being built on top. Wheels and axles are provided at each end of the truck, being inserted in roller bearings to permit easy lateral movement. The boxes are spring supported so that, when the full locomotive weight is received, the springs will deflect. This in turn seats the screws on the rail, passing the weight directly onto the foundation.

The table rails are reinforced and supported by beams, the load being carried by means of transverse channels to the driving units, which consist of screws and worm wheels with roller thrust bearings. The latter are 14 in.

in diameter and contain 56 rollers. The driving motor is mounted on the table. The control is a matter of choice, the push button types with extension cord being the most flexible.

The pit is rectangular in cross section and may be constructed straight or in conformity with the enginehouse circle. Channels are set in the wall to guide the table and to insure its being correctly positioned. Sockets are provided for the power plug. Only ordinary drainage is required, as there is nothing of a hydraulic nature about the drop table.

As the locomotive is run onto the table, the live load is taken on the locking bars, situated just under the table rail. The power is then turned on and the table run up until the weight is relieved from the locking bars. These bars are then thrown out, a single lever performing the operation. The table and load are then dropped to the low position. The table is then moved laterally by ratchets and after being moved laterally is again raised to the surface. The reverse movement is made likewise.

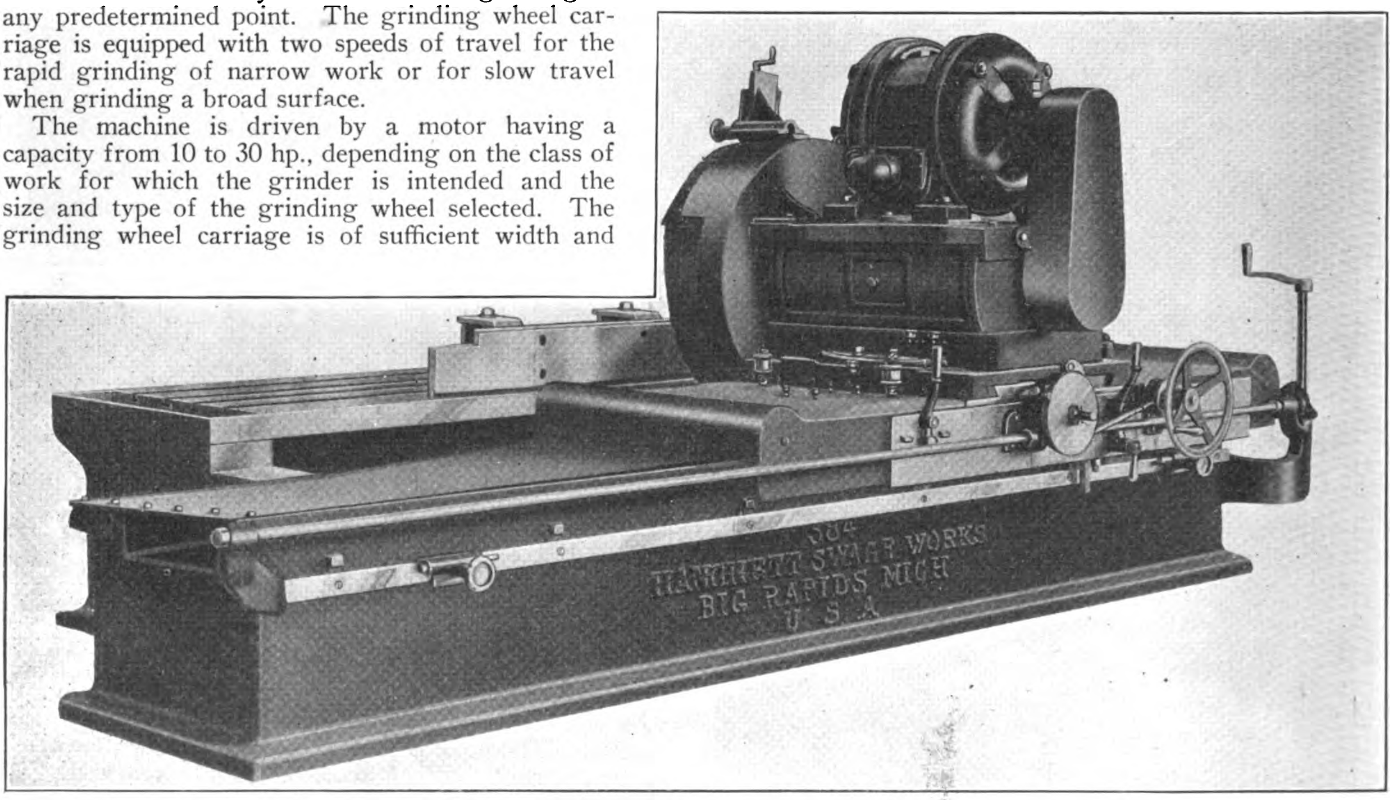
The minimum table length is about 6 ft. 8 in. and the maximum is somewhat indefinite, being controlled by practical considerations. A 10-ft. 6-in. table is capable of handling practically everything. The minimum net table thickness for an integral table is about 2 ft. 1 in. This added to the required drop gives the pit depth. Thus a drop of 6 ft. would require a pit depth of 8 ft. 1 in. The overall width varies with different designs. This equipment is manufactured by the Whiting Corporation, Harvey, Ill.

Cabinet base traveling wheel grinder

THE grinding machine shown in the illustration has a capacity for handling locomotive guide bars, knives, shear blades and general surfacing. The machine is fully automatic, adjustable for any speed of grinding and to feed the grinding wheel to the work at any speed desired, with an automatic stop and graduated dial which can readily be set to cease grinding at any predetermined point. The grinding wheel carriage is equipped with two speeds of travel for the rapid grinding of narrow work or for slow travel when grinding a broad surface.

The machine is driven by a motor having a capacity from 10 to 30 hp., depending on the class of work for which the grinder is intended and the size and type of the grinding wheel selected. The grinding wheel carriage is of sufficient width and length to prevent vibration and is operated by a silent chain and gear drive from the motor arbor, through steel gears completely enclosed in the base of the carriage and running in oil. The pump for the cooling solution is driven by a belt from the grinding wheel arbor and is held in position by sliding ways which are adjustable by a hand wheel to keep the belt at the proper tension.

The machine is equipped with a knife bar for ordinary knife grinding with a magnetic chuck, a flat platen for holding various classes of work and with revolving work holders on which one setting of the work up to full capacity of the machine—in units up to approximately half of the machine capacity—can be placed in position while another setting is being ground, thus keeping the machine in nearly continuous operation without the usual intervals for putting on and taking off work while the machine is idle. A knife bar supplied with two faces with different lengthwise or crosswise slots adapts the one bar for a variety of work. It is adjustable by a worm and gear to hold the work at any desired angle or in a vertical or horizontal plane, and when set can be locked in position. The machine is equipped with a wooden shelf or loading table level with the knife bar on which knives or shear blades can be loaded and then moved over to the bar without danger of injury of loading directly onto the iron bar. The grinding wheel carriage, in addition to the automatic feed



Grinding machine which will handle locomotive guide bars

to the work, can be rapidly withdrawn from the knife bar by a large hand wheel control to facilitate putting on or taking off work. The machine illustrated has a capacity of 84 in. and weighs approximately 11,000 lb. crated.

This machine is manufactured by the Machinery Company of America, Big Rapids, Mich.

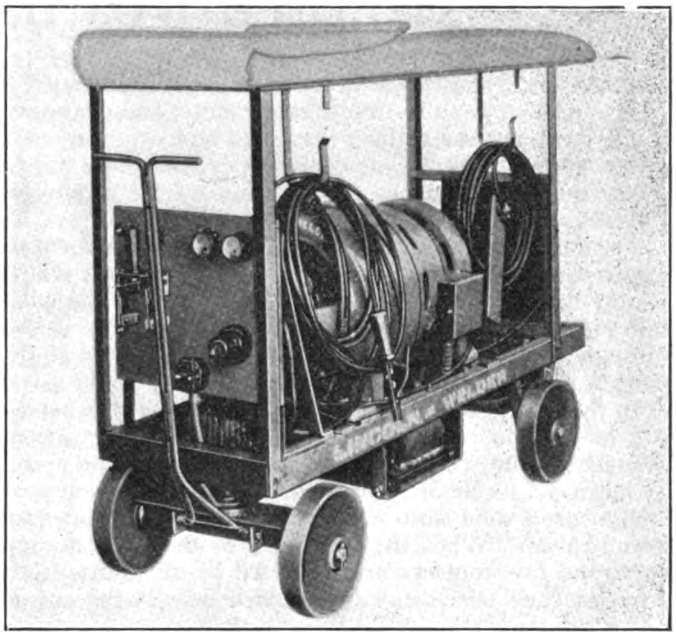
Electric welder designed for railroad shops

An electric welder especially designed for use in railroad shops has been placed on the market by the Lincoln Electric Company, Cleveland, Ohio. The equipment is said to afford unusual ease of operation and to be especially well adapted to its particular field because of its relatively narrow width. It is 21 in. wide so that it will easily pass through the narrowest aisles in a shop. It is fully equipped with large roller bearings which add to its ease of mobility.

The center of gravity of the machine is low so that it will not be liable to tip over. The frame is of structural steel, extending beyond the equipment on the truck, so that it is almost impossible to back the truck into anything which would damage the welder. This is a desirable feature owing to the rough handling equipment of this nature receives in the railroad shop.

The welder, which is a 300-amp. arc unit, uses the stable arc. This arc will weld such jobs as locomotive frames, crosshead guides, truck sides, main driving wheels, journal boxes, etc. It is said that in actual tests, from four to five feet of fire-box seam has been welded in an hour; and that from seven to ten pounds of metal has been placed on a crosshead guide in one hour.

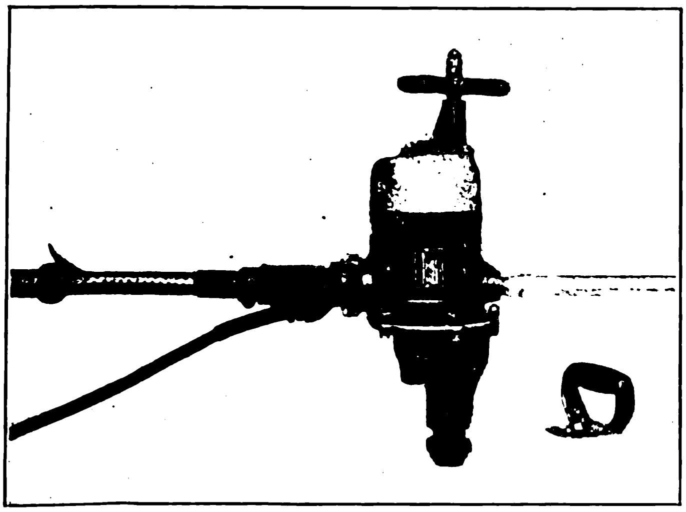
The machine is provided with water-proof covers, which can be thrown back easily and which, when dropped down, provide complete protection from the weather. A push button starter, tool box, handy but out of the way, a spring controlled handle which is out of the way when not in use, convenient cable hooks, and light total weight are some of the other features of this equipment.



Portable electric welder which can readily pass through the congested shop owing to its restricted width

An electric drill and reamer for the car shop

A direct current, compound electric drill and reamer for use in car repair work has recently been placed on the market by the Independent Pneumatic Tool Company, Chicago. It has a drilling capacity up to 1¼ in. and is especially suited for reaming 13/16 in. and 15/16 in. holes in steel car construction work. It has a maximum speed of 600 r.p.m. and weighs 60 lb.



Thor motor driven drill and reamer adaptable for car construction work

Its construction has several features which lend to its adaptability for the work for which it is intended. The one-piece bridge and housing construction of the rear end of the machine provides easy accessibility and also carries the upper armature bearing in permanent alinement with the lower one. The motor is air-cooled through vents in the starter housing. These vents are not drilled radially, but are at a tangent to the fan blade's motion. The rectangular brushes are provided with a liberal area for the maximum of current they carry. The holder, which embraces the brush, draws the heat rapidly away from the commutator surface and spreads it throughout the brush assembly. The radiation, accelerated by the increased air current of the angular vents, carries off the heat from the brushes.

To secure as nearly a perfect balance as possible, first the commutator and fan and then the complete armature are balanced separately so as to eliminate vibration. The commutator is not attached direct to the steel armature shaft because steel does not expand the same under heat as copper. The commutator is a separate unit, built up on a brass sleeve that expands and contracts evenly with the copper segments. Rectangular slots are used on the motor armature which allows the use of more wire and insu-

lation which permits the usage of double silk-covered wires for the coils.

The gears in the motor are machine cut from alloy steel. The roller bearing assembly on the center plate stud provides support for the upper end of the spindle which eliminates strain and wear on the plain bronze spindle bearing at the lower end. The machine is equipped throughout with ball and roller bearings.

The tool is provided with a side handle switch which eliminates all wire connections between the switch handle and the motor. It is a separate unit and makes contact from the motor to the line by means of brass plungers. The cable is of the three-conductor type and leads into the handle through a supporting taper coil spring. A plunger type of switch is used which is located in the handle for the convenience of the operator.

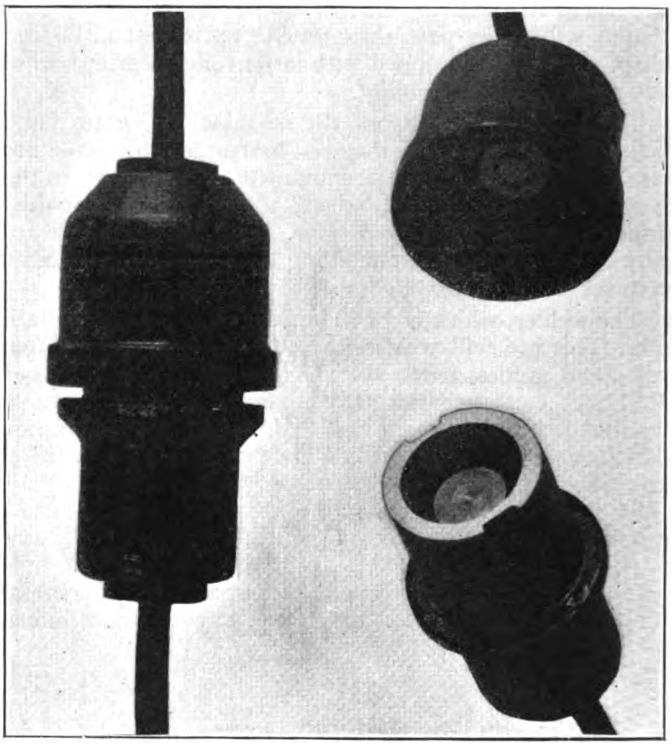
Armored weather-proof connector

A WEATHER proof connector which is intended to make it possible to instantly connect and disconnect with the line without the use of tape or tools, motor driven portable welders or other portable machines has recently been developed by the Ohio Electric & Controller Company, Cleveland, Ohio.

The socket end of the connector should always form the upper part so that any water which may fall on it will be readily drained off and not enter the connector. Asphaltum compound is filled in around the cable where it goes through the insulator so that no water can enter at this point.

In the lower or socket end of the connector, the contact is a loose fit in the insulator and is supported by a compression spring, current being carried around the spring by means of six flexible conductors. This flexible support is to insure a solid electrical contact between the upper and lower halves. When the two parts of the connector are open, the live contacts are protected by the skirt of the armored shell which extends an inch beyond the contact points.

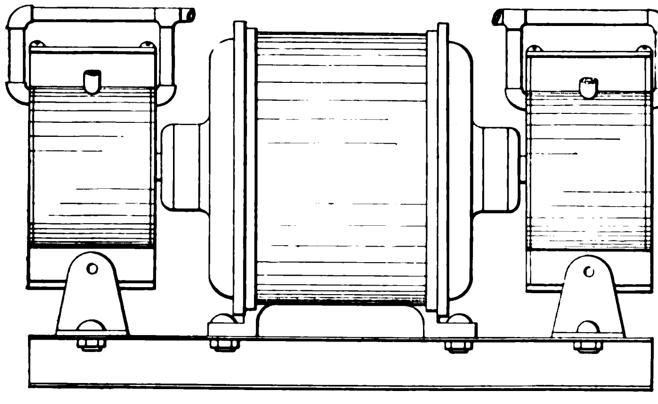
A short piece of No. 4 B. & S. flexible cable is soldered to each end of the connector and, for a short time this cable is capable of carrying 1,000 or 1,200 amperes. The continuous capacity of the connector is 150 amp. which it can carry under test with a rise of 10 deg. C. Intermittent capacity such as would be encountered by a crane motor is 300 amp. It is made only in one size, weighs 3½ lb. and can be furnished as a two or three pole connector when desired.



Weather-proof connector adaptable for motor driven portable machines and cranes

Valveless high speed synchronous air compressor

THE rotary compressor shown in the illustrations is intended for use in pumping fluids or compressing air. Compactness and simplicity of construction are its outstanding features. The ordinary inlet and outlet valves are not used in this machine. An unusual feature is the arrangement of the outlet ports which function as a check valve when they do not register or when the fluid or air is not being discharged from the machine. The operation of the compressor is practically noiseless and for many purposes operative without an air receiver. It is generally motor-driven and unloading devices are unnecessary. An unusual feature is the absence of fly-wheels, pulleys, crankshafts, etc. The rotors function as fly wheels and being located in the casing also function with the casing as suction and discharge valves.

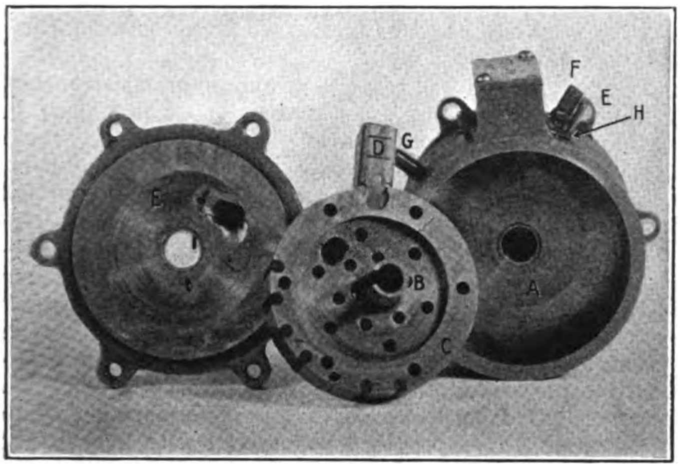


A motor with a rotary air compressor mounted on each end of its armature shaft

The machine was developed by John Milne, 273 Greenwich St., New York. It consists of a cylinder divided into two equal parts by a hollow partition, one face of which is shown at *A*, thereby forming two separate compression chambers. In each of these chambers there is a compressor which is made up of an eccentric or piston *B*, a ring *C* and the sliding partition *D*. The chambers are enclosed between covers *EE*. These compressors are arranged to balance each other, and one may act independently of the other, one being used for compression purposes and the

other for producing a vacuum. The compressed air or fluid from one chamber may be stepped up in the other to any pressure within the limits of compressor practice. One of these double compressors may be mounted on each end of the shaft of one motor, and thus four machines would be compressing at 90 deg. apart. The four units may also be arranged to perform separate functions if desired, two used for air and two for fluid, etc.

In the partition dividing the two chambers of the one machine, there is a cavity in which water or other cooling



Partially disassembled machine showing the piston ring assembled on its piston and the sliding partition *D* mounted in the piston ring

medium is circulated through the pipe shown at *F* and *G*. The shaft of the driving motor enters the bore of piston *B* and is keyed to it. The capacity of the machine is rated as ranging from ¼ cu. ft. to 10,000 cu. ft. and for operation at speeds from 350 to 3,600 r.p.m. for various pressures.

In operation, the rotation of the eccentric piston *B* produces motion of the ring *C* of a combined rotary and reciprocating nature. As the eccentric throws the ring to its maximum position off center, the ring presents the maximum opening between its periphery and the cylinder wall on the right-hand side of the sliding partition. On this side of the partition the cylinder wall carries the intake port *H*. When the rotation continues, the throw of the eccentric carries the ring around in such a manner as gradually to move the widest opening between the ring periphery and the cylinder wall clockwise, until the air or liquid is compressed against the other side of the sliding partition *D*, at which time the port in the eccentric registers with the port in the ring, giving clear outlet to the compressed air or fluid.

The sliding partition has a three-quarter cylindrical bearing in the edge of the ring. As the ring is moved it oscillates in this cylindrical type bearing or hinge and also in its change of position it slides the partition up and down in ways located in the boss on the top of the cylinder. Thus there is always a sealed division between the intake and outlet ports. The numerous small holes shown on the face of the piston and ring are intended to reduce the weight of those parts. The outlet ports in the ring, the piston and the cover register with each other at a predetermined point in each revolution of the piston and ring, and the compressed air or fluid is discharged through these alined or coacting ports at a predetermined point into the outlet in the cover.

The sliding partition *D* serves only to seal the outlet compartment from the inlet portion of the cylinder. When the outlet ports in the piston ring, piston and cover are not in line, they function as a check valve for the air or fluid in the cylinder and the air or fluid in the outlet piping.

Abutment type apron for Gray planers

The accompanying illustration shows the abutment type apron which is a recent improvement of the Gray planers manufactured by the G. A. Gray Company, Cincinnati, Ohio. This apron consists of a heavy supporting rib running across the bottom of the apron. When the apron drops back in the toolbox, this abutment bears in a finished shoulder on the bottom of the toolbox, so that the tremendous upward thrust of the tool, when taking heavy cuts, comes on this abutment rather than on the taper pin from which the apron is suspended.

This was designed not only to protect the taper pin against excessive wear, but to avoid breakage of the pin or the tool box in case of an accident. Another advantage claimed for it is the fact that it materially stiffens the apron against the tendency to curl up when a heavy clamping pressure is used on the tool clamping bolts.

The head and saddle have also been modified by the application of the twin-purpose taper gib, which is so called because it is used for the dual purpose of taking up for wear and also for clamping the sliding parts rigidly to the stationary parts. The head of the gib is held in place by two shoulders on the clamping screw. This screw has a squared end, so that the operator can apply the usual crank to this screw and with a partial turn force the gib lengthwise between the slide and the harp, thereby wedging it tight over its entire length. Because of the slight angle of the taper gib and the fine pitch of the screw, a considerable clamping pressure can be obtained by only a slight pull on the crank handle. To unclamp, the clamping screw is turned in the opposite direction until the head of the gib is pulled firmly against the cheese-
